Mitochondria don't just make ATP, they are hosts to multiple catabolic and anabolic pathways that maintain cellular metabolism and sense internal and external environmental stressors. Proper cellular and organismal function requires coordinated expression of the 37 mitochondrial-encoded and >1200 nuclear-encoded genes that have been interacting for more than 1 billon years. Disruption of these complex interactions can cause a variety of diseases and influence adaptive evolution in heterogeneous environments. To advance our understanding of how these complex genetic interactions influence organismal fitness we have constructed a panel of 90 mitonuclear genotypes built from 22 different mtDNAs (10 Zimbabwe, 10 Bejing, from D. melanogaster plus D. simulans and D. yakuba mtDNAs) placed onto two nuclear chromosomal backgrounds (OreR and DGRP375) in duplicate. Each genotype was cultured on standard Drosophila diet and a diet containing 25 mM rotenone, a natural pesticide that inhibits the activity of mitochondrial complex I, NADH dehydrogenase. Climbing speed, flight ability, development time and body weight were measured in adult males and females from each diet. This design allows for partitioning of mtDNA effects, nuclear genotype effects, diet environment, and their interactions in models that test for GxGxE effects. There were strong mitonuclear epistatic effects across the phenotypes, with further modification of epistasis by the rotenone treatment. The mtDNA, nuclear and environmental effects were different for each phenotype. OreR nuclear genomes were more sensitive to rotenone than DGRP375, but mtDNA haplotypes modified this effect. The outgroup mtDNAs of D. simulans and D. yakuba had climbing and flight performances comparable to D. melanogaster mtDNAs despite 100s of substitutions in these mtDNA genomes. Unexpectedly, certain outgroup mtDNAs rescued the detrimental effects of rotenone on climbing. Overall, the analyses identify specific mtDNA and nuclear genome pairs that show sensitivity or resistance to rotenone, amenable to further genetic mapping of epistatic (GxG) and environmental (GxE) interactions.

886S **Mechanisms of adaptation to oral infection in *D. melanogaster* upon experimental evolution** Tânia F Paulo[1], Priscilla A Akyaw[2], Tiago Paixão[2], Élio Sucena[2,3] [1]Infectious Diseases, Boston Children's Hospital. Harvard Medical School, [2]Instituto Gulbenkian de Ciencia, [3]Department of Animal Biology, Faculty of Sciences, University of Lisbon

In natural environments, metazoan hosts are constantly enduring the action of pathogens. These interactions constitute strong evolutionary motors that have driven the emergence of the immune responses.

As an animal model of reference, *Drosophila*'s immune response has been well characterized. However, most studies have relied on inbred lines, kept under laboratory conditions, with relatively weak ecological and evolutionary relevance. However, recent work has begun to study *Drosophila* immunity encompassing using natural pathogens in populations with abundant genetic variation, including previous work in the lab that established experimentally evolved populations of *D. melanogaster* under several pathogen challenges. In one such regime, an outbred population of *D. melanogaster* was selected against oral infection (BactOral) with a natural pathogen, *Pseudomonas entomophila*, acquiring after 6 generations of selection, a significantly increased survival upon infection, compared to the Control regime.

To uncover the mechanistic bases of the rapid evolutionary trajectory of BactOral we performed a multi-level phenomenological characterization, alongside transcriptomic profiling. We tested several phenotypes relevant against oral bacterial infections, including feeding and bacterial defecation rates, bacterial load dynamics, and AMP expression levels. We concluded that adaptation in BactOral relied on a combination of higher resistance and possibly stronger disease tolerance.

We conducted RNA-Seq on whole-bodies and on guts at 4 timepoints, revealing differences between populations during both infection progression and resolution. These results agreed with the previous observations of increased resistance of BactOral, at the gut level. Additionally, at the whole-organism level, BactOral exhibits an earlier downregulation of immune effectors that correlates to the its higher disease tolerance.

Finally, using conditional RNAi, we functionally validated the role of the candidate genes *Drosomycin-like 2* and *Lactate dehydrogenase* in the immune response of Drosophila, possibly in the control of bacterial loads and localized gut immunity.

In sum, this work systematically addresses several layers of the immune response, gaining a deeper understanding of how immunity be shaped by evolution. Additionally, it highlights that resistance and disease tolerance can evolve in parallel, synergizing or additively contributing to higher fitness.

887S **Rapid evolution of piRNA clusters in *Drosophila melanogaster* ovary** Satyam P Srivastav, Cedric Feschotte, Andrew G Clark Molecular Biology and Genetics, Cornell University

The piRNA pathway is a conserved mechanism to repress transposable element (TE) activity in the animal germline via a specialized class Argonuate proteins called Piwi and small RNAs called piwi-interacting RNAs (piRNAs). piRNAs are produced from discrete genomic regions called piRNA clusters (piCs). While the molecular processes by which piCs function are relatively

well understood in *Drosophila melanogaster*, much less is known about the origin and evolution of piCs in this or any other species. To investigate piC origin and evolution, we use a population genomics approach to compare piC activity and sequence composition across 15 geographically distant strains of *D. melanogaster* with high quality long-read genome assemblies. We perform annotations of ovary piCs and genome-wide TE content in each strain. Our analysis uncovers extensive variation in piC activity across strains and signatures of rapid birth and death of piCs. Most TEs inferred to be recently active show an enrichment of insertions into old and large piCs, consistent with the previously proposed 'trap' model of piC evolution. By contrast, only a small subset of active LTR families is enriched for the formation of new piCs, suggesting that these TEs have higher proclivity to form piCs. Thus, our findings uncover processes leading to the origin of piCs and principles of piC and TE co-evolution. We propose piC evolution begins with the emergence of piRNAs from a few specific LTR retrotransposon insertions that subsequently expand by accretion of other TE insertions during evolution to form larger 'trap' clusters. Our study shows that TEs themselves are the major force driving the rapid evolution of piCs.

888S **Flight, Form, and Fitness: Unveiling the Robustness of Adaptation** Saudat Alishayeva, Luisa F Pallares Friedrich Miescher Laboratory, Max Planck Society

Biological systems have a remarkable dual capacity: they are robust to mutations and developmental noise, while also evolving and responding dynamically to their environment. To gain a better understanding of robustness and evolvability, we conducted a comparative analysis of wild-type *Drosophila* reared under control conditions and those exposed to a sucrose and glucose-rich diet. Our focus encompassed three key components of phenotypic robustness: population-level analysis of wing shape morphology, developmental stability reflected in wing asymmetry, and flying performance.

Surprisingly, we observed a reduction in behavioral variation in populations reared on high-sugar diets that exhibited robust flight performance. Our results indicate that individuals exposed to stressful dietary conditions also demonstrate rapid and substantial changes in morphology and fluctuating asymmetry. Despite these alterations, functional capacity for flight was maintained, highlighting a remarkable resilience in the face of underlying morphological shifts. Tracking these phenotypic traits over 15 generations allowed us to discern both immediate and delayed adaptive responses to environmental stress.

To further probe the environmental role in adaptability, we initiated experiments implementing stabilizing selection on flies raised under two distinct conditions. In each generation, we artificially reduced variation in flight performance by selecting flies close to the mean. Remarkably, flies reared on control food exhibited faster adaptation to truncating selection, manifesting in reduced flight variation within just five generations. In contrast, flies subjected to food enriched with sugar displayed a noisier and less predictable response, suggesting a diminished adaptability to artificial selection. The fluctuations in variation observed are likely a result of genotype-by-environment interactions (GxE), influencing the heritability pattern for flight performance.

In conclusion, our study sheds light on the dynamic nature of phenotypic responses to environmental stress and the subsequent implications for adaptive evolution. The ability of organisms to maintain functional traits amidst morphological and symmetrical alterations underscores the complexity of the relationship between genotype and phenotype. These findings detangle the speed of adaptive responses in terms of behavior, morphology, and developmental stability, with potential applications in understanding and managing evolutionary processes in response to stress.

889S **Isofemale lines, genomic environment and evolution** Guy F Barbato Biology, Stockton University

Two years ago, we began collecting wild *Drosophila melanogaster* from the homes of our undergraduate Genetics lab students. Training students in the care and breeding of *Dmel*, our intent is to quantify naturally occurring variation using both morphometric, physiological and behavioral measurements. Further, we began having undergraduate research students extract gDNA from the lines to begin Oxford Nanopore sequencing.

The isofemale lines were created from student collections by using a single female fly as the progenitor of the line. In each case, three three replicate populations were started using different females. The populations were then inbred using full-sib matings for at least ten generations prior to collecting phenotypic and genomic data. We have 128 individual isofemale lines derived from 50 collection sites.

During routine reproduction of the lines, pupae are counted at 10d post-mating, with the lines having 74 ± 44.7 pupae (CV=61%). Having such large differences in reproductive fitness, we assessed gamete production in both male and female gonads of mature flies. Ovariole counts ranged from 8 – 35 per ovary per female, while spermatid counts between low and high fitness lines was an order of magnitude. The relationship between gamete production and fitness was multidimensional and not due to any single factor – meaning the poor fitness could be due to either male or female gamete production, or gametic incompatibilities. Given the nature of the lines, we were not entirely surprised to see multifaceted relationships arise.

We have also observed a three-fold difference in body size among the lines and there are large differences in sexual dimorphism with many lines exhibiting no sexual dimorphism of body size. Conversely, 10% of the lines exhibit the opposite sexual dimorphism of size than expected. That is, males are consistently larger than females.

A major thrust of the project is to obtain genomic data from the lines using the Oxford Nanopore technologies. Given that all our research is being executed by undergraduate students, we have had to develop biochemical and genetic workflows that can accommodate their class schedules. Focusing on a team-based approach, be now have specific workflows to extract poly-A-mRNA from gonads and gDNA from both live and frozen flies. We have been successful in sequencing both molecules using the MinION MK1C (v.9.4.1 chemistry) and are in the process of upgrading to the new flow cells. Existing data are being analyzed in my senior-level BioInformatics class.

890S **Mixed Wolbachia infections resolve rapidly during in vitro evolution** Cade Mirchandani[1], Pingting Wang[1], Maximilian Genetti[1], Jodie Jacobs[1], Evan Pepper-Tunick[2], Russell Corbett-Detig[1], Shelbi L Russell[1] [1]Biomolecular Engineering, University of California Santa Cruz, [2]Molecular Engineering Sciences Institute, University of Washington

The intracellular symbiont *Wolbachia pipientis* evolved after the divergence of arthropods and nematodes, but it reached high prevalence in many of these taxa through its abilities to infect new hosts and their germlines. Some strains exhibit long-term patterns of co-evolution with their hosts, while other strains are capable of switching hosts, making them important factors in symbiont-based biological control. However, little is known about the ecological interactions that occur when a promiscuous strain colonizes an infected host. Here, we study what occurs when two strains come into contact in host cells following horizontal transmission and infection. We focus on the faithful wMel strain from *Drosophila melanogaster* and the promiscuous wRi strain from *Drosophila simulans* using an in vitro cell culture system with multiple host cell types and combinatorial infection states. Mixing D. melanogaster cell lines stably infected with wMel and wRi revealed that wMel outcompetes wRi quickly and reproducibly. Furthermore, wMel was able to competitively exclude wRi even from minuscule starting quantities, indicating that this is a deterministic attribute, independent of the starting infection frequency. This competitive advantage was not exclusive to wMel's native *D. melanogaster* cell background, as wMel also outgrew wRi in *D. simulans* cells. Overall, wRi is less adept at in vitro growth and survival than wMel and its in vivo state, revealing differences between cellular and humoral regulation. These attributes may underlie the observed low rate of mixed infections in nature and the relatively rare rate of host-switching in most strains. Our in vitro experimental framework for estimating cellular growth dynamics of *Wolbachia* strains in different host species, tissues, and cell types provides the first strategy for parameterizing endosymbiont and host cell biology at high resolution. This toolset will be crucial to our application of these bacteria as biological control agents in novel hosts and ecosystems.

891S **Experimental evolutionary genomics of herbivore adaptation to toxic host plants** Noah Whiteman[1], Andy Gloss[2], Joy Bergelson[2], Diler Haji[1] [1]Department of Integrative Biology, University of California, Berkeley, [2]Department of Biology, New York University

A major problem in evolutionary biology is why and how herbivores evolve different host ranges. Oligophagy can arise through phenotypic plasticity or when there is additive genetic variation for alternative alleles. In 1953, Howard Levene proposed that spatially- or temporally varying selection can maintain functional genetic variation, enabling species to exploit a diversity of niches. Insect herbivores are biologically well suited to test this model because adults mate randomly and offspring are exposed to – and are often restricted – to different host plant chemical environments over development. We tested the Levene model by experimentally evolving the herbivorous leaf-mining drosophilid fly *Scaptomyza flava* for 10 generations on monocultures or mixtures of two natural and chemically divergent mustard host plants, *Barbarea vulgaris* and *Turritis glabra*, and then compared our experimental findings with wild-caught populations from both host plants. Scaptomyza flava evolved increased fitness and a home-court advantage on *Barbarea* and *Turritus* monocultures. These fly populations showed rapid genome-wide differentiation within 6-8 generations. Genomic differentiation occurred in opposite directions between the monocultures while mixture treatments showed intermediate differentiation. Regions of the genome exhibiting heightened differentiation between monocultures contained genes predicted to play roles in cell maintenance, xenobiotic metabolism, and stress response.

892S **Exploring the Genetic Basis of the Tan Streak Mutation in Deer Mice** Isabel Carino-Bazan[1], Shuonan He[2], Hopi Hoekstra[2] [1]Biological Sciences, Lehigh University, [2]Harvard University

Coloration varies vastly amongst organisms, even between individuals of the same species. One such example is *Peromyscus*, which are found across North America and display profound coat color changes as they adapt to distinct environments. A naturally-occurring color morph in *Peromyscus* is known as tan streak (*tns*), which gives mice a distinctive white coat with a tan-dorsal streak. However, the molecular nature of the *tns* mutation is yet to be fully explored. Melanocortin receptor (*Mc1r*)

is an important regulator of mammalian pigmentation synthesis, and deer mice carrying CRISPR-induced *Mc1r* mutations display a strikingly similar coat coloration to *tns* mice. Through our experiments, we aim to test our hypothesis that the *tns* phenotype is due to loss of function of the *Mc1r* gene. To test our hypothesis, the two methods we used were spectral analysis of the flat skin coat color, which allowed us to quantify and compare brightness, hue, and saturation along the dorsal-ventral axis, and genotyping of the *Mc1r* locus. Spectral analysis showed us that brightness, hue, and saturation in *tns* and *Mc1r*-mutants are comparable and that these measurements are significantly higher than those of the wildtype flat skins. From genotyping, we detected four nucleotide mutations, three of which resulted in amino acid changes, in the *Mc1r* coding region of *tns* samples. These two results allow us to deduce that the phenotypic similarity between *Mc1r*-mutants and *tns* mice denotes a genotypic correlation.

893S **Genetic and non-genetic effects on transcriptional and post-transcriptional gene regulation** Mallory A. Ballinger[1,2], David N. Manahan[3], Michael W. Nachman[3] [1]Biology, Utah State University, [2]Ecology and Evolutionary Biology, Cornell University, [3]Integrative Biology, University of California, Berkeley

Determining how both genetic and environmental effects influence the regulation of gene expression is key to understanding the molecular mechanisms of adaptive evolution. However, most studies on gene regulatory evolution have primarily focused on the transcript level (mRNA abundance); we know relatively little about the role of transcript structure (alternative splicing) in adaptive evolution. Due to their recent expansion into new environments, house mice (*Mus musculus domesticus*) provide an excellent opportunity to study genetic and environmental effects on transcriptional and post-transcriptional gene regulation. Here, we use short-read RNA-seq from temperate and tropical wild-derived inbred lines of house mice reared in warm and cold environments to address several key questions regarding gene regulatory evolution: Does variation in alternative splicing and mRNA abundance play complementary and/or contrasting roles in adaptive evolution? What is the relative contribution of *cis*- versus *trans*-regulatory changes to splicing and expression divergence? To what extent are transcriptional and post-transcriptional regulatory mechanisms environmentally dependent? Overall, this work broadens our understanding of the genetic and non-genetic gene regulatory mechanisms underlying adaptive evolution.

894S **Convergent evolution in response to hypoxia in *Peromyscus* mice** Peter Nimlos[1], Jonathan Velotta[1], Nathan Senner[2], Zachary Cheviron[3] [1]University of Denver, [2]University of Massachusetts - Amherst, [3]University of Montana

A powerful approach to understanding the mechanisms of adaptation is to investigate species that have independently evolved to overcome similar environmental challenges. Studying this phenomenon – known as convergent evolution – can help explain the extent to which evolution is repeatable and predictable. However, quantification of convergence has been difficult due to the complexity of intersecting genetic and physiological pathways. High altitude environments provide an apt setting to study convergence as low oxygen availability (hypoxia) and prolonged cold provide intense selection pressures leading to physiological adaptation. The ability to generate heat from aerobic metabolism (thermogenic capacity) is a critical determinant of fitness in wild high-altitude deer mice (*Peromyscus maniculatus*) and is accomplished via contraction of skeletal muscle (shivering). Indeed, populations of deer mice native to high altitude have higher thermogenic capacity relative to their lowland native conspecifics, which is thought to be driven by an increase in the density of oxidative (O2 consuming) muscle fibers. *P. maniculatus* is one of many species in the genus *Peromyscus* that have independently invaded high-altitude environments across North America, making them a unique system to test for convergent patterns of adaptation in thermoregulation. Here, we measured transcriptomic response and whole organism performance of six species of laboratory-raised *Peromyscus* mice native to either low- and high-altitudes and acclimated for six weeks to a gradient of simulated elevation (equivalent to 1,000, 3,000 and 4,500 m a.s.l.). We measured thermogenic capacity during a cold exposure, quantified muscle tissue composition, and sequenced skeletal muscle transcriptomes. Using phylogenetically-informed models, we compared gene expression between species and acclimation treatments and identified shared highland genes putatively differentiated in thermogenesis. We correlated measured thermogenic capacity with expression of candidate genes. The combination of integrated data types, broad phylogenetic sampling, and controlled laboratory acclimations lends substantial comparative power to discern the extent to which within-species acclimation response and across-species evolutionary changes represent adaptations to extreme altitude.

895S **Cross-Species Comparative Transcriptomic Analysis of Embryonic Stem Cells (ESCs)** Yifei Fang, Ellie Duan Animal Science, Cornell University

Embryonic stem cells (ESCs) have huge potential in developmental biology and regenerative medicine due to their unique pluripotent capacity to differentiate into any cell type in the organism. However, the mechanisms underlying this potential are complex and not fully understood. To unravel the complexities of pluripotency, we conducted a comprehensive comparative transcriptomic analysis of ESCs across humans, mice, rats, cattle, pigs, horses, sheep, crab-eating macaques, and marmosets. We aim to identify genes and regulatory networks controlling pluripotency that are evolutionarily conserved and those that

are species-specific. Principal Component Analysis (PCA) revealed greater variations across species than within pluripotency states. The analysis also showed a conserved trajectory among different ESC pluripotency states across species. Notably, human naïve ESCs (nESCs) is more closely resemble mouse primed ESCs (pESCs), indicating fundamental differences in these pluripotent states among different species. The hierarchical clustering analysis shows two major clusters that separate primates and non-primates. Transcriptome-based phylogenetic trees also show mice nESC is closer to humans while macaques pESCs are closer to humans, suggesting the phylogenetic distance between species can be different depending on the pluripotent states of the cells. Consistently, differential gene expression (DEG) analysis among ESCs at different states of pluripotency also showed macaque pESCs are most similar to human pESCs. Additionally, we found that nESCs commonly have more DEGs in interspecies comparisons than pESCs, suggesting the naive state may be more species-specific while the primed state may be more conserved. Moreover, we discovered 14 genes that conserved pESC species in at least three of the species. Notably, the gene C1QL2 is conserved throughout all species studied. Overall, our comprehensive comparative transcriptomic analysis across species revealed that the primed pluripotency state is more evolutionarily conserved than the naive state. These findings contribute to our understanding of stem cell biology and the evolutionary underpinnings of pluripotency.

896S **Ancient human genomic data and linear mixed models identify pervasive polygenic selection in the human genome** Jared E Decker[1], John Miraszek[2], Brooke K. Bowman[3], Caleb J. Grohmann[4] [1]Division of Animal Sciences, University of Missouri, [2]Genetics Area Program, University of Missouri, [3]Biological Sciences, University of Missouri, [4]Institute for Data Science and Informatics, University of Missouri

Identifying the loci responding to selection has been a focus of modern population genetics. Approaches using patterns of DNA variants have successfully discovered hard and soft sweeps in which strong selection changes nucleotide diversity. However, polygenic selection on complex traits results in small allele frequency changes at thousands of loci and does not leave the strong signature of a sweep. Polygenic selection does create an association between allele frequencies and time. We use reverse regression in which a proxy for generation number is fit as the dependent variable in a genome-wide association linear mixed model to identify associations between time and genotype. We analyze 11,386 ancient and modern human samples from the Allen Ancient DNA Resource and their corresponding dates before present. We have previously shown that the genomic relationship matrix in linear mixed model genome-wide association appropriately accounts for the demography of the analyzed population. Here, we also fit principal components from analyses of genotypes and missing genotypes as covariates in the statistical models to produce well-calibrated p-values. We identify 5,184 variants with genome-wide significant associations with date before present. In addition to numerous novel associations, we identify canonical targets of selection in humans, including *SLC45A2* and *SLC24A5*. Associated genes were enriched in gene ontology terms and pathways related to immunity, anatomical structure development, and nervous system development. In even our most conservative models, we find associations with *GRM5* and *NRXN1*, which are known to affect learning phenotypes. These results allow us to understand the complex history of polygenic selection in humans.

897S **Extent and effects of changes in gene dosage on the neo-sex chromosomes of parasitic nematodes** Kevin A Hackbarth[1], Tibeb S Mekonen[1], Julie C Dunning Hotopp[2,3], Eric S Haag[1] [1]Biology, University of Maryland, [2]Microbiology & Immunology, University of Maryland School of Medicine, [3]Institute for Genome Sciences

Brugia malayi and *Onchocerca volvulus* are filarial nematode parasites consequential for public health. In each species, a different autosome fused with the X chromosome to form a neo-X chromosome. As a result, their ancestrally XX/XO systems became XX/XY, where the neo-Y represents a degenerated version of the unattached autosomal homolog. As genes on the neo-Y diverge or are lost, the resulting change in gene dosage creates evolutionary pressures to rebalance expression levels, silence unpaired genes during male meiosis, and adapt the gene content on these sex-linked regions. Here, we characterize neo-X/-Y divergence and reanalyze RNA-seq datasets to reveal dosage compensation and meiotic silencing in *B. malayi* and *O. volvulus*. These findings inform our understanding of sex chromosome divergence, dosage sensitivity, transcriptional regulation, and gametogenesis in these parasitic nematodes and in organisms with neo-sex chromosome evolution generally.

898S **Exploring the distribution of ultra-rare mutations under exponential population growth** Deepjyoti Ghosh[1], Margaret C Steiner[2], John Novembre[2,3], Yuval B Simons[1,2] [1]Section of Genetic Medicine, University of Chicago, [2]Department of Human Genetics, University of Chicago, [3]Department of Ecology & Evolution, University of Chicago

Large databases of whole exome and genome sequencing studies are giving the first glimpse of the spectrum of ultra-rare alleles in human populations. This spectrum is dominated by young alleles which arose during recent explosive population growth, in which human populations increased by a factor of roughly 100,000 in less than 2000 generations. Therefore, understanding the frequency spectrum of ultra-rare alleles (frequency under 10-3) requires models of allele dynamics during such explosive population growth. We use branching processes to show that the distribution of allele frequencies in an exponentially growing population is inversely proportional to the square of the frequency. Additionally, the distribution is proportional to the mutation rate and inversely proportional to the growth rate. We use simulations to show that the scaling

with allele frequency is insensitive to the exact shape of population growth. We corroborate our results using data from whole exome sequencing of a White British population in the UK biobank, showing that the site frequency spectrum is indeed inversely proportional to the square of the frequency. These results suggest that the numbers of ultra-rare mutations in whole genome or exome sequencing studies will grow linearly with study size until the study size has reached about 5 million. At that point, every site in the genome should be segregating, except for evolutionarily constrained sites (with selection coefficient above 1%). Therefore, such large study sizes would produce a full map of all evolutionarily constrained sites in the human genome.

899S **Ancient DNA confirms crossbreeding of domestic South American Camelids in two Pre-Conquest archaeological sites** Alondra M Diaz-Lameiro[1], Jennifer L. Kennedy[2], D. Andrew Merriwether[3] [1]Biology, University of Puerto Rico at Mayaguez, [2]Binghamton University, [3]Anthropology, Binghamton University

The llama (*Lama glama*) and the alpaca (*Vicugna pacos*) are important domesticated species, endemic to South America. South American camelids helped ensure the success of humans in the Andes, much like the horse in Europe. Two wild South American camelids, the guanaco and the vicuña have been proposed as the ancestors of these domestic forms. Some scientists have hypothesized that crossbreeding started after the Spanish conquest in the 1500's, since before this event, indigenous people are thought to have kept both domestic breeding lines separate. In an effort to avoid the confounding effects of crossbreeding, ancient DNA from pre-conquest South American camelids was analysed from sites in Bolivia and Ecuador. Our mitochondrial pre-conquest results for Cerro Narrío in Ecuador show that all ancient samples which do not naturally occur in this region and were likely domesticated camelids, had maternal guanaco ancestry. At the Bolivian site of Iwawi, near Lake Titicaca, matrilineal ancestry from both wild species contributed to the domestic forms. These results help disentangle the complex ancestry of the domestic South American camelids and inform future breeding strategies. Additionally confirm the occurrence of crossbreeding between camelids pre-Spanish conquest.

900S **Genetic and Molecular Bases of Hybrid Dysgenesis in Deer Mice** Wyatt Toure, Riya Rampali, Andrés Bendesky Columbia University

Understanding the mechanisms by which incompatibilities arise between populations and species remains a fundamental problem in evolutionary biology. Three clear patterns of hybrid incompatibility ("rules of speciation") have emerged from over a century of observational and experimental work on hybrids: Haldane's rule (hybrids of the heterogametic sex are more affected), Coyne's rule (the X and Z chromosomes play an outsized role in incompatibilities), and Darwin's corollary (asymmetric hybrid effects). These patterns are phylogenetically broad, yet we still do not have a mechanistic understanding of how they manifest in mammals. Deer mice (genus *Peromyscus)* offer an opportunity to resolve the genetics and molecular biology of hybrid incompatibilities since they exhibit all three rules yet are amenable to quantitative genetic mapping of their incompatibilities. The cross in which *P. maniculatus* is the mother and *P. polionotus* is the father produces viable, fertile offspring but the reciprocal cross produces an embryonic lethal overgrowth that renders this cross inviable, except for rare female survivors. Through QTL mapping, we have revealed that the largest genetic effect contributing to the overgrowth is on the X chromosome and that it only affects males and not females. The QTL in question maps to the X inactivation center, an intriguing result, since male mice are hemizygous for the X chromosome and do not typically undergo X inactivation. Our analysis of RNA-sequencing data has revealed that the QTL associated with overgrowth leads to a global reduction in the level of X-linked transcripts in males, suggesting dosage compensation may be perturbed. Further RNA-sequencing of embryos reveals that dosage compensation perturbations are already present by day 13 of embryonic development and that the expression of imprinted genes is highly perturbed. Ultimately, by providing mechanisms for hybrid incompatibilities between naturally diverging mammalian species, we will reveal insights into the classic rules governing the maintenance and origin of species.

901S **Genomic Evolution of Phi-6 Cystovirus under Heat Shock Treatments** Sara Nayeem, Parnian Pour Bahrami, Sujayashree Jayatirtha Nilogal, Sarosh Syed, Pranav Babu, Sanika Samel, Sonia Singhal San Jose State University

Climate change can lead to increases in temperature over time, and the rate of increase may influence how populations adapt to the changing environment. For example, the number and types of mutations used for adaptation may depend on the rate of environmental change. We address this question in a model system, the RNA bacteriophage phi-6, under high temperatures. Bacteriophages (viruses that infect bacteria) are good candidates to study evolution because they have high mutation rates, high replication rates, and large population sizes, and are harmless to humans. We previously evolved populations of phi-6 for 32 days (approx. 100 viral generations) under high-temperature heat shocks in different treatments. In the Sudden treatment, populations experienced constant heat shocks at 50°C. In the Gradual treatment, heat shock temperatures increased each transfer up to 50°C. Samples were cryogenically stored at each transfer. Based on differences in selective pressures under sudden and gradual environmental change, we expect to see adaptation to heat shocks through a few mutations of large effect

in the Sudden treatment, and adaptation through mutations of smaller effect in the Gradual treatment. Here, we test these hypotheses in our phi-6 lineages. We revive the frozen populations and extract viral RNA from the samples at transfers 8, 16, and 24, representing times one-quarter, one-half, and three-quarters of the full experiment. After reverse transcribing the RNA into cDNA, we sequence the samples to identify and track any changes in the viral genetic material over evolutionary time. Our experiments provide important information on both how viruses specifically adapt to high temperatures and how organisms more broadly adapt under different rates of climate change.

902S **Best practices for identifying fast evolving non-coding elements using PhyloAcc-GT: A cases study using echolocating mammals** Gregg W.C. Thomas[1], Subir B. Shakya[1], Scott V. Edwards[2], Timothy B. Sackton[1] [1]Informatics Group, Harvard University, [2]Organismic and Evolutionary Biology, Harvard University

Comparing the genomes of multiple species in a phylogenetic context has become a common way to study how molecular changes in DNA accumulate over evolutionary timescales. One way to quantify genomic variation is to assess the rate at which it accumulates over time. Doing this, regions of the genome that evolve at varying rates on different lineages can be identified and allow us to infer when and where selection may have played a role in sequence evolution. These inferences at the genotypic level can subsequently be linked to phenotypic evolution. We recently released PhyloAcc-GT, which identifies shifts in nucleotide substitution rate along a phylogeny. Unlike codon-based models, PhyloAcc-GT can be used to infer rate shifts in non-coding elements. PhyloAcc-GT also accounts for phylogenetic discordance between the underlying loci and the species tree. Here, we show how PhyloAcc-GT can be used on a large-scale genome alignment of 241 mammals. We provide workflows and best practices to process a multiple alignment format (MAF) file to identify the putative conserved non-coding elements that PhyloAcc-GT uses as input. We provide Snakemake workflows for conserved element prediction using PHAST. We consider both explicit conserved element prediction and a more flexible identification of genomic regions with a high percentage of significantly conserved sites and with high alignment coverage. We also provide tools to work with large MAF files and extract sub-alignments, which are used as input to PhyloAcc-GT. We demonstrate our workflows by identifying non-coding elements that are convergently accelerated in lineages of echolocating mammals (bats and dolphins).

903S **Inference of selection coefficients while controlling for gene flow using ancient DNA** Xinyi Li[1], John Novembre[2] [1]University of Chicago, [2]Human Genetics, University of Chicago

Studying genetic signatures of natural selection using ancient DNA may help identify functionally important variants. However, the complex demographic history of humans can hide selection signals or lead to spurious discovery. In particular, gene flow from diverged populations can cause rapid shifts in allele frequencies that may be mistaken as selection signatures.

To address this limitation, we developed a new method to infer selection while controlling for the effects of gene flow. We model the allele frequency change of a target population as a function of genetic influx from other source populations, drift, and selection. First, we infer the posterior distribution of migration proportion parameters using SNPs from putatively neutral regions. Second, conditioning on the migration proportions, we estimate the selection coefficients for variants in interest. At each step, to obtain the posterior distribution efficiently, we use variational inference.

To test this method, we applied our method to simulated data. In these simulations, compared to a method that does not account for migration, our approach obtains a more accurate and unbiased selection coefficient. For instance, in the case of 30% pulse migration, an initial frequency of 0.01 in the target population, and a selection coefficient of 0.001, the approach without considering gene flow infers on average a 3-fold larger selection coefficient estimate (s=0.0034 vs. s=0.0012).

We applied our method to publicly available data from 481 individuals from the Carpathian Basin, including samples ranging from 5000 BCE to 900 CE (Mallick et al., 2023). Our method fits two major events of gene flow: 1) from Steppe-like ancestry during the Bronze Age and 2) from Xiongnu-like ancestry in the Medieval period. Correcting for these gene flow events, we recover known selected signals and exclude likely false positives. For instance, our method recovers a selection signal at rs5743810 which was known to be an Fst outlier (posterior mean of s= 0.006 with 95% credible interval [0.00074, 0.012]) while a method that does not account for gene flow does not have enough power (posterior mean of s= 0.004 with 95% credible interval [-0.0019, 0.011]).

While gene flow among populations has been shown to be pervasive across human history, our new method can be a powerful way to infer selection using ancient DNA without biases from gene flow.

904S **Connections between topological data analysis and identity-by-descent in biobank data** Alex Diaz-Papkovich[1], Cole Williams[1], Justin Pelletier[2], Simon Gravel[2], Claude Bherer[2], Sohini Ramachandran[1] [1]Brown University, [2]McGill University

Population structure reflects shared population history. A variety of methods are used to identify structured subgroups in

genetic datasets. One such approach is detecting pairwise shared chromosomal segments that are identical-by-descent (IBD), indicating shared ancestry, followed by clustering of those segments. Having identified IBD clusters, researchers can subsequently perform analyses of demographic history, or study associated biomedical data and environmental variables for these groups.

While IBD clustering is common, it can be computationally taxing. An efficient and now-common dimensionality reduction method in population genetics is uniform manifold approximation and projection (UMAP). UMAP works by preserving the high-dimensional topology of data and is usually applied to genetic variants rather than haplotypes. It can also be paired with density clustering to define clusters without the overhead of chromosomal phasing and parametrization of IBD calling. The UMAP-identified subgroups correlate strongly with demographic history, environmental, and phenotypic data and, similar to results of IBD clustering methods, identify very fine-scaled structure in complex genetic cohorts. Though UMAP clusters are often discussed in studies of genetic cohorts, no explicit connection has been drawn between UMAP clusters and IBD sharing. Such connections can inform researchers of the relationships between processes like coalescence and relatedness, aid in interpretation of non-linear dimensionality reduction, as well as provide an alternative set of computationally cheap and tractable tools to study clusters from structured population in large biobanks.

We present results from CARTaGENE, a cohort of residents of Québec, and the Thousand Genomes Project. We find a strong relationship between the clusters found via UMAP followed by density clustering compared to those found via IBD clustering in CARTaGENE. We use CARTaGENE, the UK Biobank, and the Thousand Genomes data to study how genetic relationships between individuals in data influence visualization and clustering. We discuss the relative strengths of the approaches and potential theoretical connections between topological clustering and IBD clustering.

905S **History repeats itself: Genetic changes underlying convergent phenotypes are revealed by comparative genomics** Nathan Clark[1], Avery Selberg[2], Maria Chikina[3], Sergei Pond[2] [1]Biological Sciences, University of Pittsburgh, [2]Biology, Temple University, [3]Computational and Systems Biology, University of Pittsburgh

A combination of comparative genomics and phylogenetics is increasingly being used to assign genotype to phenotype through an approach called PhyloG2P. Many such methods examine species sharing a convergently evolved phenotype and identify related genes that experienced parallel changes in selection in those species. If adaptive changes in a gene were responsible, positive selection or accelerated rates are expected. If, instead, the phenotype is the degeneration of a trait, relaxed constraint on related genes would be seen as accelerated rates or pseudogenization. Using these expectations, PhyloG2P methods search for positive selection, shifts in evolutionary rate, or pseudogenization associated with the branches over which the convergent phenotype evolved. To date, these approaches have identified new genes and regulatory regions controlling traits important to fitness and health. When applied to blind mammals, PhyloG2P located new ocular genes and enhancer elements. In flightless birds, new enhancers were implicated in wing development. Study of “bald” mammal species identified new microRNAs and enhancers involved in hair follicle formation, and new sperm proteins were found by studying the sperm competition in rodents and primates. A general observation across these studies is that trait losses are more powerful at identifying phenotype-related genes, because once constraint is released it produces a strong rate acceleration that continues indefinitely. Conversely, it is difficult to identify genes underlying phenotypic changes involving adaptive evolution, likely because the responsible positively selected changes were episodic and relatively few. To identify adaptive changes via PhyloG2P, the field requires tools to identify branch-specific bursts of positive selection that are absent from branches not involved in the convergent phenotype. To meet this need, we developed a custom set of likelihood models in BUSTED-PH to identify positive selection that acted specifically on branches with a convergent PHenotype. BUSTED-PH’s application to aquatic mammals identified genes involved in adaptation to diving along with skin and lung traits, presumably due to selection on impermeability and compression. PhyloG2P approaches continue to evolve just as the natural world does in response to its challenges. New developments on the horizon will examine gene expression and genomic indicators of regulatory function with respect to convergent phenotypes.

906S **Expression and Evolution of Alt-ORFs in the Human Genome** Naiqi Zhang[1], April Wei[2], Zachary Ardern[3] [1]Cornell University, [2]Computational Biology, Cornell University, [3]Wellcome Sanger Institute

Many open reading frames (ORFs) with evidence of protein translation are encoded so as to overlap known protein-coding genes, thereby reading a completely different codon sequence from the same nucleotide string.

Despite their functional relevance, the systematic study of protein-coding alt-ORFs in the human genome from an evolutionary perspective remains underexplored.

Here, we investigated sequence evolution within the human population and across mammals for a set of alt-ORFs. These

were extracted from a recently published collection of all protein-coding ORFs, which was compiled from diverse studies of ribosome profiling—mapping ribosome coverage of RNA across the genome.

We identified the sequences of the alt-ORFs within the human genome and developed a bioinformatic pipeline to trace their evolutionary trajectories across a wide array of mammalian genomes using the Zoonomia multiple mammal coding sequence alignments. In addition to examining evolutionary origin and constraint, we explored sequence variation within the human genome by utilizing the gnomAD variant database. In contrast to the previous belief that alt-ORFs are subject to more rapid evolutionary changes, our investigation reveals that many alt-ORFs are, in fact, evolutionarily conserved.

The findings suggest that alt-ORFs as a whole are not mere genetic anomalies or "junk" translation but that some may hold crucial functions that have been overlooked in genetic research. This study provides a foundation for further exploration into the complexities of the human genome and will encourage additional research into the molecular functions of alt-ORFs in humans and across species.

907S **In space no one can hear you sweep: Investigating the dynamics and outcomes of selective sweeps in continuous geographic space** Clara Rehmann[1], Peter Ralph[2], Andrew Kern[1] [1]Institute of Ecology & Evolution, University of Oregon, [2]Institute of Ecology & Evolution, Department of Mathematics, University of Oregon

Understanding the process by which organisms adapt to their environment is a driving question in evolutionary biology. At the genetic level, positive selection, including selective sweeps, contribute significantly to this process, and in doing so, play a powerful role in shaping patterns of genetic variation. While a large body of research has explored the dynamics and consequences of selective sweeps under both theoretical and empirical frameworks, that work has focused largely on sweeps in well-mixed, randomly-mating populations. However, spatial population structure also has profound effects on how genetic variation is shared in natural populations, and the impact of this structure on selection remains uncharacterized. Here, we use forward-in-time, individual-based continuous space simulation, to investigate the dynamics of selective sweeps in spatially-structured populations. We identify and describe the relationship between selection, spatial population structure, and the movement of an adaptive variant across geographic space. Using these relationships, we leverage spatial data to identify potentially adaptive variants in Anopheles mosquito populations.

908S **Interpreting differences in DNA base composition at polymorphic sites across populations** Sheel Chandra[1], Ziyue Gao[2] [1]Biology, University of Pennsylvania, [2]Genetics, University of Pennsylvania

DNA base composition is a fundamental attribute of the genome that can vary across species but can also be surprisingly conserved between some distantly related species. Understanding the evolutionary basis of these patterns can help shed light on several related genomic features, such as codon usage, methylation, and genome organization. Recently, Li et al. (2015), reported striking differences in GC content at polymorphic sites between populations within the same species that experienced or did not experience recent bottlenecks. Specifically, individuals in bottlenecked groups showed lower GC content at common single nucleotide polymorphisms (SNPs) with minor allele frequency (MAF) above 5% compared to those in non-bottlenecked groups across all eight species studied, including humans. These findings seemingly suggest rapid evolution and future divergence in base composition between populations.

In this study, we aim to probe the evolutionary forces underlying the pattern of base composition in human populations, using high-coverage sequencing data from the 1000 Genomes Project. We first replicate the observation of higher GC content in African individuals at common SNPs. Within each population, we also observe clear differences in the site frequency spectrum (SFS) across different mutation types (e.g., C>T, T>G), consistent with the effect of GC-biased gene conversion (gBGC). We hypothesized that gBGC, interacting with population demographic history, may have led to the inter-population difference in GC content. However, we observe higher GC content at strong-to-weak (S>W) mutations but lower GC content at weak-to-strong (W>S) mutations in African individuals. Further investigation into the SFS reveals that these differences in GC content come from the lower derived allele frequencies (DAF) in African populations for all mutation types at common SNPs, likely reflecting the impact of demographic history. However, there is an enrichment of derived alleles in African individuals relative to non-Africans, at rare SNPs (DAF<1%), the opposite pattern to common SNPs. In fact, the inter-population difference in GC content completely disappears when all common and rare variants are considered jointly. We also repeat this analysis for two other species in the original study and find similar results. We conclude that given current data, there is no evidence of differences in mutation bias or genomic GC content across human populations. Furthermore, although there is clear evidence of gBGC within populations, the strength of gBGC, combined with population demographic history, is not strong enough to produce discernible differences in base composition between recently diverged groups.

909S **Adaptive Evolution In *TAS2R14* and *TAS2R38* Bitter Taste Receptor Genes In Primates** Gillyoung Koh[1], Jiajia Chen[1], Kyra Kovacic[2], Barbara Domingues Bitarello[1] [1]Bryn Mawr College, [2]Children's Hospital of Philadelphia

Primates commonly avoid bitter-tasting foods as a potentially adaptive response to avoid ingesting toxic compounds. Bitter compounds bind to the extracellular N-terminus and the 7 transmembrane domains of type 2 receptors (TAS2R). A promiscuous receptor, the human TAS2R14 binds more than 150 bitter compounds. It modulates innate immune responses in the mouth and bronchodilation in the lungs in response to quorum-sensing molecules, is expressed in epidermal keratinocytes, and facilitates blood-cerebrospinal fluid barrier molecule transport. The human TAS2R38 binds to 23 known ligands and in humans and chimpanzees influences individual perceptions of phenylthiocarbamide (PTC), a synthetic compound structurally resembling natural chemicals found in *Brassica sp*.

Moderate frequency human *TAS2R38* haplotypes are associated with different PTC-tasting phenotypes, suggesting the action of long-term balancing selection (LTBS), while its recent evolution may be explained by demographic events alone, suggesting a complex evolutionary history. We previously reported that LTBS may have shaped human *TAS2R14* evolution. Natural selection genomic scans suggest increased immune surveillance has been a target of selection, including several genes: MHC, keratin (the first line of defense in the skin), and cell surface receptors broadly. We assess if the ability to bind a diverse repertoire of ligands has been targeted by selection. Specifically: are adaptive evolution (AE) signatures in *TAS2R14* and *TAS2R38* pervasive in primates or human-exclusive? Do specific sites display stronger AE signals? Do these sites tend to be located in specific portions of the protein? With molecular evolution models implemented in PAML (site models) and Hyphy (BUSTED, FEL, MEME), we looked at the nonsynonymous to synonymous substitution rates ratio (dN/dS) in alignments of 29 primate species (317 codons) for *TAS2R14* and 46 primate species (333 codons) for *TAS2R38*.

We find strong signals of gene-wide AE (non site-specific) (BUSTED, $p = 0.0067$ for *TAS2R38*; $p = 0.0234$ for *TAS2R14*). We also find strong AE signals for sites selected pervasively across the tree: 8 sites for *TAS2R38* and 12 for *TAS2R14* (FEL $p \leq 0.10$); 1 for *TAS2R38* and 22 for *TAS2R14* (PAML M7 vs M8, posterior $p \geq 0.90$); 21 for *TAS2R38* and 26 for *TAS2R14* (MEME $p \leq 0.10$). Work underway will assess if sites differ across the phylogeny, shedding further light on ligand binding mechanisms in these receptors and selective pressures driving AE.

910S **A scalable approach to estimating a genome-wide gene-conversion map from the UK Biobank data** Siddharth N Avadhanam, April Wei Cornell University

Gene conversion (or non-crossover recombination) involves short unidirectional transfer of DNA sequence between homologous chromosomes during meiosis. It is one of two mechanisms of homologous recombination (the other being crossover recombination) and has been shown to have a profound impact on the nucleotide composition of the human genome, yet there has been relatively less attention paid to simulating or measuring this process. Recent approaches to detecting gene-conversions in humans have relied on a three-generation genotyped pedigree study design. However, such data are difficult to obtain, are limited by SNP ascertainment biases and can only capture transmitted gene-conversions from a single meiosis, limiting our understanding of this important process. Here we propose a new approach that relies on sequence identity within a short genomic region between admixed haplotypes and a panel of reference haplotypes. We then propose an estimator of gene-conversion rate based on the coalescent process relating the sequence identity to their MRCA and time of admixture, allowing us to jointly model mutations, gene-conversions and sequencing errors. This approach allows us to capture information from every gene-conversion event between the MRCA and the admixed segment, affording higher resolution through the use of Whole Genome Sequence (WGS) data, and increasing the power to detect gene-conversion events through the use of unrelated admixed genomes. To validate our method, we built a pedigree simulator that incorporates both crossover and gene-conversion and outputs a ground truth localization of gene-conversion events; to our knowledge, this is the only available method to simulate such data. Using simulated genomes of mixed African and European ancestry, with gene-conversion events occurring only after admixture, we find that our approach is well-powered to detect these events. We are currently applying this new method to the UK Biobank data and we anticipate that the resulting genome-wide gene-conversion map will be a highly useful resource for simulating and modeling gene-conversions as well as for studying meiotic recombination.

911S **A phylogenetic approach to understand evolution and transmission of drug-resistant mutations of Human Immunodeficiency Virus Type 1 infections in a large US Kaiser Permanente Northern California clinic population** Marisol Contreras, Pleuni S. Pennings Biology, San Francisco State University

In 2022, 29.8 million Human Immunodeficiency Virus Type 1 (HIV-1) patients were on antiretroviral therapy (ART). Drug resistance to antiretrovirals is a big problem with transmitted drug resistance levels being around 10% and higher for those with prior ART exposure. Drug resistance in the virus of a patient can arise either through de novo evolution, where the patient is initially infected with a susceptible strain that later becomes resistant, or through host-to-host transmission, where the patient is infected with a strain that is already resistant to drugs. It is not well understood how often resistance is due to transmission versus de novo evolution. Host-to-host transmission of drug resistant strains leads to clusters of similarly

resistant strains in phylogenetic trees. The objective of this study is to analyze cluster sizes of drug resistance mutations on a phylogeny to understand the relative roles of de novo and transmission from a publicly available dataset of patients from Kaiser Permanente Northern California (KPNC). My plan is to use methods previously used in the Pennings lab to construct phylogenetic trees, to identify origins of resistance and clusters of resistance within ART-Naive patients to determine the relative importance of transmission and de novo evolution. We expect that mutations that are known to come with a fitness cost will appear in smaller phylogenetic clusters whereas mutations that are known to be benign for the virus will appear in larger phylogenetic clusters. Results will clarify the clinical significance of transmission clusters for different drug resistance mutations in the KPNC population, contributing to an improvement of healthcare practices and disease treatment strategies.

912S **Reimagining the data structures and algorithms for scalable whole-genome analyses** April Wei, Drew DeHaas, Ziqing Pan Cornell University

Millions of human genomes are now available through large biobanks, posing challenges for researchers to store, distribute and utilize these data. To date, biobank-scale genetic data are still encoded with tabular data structures, i.e, with rows and columns representing samples and variants along the genome. While tabular formats (e.g., VCF, PLINK, and BGEN) are supported by many bioinformatic tools, they become prohibitive to store and use as the number of genomes continue to grow. An existing alternative to the tabular format is the tree sequence format (TS) which embeds the polymorphism information in the Ancestral Recombination Graph (ARG). However, the TS format cannot easily support efficient algebraic calculations, and existing ARG inference methods are either not scalable enough for biobanks (e.g., Relate), do not compress the real genome very well (tsinfer), or lose information about polymorphisms (ARG-Needle). Given these limitations, there is an urgent demand for a new data structure that can losslessly compress the genetic data while maintaining the ability to perform different types of analyses. Here we introduce the genotype representation graph (GRG), a novel graph-based representation of biobank-scale whole-genome polymorphism data that can store the same information as phased VCFs, but with a few gigabytes (GB) as opposed to tens of terabytes (TB). This radical size reduction comes from leveraging the patterns of shared mutations among samples and encoding this information in a fully connected hierarchical graph. We developed and implemented an algorithm to infer GRG that scales to a million whole genomes. When applying our method to real data, GRG can represent the 2504 whole-genomes from 26 populations in 1000 Genomes Project using 10 GB of disk space, whereas VCF, PLINK, and TS take 800 GB, 50 GB and 23 GB, respectively. Using European genomes simulated by msprime, we find that GRG is able to store a million haploid whole genomes with 3 GB, saving 99.99% and 60% storage space compared to the VCF (33 TB) file and the simulated TS (7.5 GB) respectively. Moreover, we implemented graph traversal algorithms to compute population level first-order summary statistics that run as fast as the current state-of-the-art software. We anticipate that GRG based algorithms will further improve the scalability of higher order computation and help democratize biobank-scale data access by mitigating the associated computational burden.

913S **Two-Locus Genealogies under Isolation-by-Distance and Time** Arjun Biddanda Johns Hopkins University

Patterns of linkage disequilibrium (LD) in population genetic data have been foundational for drawing insights on the genetic basis of complex traits, meiotic recombination, and the impact of natural selection. The focus on LD in theoretical population genetics has focused on demographic models with spatial and time-stratified sampling independently, but not jointly within the same model framework. Here, I derive results for summary statistics of haplotype variation under models of temporal and spatially-stratified sampling. This includes 1) the correlation in the number of pairwise differences (π_t) observed between two sampled haplotypes and 2) the product of the LD coefficient, D, between two spatially and temporally separated samples and 3) the expected value of r^2 between spatial and temporally stratified samples. I additionally evaluate how asymmetric migration and barriers to gene flow between spatial demes alters the sign and magnitude of LD statistics. Importantly, I show how temporally stratified LD-statistics can be used to evaluate historical barriers to gene flow that may not be readily inferred from modern LD statistics alone. Finally, I explore how LD-statistics from a dataset of ~600 modern and 1,159 ancient Eurasian male X-chromosomes can be used to estimate the relative strength of barriers to gene-flow across latitude and longitudinal gradients. Overall, these results provide insight into how haplotypic patterns are jointly impacted by both spatial- and temporally population structure, and guide the development of future methods using temporally stratified data for the inference of population demographic history.

914S **Manipulating sex determination in *Caenorhabditis* tetraploids to evaluate Haldane's rule** Jonathan Harbin, Ronald E Ellis Molecular Biology, Rowan-Virtua SOM

In 1922 Haldane noted that when two species form hybrids, if "one sex is absent, rare, or sterile, that sex is the heterozygous sex." Haldane's rule applies to crosses between the closely related nematode species *C. nigoni* and *C. briggsae*, since Woodruff et al observed that crosses between *C. nigoni* males and *C. briggsae* hermaphrodites produced no living males, and that the reciprocal crosses between *C. briggsae* males and *C. nigoni* females produced only sterile males. Despite its broad applicability,

there is still lively debate about the factors that underlie Haldane's rule.

The *Caenorhabditis* sex determination cascade is initiated in the early embryo by the ratio between the number of *X* chromosomes and sets of autosomes. Disrupting this cascade by altering the sex determination pathway can drive animals to develop as male regardless of their *X:A* ratio. By manipulating sex determination and ploidy within nematodes we can study whether the hybrid heterozygous sex disadvantage is due to chromosome incompatibles (dominance theory) or male specific gene evolution (faster male theory). To that end, we adapted the Schvarzstein method for producing polyploid *Caenorhabditis* strains. Through inactivation of *rec-8* by RNA interference we produced a *C. nigoni* polyploid strain, a *C. briggsae* tetraploid strain already existed. DAPI staining confirmed that the *C. nigoni* female animals are tetraploid, and most likely *XXX; AAAA*, and the males appear to be *XX; AAAA*.

Remarkably, using these tetraploid strains, we can now produce fertile interspecies hybrids. These not only include fertile hermaphrodites, but also healthy fertile males. This result strongly supports the model that Haldane's rule in diploid crosses is caused by incompatibility between the genes on the single *X* (which of necessity comes from only a single species), and interacting products made by the pairs of autosomes from both species. As a result, negative interactions should be minimized in tetraploid males, which have one *X* from each parent species. We are now studying backcrosses of these hybrids to each parent species. Although the success rate for individual crosses is low, the resulting progeny tend to be healthy and vigorous.

Simultaneously, using a reverse genetic approach, the first *C. nigoni* sex determination mutations were generated in the critical sex genes *tra-1, tra-2*, and *fem-3*. Indels that result in an early stop codon were selected after injecting gravid *C. nigoni* females with Cas9 RNPs. Utilizing *tra-1* mutations that drive animals to develop as males, regardless of their *X: A* ratio, we are now studying if maleness can drive Haldane's rule in male *XX* hybrids.

915S **The Spatial Speedup Effect of Evolutionary and Ecological Dynamics** Anush Devadhasan, Oana Carja Carnegie Mellon University

Across scales of organization, understanding the mechanisms that shape and maintain diversity in a population remains a fundamental challenge and there exists a large literature in evolutionary biology describing the processes that can account for persistent coexistence within populations. At their core, the theoretical frameworks are grounded in balancing selection, including negative frequency-dependent (NFD) selection, spatial or temporal habitat heterogeneity, and heterozygote advantage. In particular, NFD selection, by favoring rare types, is often suggested as the main selective force for biodiversity and polymorphism in natural populations. In this talk I will describe an evolutionary model in which, unintuitively, the opposite occurs: NFD selection decreases coexistence relative to neutrality, for certain spatial population structures. We call this the spatial speedup effect and, using a combination of mathematical analysis and simulation, we find that the condition for this effect depends critically on the spatial arrangement of the population. We show that spatial speedup is specifically shaped by the algebraic connectivity of the population: a measure of "spatial bottleneckedness" that derives from spectral graph theory. I will discuss how spatial speedup in bottlenecked populations can significantly impact biodiversity over evolutionary and ecological timescales by analyzing fixation times and species richness as the respective proxies for coexistence.

916S **`diplo-locus`: A lightweight toolkit for inference and simulation of time-series genetic data under general diploid selection** Xiaoheng Cheng[1], Matthias Steinrücken[1,2] [1]Ecology & Evolution, University of Chicago, [2]Human Genetics, University of Chicago

Whole-genome time-series allele frequency data are becoming more prevalent as ancient DNA (aDNA) sequences and data from evolve-and-resequence (E&R) experiments are generated at a rapid pace. Such data presents unprecedented opportunities to elucidate the dynamics of adaptative genetic variation. However, despite many methods to infer parameters of selection models from allele frequency trajectories available in the literature, few provide user-friendly implementations for large-scale empirical applications. Here, we present `diplo-locus`, an open-source Python package that provides functionality to simulate and perform inference from time-series under the Wright-Fisher diffusion with general diploid selection. The package includes Python modules as well as command-line tools and is distributed on Python Package Index (PyPI). We demonstrate its superior computational speed compared with existing time-series methods and benchmarked its statistical performance with simulation. Application on UK samples in the Allen Ancient DNA Resources database recovered strong selection signals on rs4988235, well-established to regulate the expression of the lactase gene *LCT*. We further estimated the selection parameters of this SNP, showing evidence for its beneficial allele to be dominant. We believe this package will prove convenient and useful for future evolutionary genomics research.

917S **Spatial structure alters the site frequency spectrum produced by hitchhiking** Jiseon Min[1], Misha Gupta[2], Michael M Desai[2], Daniel B Weissman[3] [1]IE2, University of Oregon, [2]Harvard University, [3]Emory University

The reduction of genetic diversity due to genetic hitchhiking is widely used to find past selective sweeps from sequencing data, but very little is known about how spatial structure affects hitchhiking. We use mathematical modeling and simulations to find the unfolded site frequency spectrum left by hitchhiking in the genomic region of a sweep in a population occupying a 1D range. For such populations, sweeps spread as Fisher waves, rather than logistically. We find that this leaves a characteristic 3-part site frequency spectrum at loci very close to the swept locus. Very low frequencies are dominated by recent mutations that occurred after the sweep and are unaffected by hitchhiking. At moderately low frequencies, there is a transition zone primarily composed of alleles that briefly "surfed" on the wave of the sweep before falling out of the wavefront, leaving a spectrum close to that expected in well-mixed populations. However, for moderate-to-high frequencies, there is a distinctive scaling regime of the site frequency spectrum produced by alleles that drifted to fixation in the wavefront and then were carried throughout the population. For loci slightly farther away from the swept locus on the genome, recombination is much more effective at restoring diversity in 1D populations than it is in well-mixed ones. We find that these signatures of space can be strong even in apparently well-mixed populations with negligible spatial genetic differentiation, suggesting that spatial structure may frequently distort the signatures of hitchhiking in natural populations. This work has been published in Genetics (iyac139).

919S **Impacts of demographic history on inter-chromosomal haplotype phasing** Cole M Williams[1], Amy L Williams[2], Sohini Ramachandran[1] [1]Brown University, [2]23andMe, Inc.

Several recently developed methods have improved haplotype phasing by leveraging the regions of the genome that relatives share identical-by-descent (IBD). Given a focal individual F and a person R related to F through only one parent, one can phase F at positions covered by the IBD segments the pair shares (yielding inter-chromosomal phase). However, if R shares IBD segments with F through both parents (e.g., due to consanguinity at some point in the genealogy), this phasing procedure would not perform well. In the UK Biobank, the average individual has thousands of relatives, most of whom are distantly related. When conducting this IBD-based phasing in the UK Biobank, we found an abundance of relative pairs connected through both parents. Using IBD segments enables inter-chromosomal phasing but can be stymied if an individual is related to a focal sample F through both F's parents. Here we study the population genetic properties of these genealogical reticulations in the context of a population's demographic history. In a constant-sized population of N, for example, we expect two individuals' sets of ancestors to completely overlap log2(N) generations in the past. If two IBD segments date back to more than log2(N) generations in the past, their paths through the population genealogy should be independent, and the assumption that the pair is related through only one parent will frequently be violated. Thus, the frequency of relatives who are related to both parents may offer insight into the demographic history of the population, the degree of pedigree collapse, and provide guidance for IBD-based phasing. Heterogeneity between some individuals in the co-inheritance of IBD segments may offer additional insights into the degree to which random mating is violated and may help to detect population structure. We analyzed two datasets: 1029 UK Biobank samples (trio children) and genomes simulated through the Quebec BALSAC genealogy. In the UK Biobank, we find that the likelihood of a relative being related to both parents increases as relatedness decreases, such that 30% of 9th degree relative equivalents are related to both parents. In the simulated Quebec genomes, which underwent a strong founder event, the highest rate is 40% (but for 5th degree relatives) and then proceeds to decrease with decreased relatedness. These results suggest that the performance of IBD-based phasing using distant relatives depends on the dataset, and in particular the demographic history of the dataset.

920S **A population genetic model for effect size correlations in GWAS** Evan M Koch[1], Mikhail Moldovan[1], Colby Chiang[2], Shamil Sunyaev[1] [1]Biomedical Informatics, Harvard Medical School, [2]Boston Children's Hospital

The availability of well-powered genome-wide association studies (GWAS) for many complex traits has driven a large body of work on how selection shapes genetic architecture. One finding has been that GWAS loci experience negative selection that increases with the magnitude of allelic effects. What remains uncertain is how trait-level selection generates this variant-level selection. Stabilizing selection is an appealing hypothesis because it is routinely measured in natural populations and has been evidenced for some traits in modern humans. A phenotypic optimum is also suggested by symmetric negative selection between trait-increasing and decreasing alleles. However, we lack direct evidence that stabilizing selection is sufficiently widespread to explain the ubiquitous negative selection on GWAS variants. One path forward may lie in the correlation of variant effects along the genome. The Bulmer effect describes how stabilizing selection creates weak negative linkage disequilibrium (LD) between unlinked variants throughout the genome that when summed reduces the genetic variance. Recent analyses of GWAS summary statistics have found strong negative correlations at short genomic distances, suggesting a local Bulmer effect and the action of stabilizing selection. We developed a population genetics model for effect size correlations between pairs of completely linked sites using recent theory for LD between rare alleles as well as simulations. Results suggest at least two forces are qualitatively capable of generating negative effect size correlations. As expected, fitness functions resembling stabilizing selection yield negative correlations as haplotypes with opposing effects are able to drift to higher frequencies. Alternatively, when mutation is biased towards trait-increasing or decreasing effects,

symmetric fitness functions may also yield negative correlations through Hill-Robertson interference. Extending the model to consider distributions of mutational effects, we find that substantial asymmetry is necessary to generate measurable effect size correlations, but that nearly neutral mutations contribute most per-site to negative correlations under stabilizing selection. Finally, we explore extensions to pleiotropy and mutational autocorrelation. Stabilizing selection remains a plausible explanation for negative effect size correlations, but further analyses of mutational asymmetry are warranted.

921S **NovelTree: Highly parallelized phylogenomic inference** Austin H Patton[1], Feridun Mert Celebi[1], Seemay Chou[1], Jonathan Eisen[2], Megan L Hochstrasser[1], Elizabeth A McDaniel[1], Erin McGeever[1], Taylor Reiter[1], Dennis Sun[1], Ryan York[1] [1]Arcadia Science, [2]University of California, Davis

Phylogenomic analysis of thousands of gene families across diverse taxa are increasingly commonplace. However, with relatively few exceptions, implementation of complete phylogenomic analyses has been largely piecemeal, requiring that users write custom workflows that string together software implementing each each constituent step. Although such an approach allows researchers to tailor their analyses to specific use cases, this increased specificity is gained at the expense of reproducibility and comparability across studies. Furthermore, the significant computational challenges innate to phylogenomic analysis still frequently imposes practictal contraints on both the number of species, and number of gene families studied. Consequently, we developed NovelTree, a nextflow workflow designed to reproducibly conduct phylogenomic studies of gene family evolution at scale. The workflow takes proteomes (i.e. one protein amino acid sequence for each gene in a genome) from diverse organisms and infers orthology, gene family trees, species trees, and gene family evolutionary dynamics. To demonstrate NovelTree's utility for phylogenomic and comparative evolutionary inference, we applied the workflow to a dataset of 36 TSAR eukaryotes (Telonemia, Stramenopila, Alveolata, and Rhizaria).

922S **Cis-regulatory evolution of Wnt-family genes underlies morphological evolution in the domesticated silkworm** Kenta Tomihara[1], Ana Pnharanda[2], Andrew Taverner[3], Patrick F Reilly[3], Matthew L Aardema[4], Laura Kors[5], Lin Poyraz[2], Takashi Kiuchi[1], Takashi Kiuchi[1], Peter Andolfatto[2] [1]Agricultural and Environmental Biology, University of Tokyo, [2]Biological Sciences, Columbia University, [3]Lewis-Sigler Institute for Integrative Genomics, Princeton University, [4]Ecology and Evolutionary Biology, Princeton University, [5]Biology, Barnard College

Closely-related species often exhibit distinct morphological structures that can contribute to species-specific adaptations and reproductive isolation. One example are Lepidopteran caterpillar appendages, which have evolved convergently and divergently across species. Specifically, Bombycoidea moth caterpillars evolved a distinct posterior "caudal horn" that varies in size and shape among different species within the group. To understand the genetic mechanisms responsible for the caudal horn size difference distinguishing *Bombyx mori* and its wild progenitor *B. mandarina*, we conducted a high-resolution quantitative trait locus (QTL) analysis. We detect 12 QTLs contributing to the reduced caudal horn size in *B. mori*. Notably, one QTL on chromosome 4 accounts for 12% of the mean length difference between species and encompasses a conserved cluster of Wnt-family genes, which are known to regulate morphological development in animals. By examining the expression of genes within this QTL region, we identified *Wnt1* and *Wnt6* as having caudal horn-specific cis-regulatory changes that reduce levels of expression of the *B. mori* allele. To further validate these findings, we show that CRISPR/Cas9-mediated allele-specific knockouts in F1 hybrids that reduce dosage of *Wnt1* and *Wnt6* result in a shorter caudal horn but increase body size. Despite the large contribution of *Wnt1*/*Wnt6*, our results suggest that the trait architecture is of intermediate polygenicity.

923S **Selection and introgression at sea urchin gamete recognition proteins** Matthew Glasenapp, Grant H Pogson Ecology and Evolutionary Biology, University of California, Santa Cruz

Many species of broadcast spawners exhibit species-specific fertilization mediated by gamete recognition proteins (GRPs) located on the surfaces of sperm and egg cells. GRPs often evolve rapidly under positive selection and have been implicated in establishing reproductive isolation early in speciation. However, little is known about the forms of selection responsible for GRP divergence. We incorporated data from all nine species of the strongylocentrotid sea urchin family to test for positive selection at the sea urchin GRPs bindin and EBR1, finding strong signatures of selection at both genes. Although bindin and EBR1 have been implicated in establishing reproductive isolation, both genes show signals of historical introgression, a pattern inconsistent with the hypothesis of speciation via the rapid evolution of GRPs.

924S **DNA of lizards with introgressed mtDNA shows reduced damage from Reactive Oxygen Species** Greg Haenel[1], Chase Solomon[2], Eliza Boudett[3] [1]Biology, Elon University, [2]Kennedy Krieger Institute, [3]Parexel International

Introgression of mitochondrial DNA occurs frequently where ranges of closely related species overlap and hybridization occurs. Hybrid offspring often have lower fitness due to genetic incompatibilities. Previous analyses of mitochondrial function in hybrids of the lizards *Urosaurus graciosus* and *Urosaurus ornatus* found that mitochondria from individuals with introgressed

mtDNA experienced increased rates of ATP production and oxygen consumption. Higher ATP production increases reactive oxygen species (ROS) production and high levels of ROS are one of the main causes of damage to DNA. The hybrid lizard populations have persisted and show genetic divergence so we predicted they should have mechanisms for handling higher levels of ROS in order to protect their DNA. To test this we compared levels of DNA damage from ROS in liver cells of the two parental type lizards to those of lizards with introgressed mtDNA. Isolated liver cells were treated with hydrogen peroxide, a source of ROS. Single-cell gel electrophoresis was then used to assess DNA damage. Both *U. graciosus* and *U. ornatus* tissue showed significantly higher damage than DNA from liver cells from individuals with introgressed mtDNA. We explored potential mechanisms that could explain the lower DNA damage by comparing melanin content of livers, expression levels of genes with known antioxidant function, and expression of genes with known DNA repair functions. Melanin has strong antioxidant properties but was not more concentrated in livers showing the least DNA damage. The overall gene expression profile of hybrids was very similar to *U. graciosus* and very different from *U. ornatus*, the mtDNA donor species. Seventeen antioxidant genes showed significant levels of differential expression but were not expressed consistently higher in individuals with introgressed mtDNA. SOD3 was the one antioxidant gene that had unique expression levels in hybrids. SOD2 was elevated in hybrids but not quite to the point of statistical significance. No DNA repair genes showed differential expression between *U. graciosus* and hybrids. Our results indicate that individuals with introgressed mtDNA have a mechanism operating at the cellular level that helps protect their DNA from damage by ROS. This mechanism is unknown but the superoxide dismutases, SOD2 and SOD3, warrant further investigation of their functional roles in these hybrids.

925S **Do Immune Genes Contribute to Genetic Diversity in Natural Populations? A Case Study in European Daphnia pulex** Madison Doceti, Connor Murray, Robert Porter, Alan Bergland Department of Biology, University of Virginia

The innate immune system is the first line of defense in many organisms, ranging from invertebrates to vertebrates. The Toll and Imd pathways are components of this system that target gram-negative bacteria, gram-positive bacteria, and fungal pathogens. *Daphnia pulex*, an organism critical to studying evolutionary dynamics and complex environmental interactions, contains many of the conserved proteins in these pathways. However, how the gene families of the innate immune system in *Daphnia* have changed and developed over time is unknown. In order to conduct this study, we will first identify orthologs in our species using other *Daphnia* species. Then, we will analyze the gene sequences by calculating nucleotide diversity and Tajima's D, and using the McDonald-Kreitman test. We expect that the proteins involved with pathogen recognition and defense will have diversified the most over time. Transduction proteins, however, should undergo less adaptive selection due to less interaction with outside pathogens. By obtaining these results, we can add to our understanding of coevolutionary dynamics by focusing on how the immune system adapts to its environment. Further, we will explain how changing environments can affect this adaptability, which may explain how immune genes contribute to diversity in natural populations.

926S **High-resolution mapping of recombination events in a vertebrate species lacking PRDM9, the zebra finch (*Taeniopygia guttata*)** Djivan Prentout, Marc de Manuel, Carla Hoge, Molly Przeworski Columbia University

In vertebrates, meiotic recombination is concentrated in short regions of 1-2 kb, known as hotspots. In many vertebrates, including mice and humans, a protein called PRDM9 directs recombination to the genome by making two histone modifications (H3K4me3 and H3K36me3). In species lacking PRDM9, such as canids and birds, little is known about the underlying mechanism, but analyses of linkage disequilibrium data indicate that historical recombination rates are increased near promoter-like features (notably, transcription start sites and CpG islands). To learn more about properties of recombination in the absence of PRDM9, we focused on the zebra finch (*Taeniopygia guttata*), a species with an excellent assembly, and resequenced whole genomes from three-generation pedigrees (totaling 54 meiosis). Given the high nucleotide diversity within the species (~1%), this approach allowed us to resolve ~1100 crossovers (CO) events within a median interval length of 650 bp and to call ~500 non-crossover (NCO) events. Overall, there is no significant difference in rates of CO or NCO between sexes (sex-average rate = 2.28 cM/Mb). Crossovers are enriched in telomeric regions of macrochromosomes, whereas non-crossover events appear to be more uniformly distributed. Both recombination resolutions are enriched near promoter-like regions, suggesting that double strand break rates are indeed increased near these features. Focusing on NCO, we estimate that conversion tracts of NCO events are on average only 27 bp, similar to estimates in mice. In turn, while we see evidence for GC-biased gene conversion, the strength appears to be slightly lower than what has been reported for mice. More generally, our approach illustrates how the analysis of a relatively small number of pedigrees in a species with high nucleotide diversity can help to characterize basic parameters of recombination.

927S **Beyond Resistance: Tracing the Ancient Threads of Antibiotic Evolution and Their Impact on Microbial Genomes** Alejandro Marcos Gil Gomez Ecology and Evolution, Stony Brook University

Antibiotic resistance has become a pressing biomedical challenge in the twenty-first century, yet its origins trace back billions of years when soil microorganisms evolved resistance to natural compounds. This evolutionary phenomenon, paralleling the development of natural antibiotics, is exemplified by Streptomyces bacteria, responsible for over two-thirds of modern

antibiotics. These bacteria employ biosynthetic gene clusters (BGCs) in their genomes, encoding enzymes, efflux pumps, and self-resistance genes crucial for antibiotic production.

This study explores the hypothesis that the evolution of antibiotics has exerted a profound influence on the rate of evolution of antibiotic targets and prompted compositional changes in bacterial genomes. Aminocoumarins and aminoglycosides, two classes of natural antibiotics, serve as focal points for the investigation. I employed phylogenetic reconciliation techniques, utilizing time-calibrated species trees of antibiotic-producing organisms and gene trees for BGC genes. These gene trees are reconciled to the species tree, providing dating estimates for the most recent common ancestor of each gene and thus offering insights into the origin of aminocoumarin and aminoglycoside antibiotics.

To test the hypotheses, the study explores shifts in the evolutionary rates of antibiotic targets by comparing the distribution of evolutionary rates of branches that split before and after the evolution of antibiotics.

The results indicate that the emergence of both aminocoumarin and aminoglycoside BGCs triggered a significant shift in selective forces, influencing both the evolutionary rates of their targets. This evolutionary transition, dating back hundreds of millions of years, represents a landmark event in the trajectory of microbial life. Understanding the far-reaching consequences of this major evolutionary shift is crucial for predicting the impact of new synthetic antibiotics on global evolutionary patterns in pathogens and other microbes. This research contributes valuable insights into the intricate interplay between antibiotics, microbial evolution, and the broader implications for global health.

928S **Gene and Dental Morphology Association** Julia Aloi[1], Wynn Meyer[2], Michael Tene[1], Matthew Pollard[3], Emily Puckett[3] [1]Biological Sciences, Lehigh University, [2]Lehigh University, [3]University of Memphis

Dental morphology – the study of the size, shape, and pattern of teeth – has been used to identify similarities in dental traits across different mammalian lineages, providing key insights into diet patterns. Teeth morphology can additionally be understood within the realm of convergent evolution. This occurs when, despite having distinct evolutionary histories, species may independently evolve similar dental features to adapt to their specific dietary habits and ecological niches. Understanding these convergent patterns is crucial for deciphering the underlying principles governing dental morphology in mammals.

Our research explores the relationship between genetic evolution and dental morphology in mammals by investigating the correlation between the relative evolutionary rates of genes and the evolution of convergent binary or continuous dental morphological traits across a phylogeny. This endeavor focuses on the relationship between genetic factors and the development of dental patterns in mammals, providing valuable insights into the evolutionary processes shaping their diverse dental morphologies.

To achieve this goal, we used the Relative Evolutionary Rate Convergence (RERConverge) method to quantify the association between the evolutionary rates of conserved non-coding elements and dental morphological traits. For dental morphology, we collected raw dental measurements and calculated metrics including Orientation Patch Count (OPCR) and Dental Morphological Trait Analysis (DMTA). These datasets cover a broad spectrum of mammalian species, both extinct and extant, enabling a comprehensive analysis of dental morphology across evolutionary time scales. For genetic data, non-coding regions[2] near tooth development genes taken from Zoonomia's mammalian genetic dataset were used.

By associating the evolutionary rates of specific non-coding elements to the convergent evolution observed in dental features, we focus on the potential influence of genetic factors on the development and adaptation of mammalian dental patterns. Through the analysis of diverse datasets and the application of RERConverge, we analyze the interplay between genetic evolution and the convergent development of dental traits in mammals. This knowledge holds the potential to enhance future understanding of broader evolutionary processes and the adaptations that have shaped the diversity of mammalian dental morphology.

929S **Developing a speciation model derived from polygenic epistasis** Emmanuel D›Agostino[1], Diogo Melo[1], Julien Ayroles[2,3] [1]Princeton University, [2]Ecology and Evolutionary Biology, Princeton University, [3]Lewis-Sigler Institute of Integrative Genomics, Princeton University

The Dobzhansky-Muller incompatibility (DMI) model of speciation, in which postzygotic isolation arises from deleterious epistatic interactions in hybrid genomes, has held up for over a century. However, the recent finding that weak deleterious epistasis is widespread within species calls into question exactly how DMI speciation proceeds: can many small-effect interactions between not-yet-fixed alleles reduce gene flow between populations enough to reproductively isolate them? Using forward-genetic simulation, we compare scenarios in which many weak incompatibilities drive divergence to those

in which fewer, stronger ones do, and measure the accrual of reproductive isolation and genetic differentiation as well as the maintenance of DMI alleles. We also explore the relative contributions of drift and selection to these models by varying population sizes, the marginal and epistatic effects of incompatible alleles, and the initial distributions of these alleles in populations after divergence. Our results show that many small-effect DMIs can lead to the accumulation of divergence about as rapidly as fewer, larger ones, in some cases. Specifically, non-homogeneous initial distributions of DMI alleles and larger population sizes were among the factors that facilitated many weak DMIs driving comparable divergence to few strong ones. Taken together, this work explores the cases in which negative fitness epistasis can be indicative of a path to postzygotic reproductive isolation and speciation outside of the large-effect "speciation gene" paradigm, and some of the parameter spaces in which it occurs.

930S **Variation Graph Pangenomes Improve Read Mapping and SNP Calling Accuracy in Divergent Diploid And Allopolyploid Populations** Justin Conover[1], Ryan N Gutenkunst[2], Michael S Barker[3] [1]University of Arizona, [2]Molecular and Cellular Biology, University of Arizona, [3]Ecology and Evolutionary Biology, University of Arizona

A fundamental first step in population genomic analyses is choosing a reference genome to map sequencing data against for variant discovery. When considering an analysis of divergent populations or species, the population that is more distantly related to the reference genome will typically have less accurate variant discovery than the more closely related population, a phenomenon known as "reference bias". Allotetraploid genomes present a unique bioinformatic challenge. These polyploid genomes are composed of two complete chromosomal complements from two divergent progenitor species. Hence, using either diploid progenitor's genome as the reference will necessarily lead to a reference bias for variants in the subgenome from the other parental species. Additionally, recombination between duplicated homologous chromosomes (homoeologous exchange) can alter the dosage expectation of a given chromosomal region, further complicating variant discovery in allotetraploids. Here, we explore reference biases in a population of allotetraploid Brassica napus and its diploid progenitors, B. rapa and B. oleracea. We find that although reference biases abound when mapping to the reference genome of either diploid reference, these biases are largely ameliorated by creating and mapping reads to a variation graph pangenome composed of both diploid reference genomes. We also find that the method used to construct the variation graph pangenome, and the variant discovery pipeline, have significant effects on the accuracy of variant discovery.

931S **Common segregation of clonal seed production and polyploidy in diploid wild plants** Yvonne Willi[1], Jana Flury[2] [1]Environmetnal Sciences, University of Basel, [2]University of Basel

Some angiosperm plant genera and families have been renowned for containing species with a diversity of clonal and sexual reproductive systems. Clonal reproduction can include the growth of secondary roots from shoots or secondary shoots from roots, and the clonal production of seeds, termed apomixis. The latter sometimes depends on sexual mating, as apomictic seed and embryo development can require the stimulus of pollination, which may be easily achieved by self-pollination. For the combined shift to apomixis and the breakdown of self-incompatibility, polyploidization has been considered the ultimate trigger, and indeed, the syndrome of polyploidy, self-compatibility and apomixis has been confirmed in a number of larger plant taxa.

Our research suggests that the syndrome, or parts of it, are more common than thought so far. We selected 8 crucifer species that were previously described as diploids and non-apomicts. We Illumina paired-end-sequenced 10 individuals of 3 or 6 populations of each species and estimated ploidy, the mating system, and the occurrence of apomixis. We found that species were either predominantly outcrossing or selfing. The two outcrossing species were diploid, with the exception of one individual that was tetraploid, and they showed no signs of apomixis. The 6 self-compatible species contained a few to a considerable number of polyploid individuals per population. Furthermore, 4 of the selfing species had some populations with a high fraction of detected apomicts. Our work suggests that the segregation of polyploids and apomicts in otherwise diploid and sexually reproducing plant species has probably been greatly underestimated. Individual-level whole-genome sequence data allows for the easy detection of polyploids and clonals, and can serve as the starting point for the study of the adaptive significance of this diversity of reproductive and genetic systems.

932S **Novel mechanisms and evolutionary dynamics of metacaspase-dependent apoptosis** Darren K Lam, Gavin Sherlock Department of Genetics, Stanford University

Apoptosis in unicellular species results exclusively in organismal death. Nonetheless, apoptosis is conserved across Bacteria and Eukarya, which has driven long-standing questions about whether apoptosis plays an adaptive role in unicellular species. Moreover, the mechanisms underlying unicellular apoptosis remain poorly understood. Even in S. cerevisiae, one of the best-studied model organisms for unicellular programmed cell death, many components of the apoptosis pathway(s) remain unidentified. To this end, I have performed multiple sequence alignment on the known apoptotic machinery in yeast. My preliminary data suggest the evolution of a complex regulatory mechanism by which the yeast metacaspase Yca1 initiates

apoptosis based on the level of cellular proteotoxicity; I am currently developing an optical assay to evaluate this hypothesis. In addition, I have designed a set of CRISPRi and CRISPRa screens to provide an orthogonal bottom-up approach for the characterization of a novel metacaspase-dependent apoptosis pathway. Finally, to address whether apoptosis plays an adaptive role in unicellular species, I will evolve barcoded yeast libraries and directly measure the impact of metacaspase-dependent apoptosis on long-term population fitness.

933S **The evolution of recombination rate modifiers during selection for complex traits** Enrique Schwarzkopf, Nathan Brandt, Caiti Smukowski Heil Biological Sciences, North Carolina State University

Recombination rates vary between populations and species across the tree of life. It has been observed that domesticated plant varieties often have higher recombination rates than their wild congeners. As such, artificial selection on traits of interest appears to indirectly select for higher recombination rates. Variants of genes that increase overall recombination rates–referred to as recombination rate modifiers–are expected to increase fitness under certain forms of selection (e.g., fluctuating selection or selection on multi-locus traits). We will use a panel of outbred populations of *Saccharomyces cerevisiae* experimentally evolved under different strengths of selection (which show evidence of selection at different sets of loci) to explore how different forms of selection affect recombination rates. We will also use evolutionary simulations in SLiM to expand the parameter space of possible strengths of selection and sets of loci under selection to gain further insight into how recombination rates are modified.

934S **Comparing Carnivorous and Herbivorous Mammalian Serine Dehydratases by Growth Rate in Saccharomyces cerevisiae** Julia Adamowicz[1], Michael Tene[1], Helberth Quisbert[2], Greg Lang[1], Cal Shutack[1], Wynn Meyer[1] [1]Lehigh University, [2]St. Peter's University

Convergent evolution is a biological process in which independent lineages experience natural selection that leads to the development of similar traits or phenotypes. This phenomenon generates distinctive molecular patterns in the genetic makeup of organisms facing similar selective pressures. In prior work, we used convergent evolution to connect genes with phenotypes. In this study, we functionally verify proteins we associated with mammalian carnivory/herbivory differentiation using Saccharomyces cerevisiae . Specifically, we are focusing on the genes responsible for serine/threonine catabolism, SDS (Serine Dehydratase) gene and SDSL (Serine Dehydratase-like) genes, and the yeast homologue of both genes cha1. Our prior work determined that the geneset with the strongest connection to diet was the genes involved in branched chain amino acid metabolism. To assess the in-vivo functionality of the orthologs, we measured the ability of the ortholog to metabolize serine/threonine using S. cerevisiae. For this, we selected a preliminary set of orthologs from carnivorous and herbivorous mammals. These were chosen by selecting a pair of closely related carnivore and herbivore clades, and selecting a representative [elaborate] species from within each clade.We designed plasmids to replace the yeast homologue cha1 with our chosen mammalian orthologs of SDS or SDSL, enabling their expression in yeast. We anticipate observing growth rate differences between carnivore genes and herbivore genes in conditions where the enzyme's substrate is the primary nitrogen source. Specifically, we expect Carnivore-cha1 to exhibit increased growth on Serine and Threonine as a nitrogen source relative to Herbivore-cha1. We expect differences in growth rates between carnivores and herbivores, which will serve as compelling evidence of the impact of convergent selection and further validate the computational findings.

935S **Experimental evolution of biofilms in environmental isolates of the budding yeast *Saccharomyces cerevisiae*** Jennifer Lin[1], Despina Mason[1], Benjamin Epley[2], Helen Murphy[3] [1]Biology, William & Mary, [2]Ecology & Evolution, University of Chicago, [3]William and Mary

In environmental and clinical settings, many microbes form biofilms. These are communities in which cells produce an extracellular matrix, adhere to a surface and one another, and are resistant to environmental stressors. Biofilms and other adherence phenotypes are associated with pathogenic microbes, including fungal pathogens, because these traits allow them to persist in the face of insults, such as antibiotics. Opportunistic fungal pathogens that normally live in the environment, but are capable of infecting hosts when presented with one, are of increasing concern [1]. To investigate the process of a fungal environmental isolate becoming a potentially pathogenic one, we evolved replicate populations of *Saccharomyces cerevisiae* under selection for adherence to a plastic surface. Isogenic colonies from three different backgrounds (oak isolate YPS681, wine isolate L-1528, and lab isolate SK1) were used to initiate replicate populations. Experimental populations were grown in the presence of a plastic bead and only those cells that adhered to the bead were used to inoculate the next growth tube, while control populations were grown without beads; half of the populations were punctuated with sexual reproduction. After 600 generations, plastic adherence increased by at least one order of magnitude in all experimental populations, despite the different genetic backgrounds beginning with different adherence abilities. Overall, sexual populations evolved at a faster rate than asexual populations. At the end of the experiment, individual clones were isolated from the final timepoint of all replicate populations and assayed for other adherence phenotypes. All genetic backgrounds had at least some final clones that

produced biofilm colonies, grew invasively in agar, and/or formed floating mats (flors). Thus, selection on plastic adherence led to the incidental evolution of other biofilm-related phenotypes. Finally, populations were sequenced at timepoints throughout the experiment and the dynamics of the mutations that accrued during the experiment were characterized. Our results demonstrate that fungal sexual reproduction can contribute to the accelerated phenotypic and genetic evolution of a of virulence-related trait, that adherence traits can be correlated, and that environmental isolates can evolve pathogenic traits in a relatively short time period.

[1] (2022) World Health Organization fungal priority pathogens list to guide research, development and public health action.

936S **Hybrid genetic analysis reveals large chromosomal effects on thermal divergence in the *Saccharomyces* species** Nilima Walunjkar, Lydia Levesque, Justin Fay Biology, University of Rochester

Thermal adaptation is universal across life and organisms have colonized a wide variety of temperature niches. Understanding the genetic basis of thermal range shifts is challenging due to the long evolutionary timescales over which they have occurred. High divergence between species with distinct thermal profiles impedes genetic mapping, as interspecies hybrids are either inviable or sterile. To address this limitation, we used a combination of novel hybrid genetic approaches.

In the *Saccharomyces* yeast species, *S. cerevisiae* and *S. uvarum* have diverged for 15 million years and differ by 8°C in their upper thermal growth limits. Interspecies hybrids are sterile and inherit thermotolerance from *S. cerevisiae*. We generated aneuploid hybrids, each missing a single *S. cerevisiae* chromosome, and found multiple chromosomes are necessary but not sufficient for thermotolerance as well as multiple chromosomes without large effects on thermotolerance. In *S. kudriavzevii*, another thermally sensitive species, all the chromosomes tested had a large effect on thermotolerance, suggesting an independent and parallel loss of thermotolerance in *S. uvarum* and *S. kudriavzevii* lineages. We validated one chromosome (chr5) in the *S. cerevisiae* – *S. uvarum* background, through reciprocal chromosome aneuploidy and used CRISPR-generated loss of heterozygosity (LOH) to fine map thermotolerance to both arms of *S. cerevisiae* chromosome 5. We also observe a gain in low temperature growth as a consequence of loss of heterozygosity in chromosome 5, indicating a tradeoff between thermotolerance and cold temperature growth.

Our results support a model of multiple genes of large effect that together are required for thermotolerance but do not exclude the possibility that each gene evolved through multiple changes over long evolutionary time scales.

937S **Mutation rate and spectrum evolution in *Saccharomyces*** Pengyao Jiang[1,2], Vidha Sudhesh[2], Megan M. Phan[2], Ishan Bansal[2], Alan J Herr[3], Maitreya J Dunham[2], Kelley Harris[2] [1]Center for Mechanisms of Evolution, Arizona State University, [2]Genome Sciences, University of Washington, [3]Department of Laboratory Medicine and Pathology, University of Washington

Mutations are the source of genetic variation and a prerequisite for evolution. Despite their fundamental importance, their rarity makes them expensive to detect and difficult to study. To address this limitation, we leverage natural polymorphisms, which are historical mutations that passed the sieve of evolution, as a tool for detecting the change of mutational process in evolutionary history. We performed PCA analysis on the mutation spectra from natural polymorphisms on a few species of Saccharomyces yeasts, chosen for extensive prior population genomic and ecological knowledge, genome engineering, and amenability for controlled lab studies. We found the most evident difference being the domestication state, rather than the phylogenetic distance as previously observed in mammals. Intriguingly, strains from *S. cerevisiae* African beer population exhibited a conspicuous pattern in mutation spectrum, in the opposite direction from other strains, even surpassing some inter-species mutation spectrum variations. Notably, a subset of French dairy strains displayed intermediate mutation spectra, and further *in silico* analysis is consistent with the presence of mutator alleles for A>C mutations introgressed from African beer strains. To test this hypothesis, we integrated a reporter into the genomes of several African beer and French dairy strains to be able to perform the modified fluctuation assays. Our *de novo* mutation spectra in these strains are in support of this hypothesis, with a very mild mutator effect. *De novo* mutations also surprisingly exhibited greater variation in mutation types beyond A>C, suggesting that mild mutators are more likely to preserve during evolution than strong ones. In summary, our study reveals patterns and processes of mutation rate and spectrum evolution in natural populations of budding yeast.

938S **Living with a killer: how coevolved *Saccharomyces cerevisiae* become toxin resistant** Michelle Hays[1], Angelina Chan[1], Magdalena Pieczynska[2], Arjan De Visser[3], Gavin Sherlock[1] [1]Genetics, Stanford University, [2]University of Warsaw, [3]Wageningen University

Some yeasts are killers. They secrete toxins that kill neighboring cells, but protect themselves with an intracellular antidote. Killers have an advantage in mixed populations, although toxin production comes at a metabolic cost. Many *Saccharomyces cerevisiae* strains require two viral genomes to be killers. Along with sensitive cells in the environment, this is a complex

genetic conflict: yeast and viral genomes alike are capable of adaptation and fitness tradeoffs abound at many levels. Our research dissects the molecular basis of adaptation in the face of these competing selection pressures to understand evolutionary outcomes.

We identified beneficial mutations that arose in coevolved killer and sensitive yeast, including mutations responsible for toxin-resistance. Through bulk segregant analysis, we identified a putative gain-of-function missense mutation in the HOG osmoregulatory pathway component *SSK1*. Preliminary data suggest this dominant-acting polymorphism is sufficient to protect yeast from the coevolved toxin, and other killer toxins. Ongoing experiments aim to determine the mechanism by which this polymorphism creates toxin-resistance and any host tradeoffs associated with the coevolved allele. Preliminary data suggest this mutation may affect protein-protein interactions, leading to impacts on both HOG and Cell Wall Integrity (CWI) pathways. This mutation is fit under laboratory coevolution conditions, but falls in a domain that is strictly conserved in natural isolates. *SSK1* is required for multiple drug resistance in *Candida auris*, and our ongoing work will address whether this gain-of-function allele might be present in fungi associated with human pathogenicity and drug resistance. In future, we aim to further understand how killer yeasts counter-adapt in the face of these resistant competitors, and how viral genomes evolve as competing host population composition changes.

939V **Navigating the genomic diversity landscape of the hyper-polymorphic nematode *Caenorhabditis brenneri*: insights and challenges** Anastasia Teterina[1], John H Willis[1], Murillo F Rodrigues[1], Angel G Rivera-Colón[1], Peter L Ralph[1,2], Andrew D Kern[1], Patrick C Phillips[1] [1]Institute of Ecology and Evolution, University of Oregon, [2]Department of Mathematics, University of Oregon

Patterns of genetic variation carry footprints of population history and evolution of the species. However, it is challenging to decode these signals and dissect what events and forces have shaped the diversity landscape. This task becomes even more complex for species with high levels of genetic variation, including structural, as most of the standard population genetic approaches use only diallelic single nucleotide variants and exclude all other variation. What are the implications of such bioinformatic choices on inference of population processes in hyper-polymorphic species? In the era of haplotype-resolved individual genomes, how can we enhance our approaches to studying population processes?

Caenorhabditis brenneri is an outcrossing species of nematodes in the ‹Elegans› subgroup (Rhabditida; Sudhaus & Kiontke 2007), which is currently known to be one of the most genetically diverse eukaryotes, with nearly one in ten nucleotides being polymorphic, making its population diversity level comparable to that of bacteria (Dey et al. 2013). We generated a gapless reference genome for *C. brenneri* and sequenced several individual nematodes from different parts of its range using long reads (PacBio HiFi). We employed and compared various bioinformatic approaches, including standard mapping to the reference, variation graphs, and alignment of individual assemblies to analyze the genetic variation and structural variation landscapes in *C. brenneri*. Additionally, we tested with simulations how the exclusion of multiallelic sites can affect the inference of population history and estimation of diversity for populations with different levels of genetic variation. Our results denote a potential step forward in achieving a more comprehensive analysis of high-quality population data for highly polymorphic species, contribute to a deeper understanding of the population history of *C. brenneri*, and enable more precise estimations of genome-wide diversity patterns within its population.

940V **Evolutionary graph theory beyond single mutation dynamics: on how network structured populations cross fitness landscapes** Yang Kuo[1], Oana Carja[2] [1]Computational biology, Carnegie Mellon, [2]Carnegie Mellon

Spatially-resolved datasets are revolutionizing knowledge in molecular biology, yet are under-utilized for questions in evolutionary biology. To gain insight from these large-scale datasets of spatial organization, we need mathematical representations and modeling techniques that can both capture their complexity, but also allow for mathematical tractability. Evolutionary graph theory utilizes the mathematical representation of networks as a proxy for heterogeneous population structure and has started to reshape our understanding of how spatial structure can direct evolutionary dynamics. However, previous results are derived for the case of a single new mutation appearing in the population and the role of network structure in shaping fitness landscape crossing is still poorly understood. In my talk, I will study how network structured populations cross fitness landscapes and show that even a simple extension to a two-mutational landscape can exhibit complex evolutionary dynamics that cannot be predicted using previous single-mutation results. I will show how our results can be intuitively understood through the lens of the two main evolutionary properties of a network, the amplification and deceleration factors, and further discuss how to link these models to spatially-resolved datasets of cellular organization.

941V **Rapid changes in the recombination landscape shape patterns of genetic diversity and molecular evolution in *Drosophila*** Ana Pinharanda[1], Sheel Chandra[1], Kevin Deitz[1], Lucas Hemmer[2], Mitra Kardestuncer[3], Young Mi Kwon[1], Naima Okami[1], Julie Peng[4], Patrick Reilly[4], David Stern[3], Justin Blumensteil[5], Peter Andolfatto[1] [1]Columbia University, [2]University of Kansas, [3]The University of Chicago, [4]Princeton University, [5]Howard Hughes Medical Institute

Recombination shapes genomic diversity by determining patterns of linkage disequilibrium and the degree to which selected sites impact the evolutionary dynamics at linked sites. Despite its importance, we are only beginning to appreciate the extent to which broad-scale recombination rates vary between closely-related species and how that may influence species-specific patterns of genomic variation and molecular evolution. Here, we construct detailed genetic maps by individually genotyping over 16 thousand recombinant flies from three species in the *Drosophila melanogaster* species complex (*D. simulans*, *D. yakuba*, and *D. teissieri*) and compare them to an existing high-resolution map for *D. melanogaster*. While autosomal recombination rates remain broadly conserved between species, we identify big differences in the recombination landscape of the X chromosome and the extent of centromeric suppression of recombination in the *D. yakuba* lineage. Our findings highlight how the rapid evolution of the genomic recombination landscape influences lineage specific patterns of molecular evolution and adaptation.

942V **Long-Term Stability in Genomic Clines in Natural North American Populations of Drosophila melanogaster** Vitoria Horvath Miranda[1], Murillo F. Rodrigues[2], Rodrigo Cogni[3] [1]Genetics, University of Sao Paulo - Institute of Biosciences (IB-USP), [2]Institute of Ecology and Evolution - University of Oregon, [3]Ecology, University of Sao Paulo - Institute of Biosciences (IB-USP)

Sequencing and comparing historical and recent samples is a fruitful approach in the study of evolution, and it can be used to investigate possible evolutionary responses to climate change. Similarly, sampling spatially distributed populations, enables us to find links between genotypic and phenotypic variants to environmental variables. Clines are the correlation of measurable genotypic or phenotypic traits with a geographic gradient, such as latitude or altitude. *Drosophila melanogaster* displays many clinal traits, such as body size and melanization, and it is an ideal system to study the evolutionary consequences of climate change. We sequenced samples of *Drosophila melanogaster* natural populations spread along the east coast of the United States from two different time points: 1997, and 2009/2010. Additionally, we also sampled two North American populations in 2017 and 2022. In total, 16 populations were sequenced with pool-seq, SNPs were called and annotated, and their frequencies were computed. To identify clinal SNPs, we ran a generalized linear model with a binomial link function of allele frequency against latitude for each site in each period. We compared clinal SNPs of 1997 and 2009/2010 with SNPs that systematically changed between 1997 and 2022 in the northern populations. We estimated the frequencies of all seven cosmopolitan inversions to investigate their clinality. There are fewer clinal SNPs in 2009/2010 samples than in 1997. Most of this difference is driven by the reduction in south samples› frequencies of the *In(3R)Payne* chromosomal inversion. This reduction is intriguing since the increase of this inversion between 1979 and 2004 in the Australian latitudinal cline was credited to global warming. Other inversions were not clinal in either period or remained stable throughout the years. We also sequenced isochromosomal lines for the second and third chromosome prepared with three populations of 1997. With those samples, we were able to look for signs of selection and ran admixture analyses using African and European *D. melanogaster* populations as reference.

943T **Natural variation in C. elegans responses to per- and polyfluoroalkyl substance (PFAS) pollutants** Tess Leuthner, Ryan Baugh Department of Biology, Duke University

An estimated 200 million US residents are drinking water contaminated with per- and polyfluoroalkyl substances (PFAS) and 99% of all human blood serum samples tested in the US contain PFAS. Epidemiological evidence suggests that exposures to these “forever chemicals” are associated with major diseases, including cancer. However, the mechanisms of toxicity of practically all the >12,000 emerging, structurally complex PFAS remain entirely unknown. Therefore, we leveraged natural genetic variation of wild *C. elegans* to identify structure-specific molecular mechanisms of PFAS toxicity. We are investigating toxicity of ten PFAS chemicals that vary in three structural attributes (chain length, functional group, and chain composition) and the contribution of natural genetic variation on response to PFAS exposures. We first conducted a 48 hr toxicity assay in the laboratory-adapted reference strain, N2, to determine the effective concentration in which we observed a 50% reduction in growth (EC50). There was significant variation in EC50 values among PFAS chemicals which was driven by specific structural attributes of PFAS. We repeated this toxicity assay using 11 genotypically different strains from the *Caenorhabditis elegans* Natural Diversity Resource (CeNDR). We observed variation in toxicity (EC50 values) among strains within PFAS chemicals, suggesting that underlying genetic variation causes variation in response to exposures. Furthermore, we observe variation among wild *C. elegans* strains between chemicals that vary by specific molecular structures, which suggests specific gene-environment interactions in response to PFAS exposures. Next, I will pool a population of 192 naturally diverse *C. elegans* strains, expose to PFAS, and sequence the population, applying an approach developed in our lab (MIP-Seq, Webster et al. 2022) to identify sensitive and resistance strains and quantitative trait loci (QTL). I will then use various genetic and genome-editing approaches to explicitly identify the role of one or more gene variants that contribute to structure-specific toxicity of PFAS chemicals. Overall, this approach demonstrates the power of using genetics to investigate molecular mechanisms of toxicity and will result in a better understanding of variation in susceptibility to environmental contaminants.

944T **The genetic architecture of transposable element-mediated heterochromatin formation in *Drosophila***

melanogaster Kayla Ly, Yuheng Huang, Anthony D Long, Grace YC Lee Ecology and Evolutionary Biology, University of California, Irvine

Transposable elements (TEs) are mobile genetic elements capable of replicating within eukaryotic genomes, often at the expense of host fitness. Host genomes employ small RNA-based mechanisms to silence euchromatic TEs, typically through the enrichment of repressive epigenetic marks, such as H3K9me2/3. Although this mode of silencing works to inhibit TE propagation, the resultant epigenetic modifications can "spread" up to 20kb from the TE insertion site, potentially silencing neighboring genes. The enrichment of these repressive epigenetic marks around TE insertions in the euchromatic genome mirrors the well-known spreading of repressive marks from constitutive heterochromatin. However, it remains unclear which genes harbor natural variation that influences the extent and magnitude of this mark-spreading at euchromatic TEs. To unbiasedly address this knowledge gap, we use extreme-QTL mapping (X-QTL) to identify genetic loci contributing to varying spreading of repressive marks from silenced euchromatic TEs. X-QTL powerfully combines traditional QTL mapping with bulk segregant analysis, in which individuals displaying extreme phenotypes in synthetic multiparent populations are pooled and sequenced to identify causal variants. Our initial experiment demonstrated that there is variation segregating among the Drosophila Synthetic Population Resource (DSPR) founders that drives differences in mCherry fluorescence intensity from a reporter construct sensitive to TE-mediated repressive marks. This finding has propelled our current work to perform X-QTL on an outbred population of DSPR recombinant inbred lines (RILS) by similarly crossing our reporter strains to the mapping population and obtaining F1 individuals with extreme phenotypes of interest. Importantly, we have established experimental protocols for conducting large-scale crosses and implementing imaging techniques to select individuals displaying extreme levels of TE-silencing, including both weak and strong cases. Our X-QTL mapping approach will allow for the identification of previously unknown genes contributing to TE-mediated enrichment of repressive marks, and increase our understanding of natural variation in host regulatory mechanisms pertaining to selfish DNA elements.

945T **Dissecting the genetic basis of zinc toxicity resistance in *Drosophila melanogaster* using an extreme QTL (XQTL) mapping approach** Katherine M Hanson[1], Anthony D Long[2], Stuart J Macdonald[1] [1]Molecular Biosciences, University of Kansas, [2]Ecology and Evolutionary Biology, University of California

Human exposure to toxic levels of various heavy metals has risen due to environmental contamination resulting from mining, agricultural and industrial practices. Heavy metal toxicity can damage cells by damaging DNA via reactive oxygen species and oxidative stress, altering the balance of essential elements and affecting enzymatic activity. However, heavy metals like zinc are essential and it is critical appropriate levels are maintained. Zinc toxicity has been demonstrated to be a complex, polygenic trait, but has primarily been studied via traditional genetic knockdown studies which have limited genetic backgrounds. Our goal is to identify genes segregating for allelic variation for zinc resistance using an unbiased genome wide mapping approach. *Drosophila melanogaster* is an excellent model to study zinc resistance since it possesses orthologs of critical zinc homeostasis genes such as *MTF-1* (a metal response transcription factor) and has previously been successfully used to model a range of heavy metal response traits. To genetically dissect zinc resistance, we employed extreme QTL (XQTL) mapping, a powerful technique that bulk selects and sequences pools of outbred individuals with extreme phenotypes. Our outbred population was derived from the 8 *Drosophila* Synthetic Population Resource Population A founder lines, and we raised 12 large cohorts from this population on media supplemented with a toxic level of zinc, sequencing pools of emerging, zinc resistant females and matching controls. Using the known founder sequences, we estimated the founder composition for each pooled sample for windows along the genome and identified 7 QTL with significant allele frequency shifts between control and selected pools. Our QTL harbor 629 genes and 24 of these were assessed as strong causal candidate genes based on existing data. We tested 18 of these candidates for impacts on developmental zinc resistance via midgut specific RNAi by measuring emergence (the percent of eggs that reach adulthood) and development time. Knockdown of 11 of our genes impacted one or both of our phenotypes and this included *MTF-1*, *pHCl-2* (produces a zinc sensor protein) and *Mekk1* (a gene implicated in resistance to other heavy metals). Additionally, we used RNAseq to characterize regulatory changes underpinning zinc resistance. We used zinc selected and control populations developed via the same approach employed for XQTL and profiled larvae from both populations following 20-hour exposure to zinc or control media. We identified over 1200 genes whose expression change due to zinc significantly differed between the zinc selected and control populations; 54 of these genes were within our QTL intervals and included 2 of our candidates. Using a variety of techniques and genetic backgrounds, our work highlights both recognized and novel contributors to zinc resistance, and possibly resistance to other heavy metals in flies.

946T **Comparing Methods and Strategies for Complex Trait Prediction from Gene Expression** Noah K Klimkowski Arango, Fabio Morgante Department of Genetics & Biochemistry, Clemson University

Accurate prediction of complex traits is an important task in quantitative genetics. While prediction of complex traits has been pioneered in agriculture for selection purposes, it has become important in human genetics as well, in the context of personalized medicine. Genotypes have traditionally been used for trait prediction using a variety of methods such as

mixed models, Bayesian methods, and machine learning methods. Recent studies in different species have shown that gene expression levels can produce higher prediction accuracy than genotypes. However, only a few prediction methods were used in these studies. Thus, a comprehensive assessment of methods is needed to fully evaluate the potential of gene expression as a predictor of complex trait phenotypes.

Here, we used data from the *Drosophila* Genetic Reference Panel (DGRP) to compare the ability of several existing regression methods to predict starvation resistance from gene expression in the two sexes separately. The methods considered differ in the assumptions about the distribution of gene effect sizes – ranging from models that assume that every gene affects the trait to more sparse models – and their ability to capture gene-gene interactions. We also used functional annotation such as Gene Ontology (GO) as an external source of biological information to inform prediction models.

The results show that differences in prediction accuracy between methods exist, although they are generally not large. Machine learning methods tended to perform worse than the other methods, while Bayesian variable selection methods provided the highest prediction accuracy in both sexes. Incorporating GO annotations into Bayesian models further improved prediction accuracy and highlighted a few GO terms that were particularly predictive of the trait.

Our results confirmed the potential of transcriptomic prediction and highlighted the importance of selecting appropriate methods and strategies in order to achieve accurate predictions.

947T **Mediation analysis of key hepatic drug metabolizing enzymes and transporters in collaborative cross mice to characterize causal pathways of genetic regulation of drug metabolism as a resource for pharmacogenetics** Teresa McGee[1], Yanwei Cai[1], J. Scott Eaddy[2], John K Fallon[3], Rani J Qasem[3], Phil Smith[3], Merrie Mosedale[3], William Valdar[1] [1]Genetics, University of North Carolina at Chapel Hill, [2]Institute for Drug Safety Sciences, University of North Carolina at Chapel Hill, [3]Eshelman School of Pharmacy, University of North Carolina at Chapel Hill

Genetic variation in drug metabolism and disposition contributes to patient variability in drug response. Preclinical studies to test drug toxicity are often conducted in animal models that do not reflect human genetic diversity and fail to accurately predict human drug responses. The Collaborative Cross (CC) mouse genetic reference population is a promising preclinical model to more accurately model potential drug toxicity in humans. However, characterization of genes affecting drug response in CC mice has so far been limited. To investigate genetic effects on drug metabolism, we performed quantitative trait loci (QTL) mapping in 45 CC strains on both gene expression level and targeted proteomics measurements of key drug-metabolizing enzyme and transporter (DMET) genes. This revealed multiple genetic loci associated with variation in the DMET pathway. To study causal relationships between these loci, proteins, and transcripts, we used mediation analysis, testing for relationships between each pQTL, potential transcript mediators and protein levels. In particular, whereas standard mediation analysis tests relationships between a causal SNP (X), the phenotype of interest (Y), and a mediator (M), limiting the method to the analysis of a single mediator, we build upon previous methods to consider multiple mediators simultaneously. We extended our laboratory's existing Bayesian model selection framework for mediation analysis, bmediatR, to test multiple potential mediators for one proteomics phenotype. We apply this model to DMET data to better characterize causal pathways for variation in drug metabolism. This study provides a comprehensive analysis of DMET pathway variation in the CC population, and provides a rich data set to support the design and analysis of future pharmacogenetic studies in the CC.

948T **Chromosome 15 hotspot robustly associated with CAST/EiJ tuberculosis resistance** Rachel K Meade[1], Mohab Helmy[2], Marco Gontijo[1], Bailey Francis[2], Sherry Kurtz[3], Fred Boehm[4], Karen Elkins[3], Thomas Keane[2], Clare M Smith[1] [1]Molecular Genetics & Microbiology, Duke University, [2]European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, [3]Center for Biologics Evaluation and Research, Food and Drug Administration, [4]Biostatistics, University of Michigan

Each pathogenic infection is part of an evolutionary battle between host and invader. For *Mycobacterium tuberculosis* (*Mtb*), the causal agent of tuberculosis (TB), a host-pathogen arms race spans over millennia, making *Mtb* an enduring adversary of the human species. TB prognoses vary, from asymptomatic infection to severe morbidity, implicating host determinants of TB outcome. Mice are powerful, reproducible mammalian systems able to dissect complex infection dynamics, yet classical mouse studies often utilize only one host genotype, limiting understanding of diverse *Mtb* immunity. C57BL/6J (B6) mounts an IFN&gamma driven, T_H1-skewed response leading to relative TB resistance, robustly modeling only one TB outcome. To model natural human diversity, the Collaborative Cross (CC) mouse panel was born. This systems genetics resource consists of ~100 strains bred by intercrossing wild-derived and laboratory inbred lines; each CC strain has a unique yet reproducible host genome.

To illustrate the spectrum of *Mtb* immunity, we infected 50+ CC strains and measured disease metrics at a month post-infection. Comparing collected traits to the CC genomes, we mapped quantitative trait loci (QTL) associated with TB outcomes.

We located a 2Mb hotspot on Chromosome 15, containing 3 overlapping QTL, significantly linked with TB resistance. CC strains that inherited CAST/EiJ (CAST) haplotype at this locus exhibited lower lung *Mtb* burden and IL17 levels. To validate screen findings, we infected an F2 cohort bred from *Mtb*-resistant CC001, which inherited the Chr15 locus from CAST, and *Mtb*-susceptible CC042, which did not. F2 mice with the CAST region exhibited lower IFN&gamma levels in lung. This result replicates a unique feature of CAST mice, which exhibit very low lung IFN&gamma levels during infection, highlighting a non-canonical TB resistance mechanism.

To assess genetic features underlying the QTL hotspot, we used a novel telomere-to-telomere CAST genome assembly to reveal the unique chromosome architecture and strain-specific genes in the hotspot that may enable this unique *Mtb* response. We are also breeding congenic mice, which will allow mechanistic study of the region while refining the causal interval. Genetic and functional interrogation of this novel T_H1- and T_H17-independent TB resistance complex will expand field understanding of *Mtb* immunopathology. This investigation highlights genomic diversity as a vital host protective strategy against pathogens as prolific as *Mtb*.

949T **Mutational biases contribute to the neutral complexification of protein interaction networks following gene duplication** Angel F Cisneros Caballero[1], Lou Nielly-Thibault[1], Saurav Mallik[2], Emmanuel D Levy[2], Christian R Landry[1] [1]Université Laval, [2]Weizmann Institute of Science

Biological systems can gain complexity over time. At the molecular level, one example is heteromeric complexes replacing homomeric ones following gene duplication. While some of these transitions are likely driven by natural selection, we lack a neutral model to examine if such replacements could take place through the action of mutations alone. Here we build a biophysical model and examine if and how, without selection for new functions, mutations alone could favor these transitions. We use available protein structures to infer distributions of biophysical effects of mutations and simulate the evolution of homomers and heteromers following gene duplication. For most structures, the relative concentration of the heteromer increases over time, even when there is no inherent benefit of doing so. Different factors affect this trend, such as the distribution of mutational effects, the relative supply of mutations affecting synthesis rates, and differences in specific activity among the complexes. Our results show mutations alone can neutrally favor the accumulation of more complex protein quaternary structures, and that natural selection would be needed to reverse this tendency.

950T **Interpreting SNP heritability in admixed populations** Jinguo Huang[1], Saonli Basu[2], Mark D Shriver[1], Arslan A Zaidi[2] [1]Penn State University, [2]University of Minnesota

Heritability (h2) is central to our ability to describe, predict, and infer the genetic variation underlying complex traits. SNP heritability (h2SNP) allows one to estimate heritability in unrelated individuals and is an important aspect of the design of genetic studies. Despite the simple intuition and utility of h2SNP, its interpretation and equivalence to h2 is unclear, particularly in the presence of population structure and assortative mating, which limits our understanding of complex traits in admixed populations. It is known that h2SNP estimates can be inflated in structured populations because of confounding due to shared environment and linkage disequilibrium. Here, we present a theoretical analysis of the effect of population structure in admixed populations on h2SNP estimation.

We show that h2SNP estimates are biased in admixed populations compared to h2, even in the absence of confounding and even when all causal variants are known. We traced the source of this bias to two assumptions underlying random-effects models used to estimate h2SNP: (i) that the causal effects are independent, and (ii) that the population mates randomly. Both assumptions can be violated in recently admixed populations, leading to bias in h2SNP estimates. Importantly, h2SNP can be under- or over-estimated and we describe the behavior of the bias as a function of admixture history, ancestry-based assortative mating, and genetic architecture of the trait. We show that we can correct the bias in h2SNP estimates, but it is not always possible to do so, especially if individual ancestry is included as a covariate in the model – a common practice intended to correct for confounding effects of shared environment. This practice can result in overcorrection and will therefore yield underestimates of h2SNP, regardless of trait architecture.

Our findings provide a clear interpretation of SNP heritability in admixed and structured populations, where h2SNP estimate is not an unbiased estimator. We interpret the difference between h2 and h2SNP not as bias in the estimate, but because the estimand h2SNP itself as defined under the random-effects model is not equal to h2. We discuss the implications of the discrepancy between the h2SNP and h2 for the design of genome-wide association studies and polygenic risk prediction in diverse cohorts.

951T **A Litmus Test for Confounding in Polygenic Scores** Samuel Pattillo Smith[1], Hakhamanesh Mostafavi[2], Jeremy Berg[3], Dandan Peng[4], Graham Coop[5], Michael D Edge[4], Arbel Harpak[1] [1]Department of Population Health, University of Texas at Austin, [2]Department of Population Health, New York University, [3]Department of Human Genetics, University of

Chicago, [4]Department of Quantitative and Computational Biology, University of Southern California, [5]Department of Evolution and Ecology, University of California - Davis

Polygenic scores (PGS) are being rapidly adopted for trait prediction in the clinic and beyond. In addition to "direct" effects of one's genotype on one's trait value, PGS and their predictive accuracy can depend on environmentally or culturally-mediated factors such as Stratification, Assortative mating, and Dynastic (indirect) genetic effects ("SAD effects"). Despite the accumulating qualitative evidence, there is currently no estimation method to quantify the relative contribution of SAD effects to variation in a given PGS. We therefore developed a method that measures how much of the variance in a PGS (in a given sample) is driven by direct effects, SAD effects and their covariance. We leverage a comparison of a standard-GWAS based PGS and a PGS based on a sibling-GWAS—which is immune to SAD effects. Furthermore, the method breaks down effect variance components into principal axes of genetic ancestry, allowing for a nuanced interpretation of SAD effects. We applied our method to a range of PGS from the UK Biobank and large meta-analyses for anthropometric, biomedical and behavioral traits and found large and interpretable SAD signals in some of them. For example, we estimate that most of the variance in height PGS based on the GIANT study is appropriated to SAD effects and nearly 40% of the variance aligns specifically with the main North-South genetic ancestry axis, highly suggestive of stratification effects. Our method shows how the power of large GWAS can be married with the articulation of family designs to aid in the interpretation of PGS.

952T **F_{ST} based marker prioritization within QTL regions and its impact on genomic selection accuracy: Insights from a simulation study with high-density marker panels** Sajjad Toghiani[1], Samual Aggrey[2,3], Romdhane Rekaya[3,4] [1]USDA, [2]Department of Poultry Science, The University of Georgia, [3]Institute of Bioinformatics, The University of Georgia, [4]Department of Animal and Dairy Science, The University of Georgia

High-density SNP panels and sequence data have advanced the study of complex traits. However, the increase in the number of markers will likely result in a high rate of false positives and a potential reduction in genomic selection (GS) accuracy. The fixation index (F_{ST}) can be used to identify genome regions under selection pressure that can be prioritized in association analyses. In this study, the impact of different F_{ST} prioritization strategies on the estimation of the heritability and accuracy of GS were assessed. The QMSim software was used to generate datasets for a trait with heritability of 0.4 (SIM1) and 0.1 (SIM2). In both scenarios, the total genetic variance for the trait was assumed to be explained by 500 QTL. Each dataset was replicated 5 times. The simulated population comprised 30K animals from the last two generations of a ten-generation selective breeding program and genotyped using a 600K SNP marker panel. The correlation between true and estimated breeding values for 5,000 randomly selected animals from the last generation was used to assess the accuracy of GS. The top and bottom 5% of genotyped animals in the 9th generation, based on phenotype distribution, were grouped in two subpopulations and the F_{ST} scores were calculated for all 600K SNPs. The proposed algorithm consisted in computing the average F_{ST} scores for different SNP-windows (50, 100, 200, and 400 SNPs) surrounding each QTL position. SNP-windows with average F_{ST} scores surpassing a predefined threshold (e.g., 25% quantile of F_{ST} score distributions) were identified. Two F_{ST} prioritization scenarios were evaluated: 1) the 1% SNPs with the highest F_{ST} score were prioritized, and 2) Twelve SNPs within each SNP-window surrounding each QTL were prioritized based on their F_{ST} scores. Using all 600K SNPs, GBLUP-based prediction accuracy and estimated heritability for SIM1 (SIM2) were 0.77 (0.66) and 0.37 (0.10), respectively. However, prioritizing SNPs based on F_{ST} scores, particularly by selecting a 50 SNP-window around each QTL and randomly prioritizing 12 SNPs within that window resulted in a substantial increase GS accuracy of SIM1 (0.88) and SIM2 (0.78). Heritability estimates were slightly lower (0.34 for SIM1 and 0.09 for SIM2) compared to when all SNPs were used. The 50 SNP-window approach outperformed the 1% SNPs with the highest F_{ST} scores prioritization scenario. Testing of the algorithm when the number and position of QTL are unknown is warranted.

953T **Childhood sleep duration modifies the cumulative effects of fat mass-associated variants on BMI among preschool children** Mengna Zhang[1], Jianfei Lin[2], Shijian Liu[3], Fan Jiang[4], Hao Mei[5] [1]Data Science, University of Mississippi Medical Center, [2]Department of Developmental and Behavioral Pediatrics, Shanghai Jiao Tong University, [3]Department of Clinical Epidemiology and Biostatistics, Shanghai Jiao Tong University, [4]Shanghai Jiao Tong University, [5]Department of Data Science, University of Mississippi Medical Center

Background: Childhood obesity results from the combination of genetic and environmental factors, with sleep playing an increasingly significant role. Accumulating evidence has identified that sleep duration acts as a regulator of fat mass-associated genes in relation to obesity, but conflicting results were reported. This study aims to employ polygenic risk score (PRS) to confirm known obesity-related loci in preschool children and to investigate the impact of sleep duration on these associations in children.

Methods: 271 preschool children were recruited from the cross-sectional study from April to June 2011 in Shanghai, China. They all completed questionnaires, had physical exams, and provided blood samples. Ten genes linked to childhood obesity,

sleep issues, and HPA-axis regulation were genotyped. The cumulative effect of candidate variants for target traits were evaluated through unweighted polygenic risk score, while controlling for age, biological sex, and appetite. To study the modification effect of sleep duration, we created a PRS_{BMI} weighted from an external BMI GWAS and compared its effect on obesity and anthropometric traits between children with short and adequate sleep.

Results: After quality control, 21 SNPs remained. The unweighted PRS comprising these 21 variants showed a positive association with obesity (Beta=1.56; SE=0.43; p=0.00), and various anthropometric measurements. Using weights and a p-value threshold of 0.05 applies to a BMI GWAS in the Biobank Japan, three variants were selected to construct the PRS_{BMI}. Our cohort revealed that sleep duration modified the associations between the PRS_{BMI} and BMI, weight, arm circumference, and subscapular skinfold. In the group with adequate sleep, each unit increase in standardized PRS_{BMI} corresponded to increased BMI (Beta=0.28; SE=0.14; p=0.05), weight (Beta=0.57; SE=0.26; p=0.03), arm circumference (Beta=0.29; SE=0.14; p=0.04), and subscapular skinfold (Beta=0.32; SE=0.15; p=0.04), while such effects were absent in the short sleep group.

Conclusion: Candidate genetic variants cumulatively contribute to childhood obesity, BMI, and several anthropometric traits. Short sleep duration diminishes the genetic effects of selected fat mass and obesity-associated SNPs on BMI, weight, arm circumference, and subscapular skinfold among children. Our findings offer insights for informing future strategies to reduce childhood obesity by improving lifestyles, with a focus on sleep conditions.

954T **MAGE: Sources of gene expression in a globally diverse human cohort** Dylan J. Taylor[1], Surya B. Chhetri[2], Michael G. Tassia[1], Arjun Biddanda[1], Alexis Battle[2,3,4,5], Rajiv C. McCoy[1] [1]Department of Biology, Johns Hopkins University, [2]Department of Biomedical Engineering, Johns Hopkins University, [3]Department of Computer Science, Johns Hopkins University, [4]Department of Genetic Medicine, Johns Hopkins University, [5]Malone Center for Engineering in Healthcare, Johns Hopkins University

Genetic variation influencing gene expression and splicing is a key source of phenotypic diversity. Though invaluable, studies investigating these links in humans have been strongly biased toward participants of European ancestries, diminishing generalizability and hindering functional and evolutionary research. To address these limitations, we developed MAGE, a resource for **M**ulti-ancestry **A**nalysis of **G**ene **E**xpression. MAGE is an open-access RNA-seq data set of lymphoblastoid cell lines from 731 individuals from the 1000 Genomes Project spread across 5 continental groups and 26 populations. Most variation in gene expression (92%) and splicing (95%) was distributed within versus between populations, mirroring variation in DNA sequence. We mapped associations between genetic variants and expression and splicing of nearby genes (cis-eQTLs and cis-sQTLs, respective), identifying >15,000 putatively causal eQTLs and >16,000 putatively causal sQTLs that are highly enriched for relevant epigenomic signatures. These include 1310 eQTLs and 1657 sQTLs that are largely private to previously underrepresented populations. Our data further indicate that the magnitude and direction of causal eQTL effects are highly consistent across populations and that apparent “population-specific” effects observed in previous studies were largely driven by low resolution or additional independent eQTLs of the same genes that were not detected. Together, our study expands understanding of gene expression diversity across human populations and provides an inclusive resource for studying the evolution and function of human genomes.

955T **A Bayesian model selection framework for categorizing gene-by-treatment effects for molecular count phenotypes** Yuriko Harigaya, Nana Matoba, Brandon Le, Jordan Valone, Jason Stein, Michael Love, William Valdar University of North Carolina at Chapel Hill

Genetic effects on a phenotype of interest can differ, sometimes markedly, in response to an applied treatment. Such gene-by-treatment interactions (GxT) can be highly consequential in biomedicine and agriculture. An effective approach to identifying GxT signals and gaining insight into molecular mechanisms is mapping quantitative trait loci (QTL) of molecular count phenotypes, such as gene expression and chromatin accessibility, under multiple treatment conditions. Current practice, however, exhibits at least two limitations. First, a typical mapping analysis returns a list of feature-SNP pairs with significant GxT interactions but does not provide a principled approach to prioritizing GxT interaction of particular types. For example, treatment may have an impact on individuals of a certain genotype but not on others. In other cases, with similarly significant GxT interactions, treatment may affect all individuals but to different extents depending on their genotype. Formally assigning probabilities to these cases can facilitate the prioritization of response molecular QTLs for further investigation. A second potential limitation is the frequent assumption of linearity between the phenotype and the genotype after a variance-stabilizing transformation, such as the logarithm, which is routinely applied to molecular count phenotypes. This can lead to nontrivial model misspecification and inaccurate inference. Previous studies have shown that, consistent with the biologically reasonable assumption of common allelic additivity on molecular traits, such as expression, the linear relationship holds in the original count scale, but not in the transformed scale (PMID: 29021289, 29073327).

To address the first limitation, we have developed a downstream method for categorizing response molecular QTLs. Our method uses Bayesian model selection and assigns posterior probabilities to different types of GxT interactions for a given

feature-SNP pair. To address the second limitation, we have adapted nonlinear regression to account for the inherent relationship between the genotype and phenotype. After simulation analysis, we apply our method to response molecular QTLs previously identified in human primary neural progenitor cells from genetically diverse fetal donors with and without growth stimulation (PMID: 36798360). Our method provides an intuitive way to report the evidence for different types of GxT interaction across a set of feature-SNP pairs.

956T **Genomic regulation of pedicel characteristics of apple** Jairam Baba Danao[1], Jahed Khalil[2], Kranthi Varala[3], Peter Hirst[3] [1]Horticulture, Purdue University, [2]Alson H. Smith Jr. Agricultural Research and Extension Center, Virginia Tech, [3]Horticulture, Purdue university

Apple fruit development is significantly influenced by the pedicel, a slender stalk attaching the fruit to the tree. This study delves into the genetic control of pedicel characteristics, which are complex traits regulated by multiple genes. Our research focuses on two hybrid apple populations: 'Twenty Ounce' x 'Prairie Fire' crab apple and 'Edward VII' x 'Prairie Fire' crab apple. These populations vary in size, allowing us to investigate how pedicel attributes relate to apple fruit size. Our previous work established a clear connection between pedicel features and apple fruit mass. Specifically, pedicel length shows an inverse relationship, while pedicel diameter is directly related to fruit mass. Shorter, broader pedicels putatively facilitate improved water and nutrient transport. Efforts have been taken in *Arabidopsis thaliana* and *Nicotiana tabacum* to identify genes governing pedicel development. In *Arabidopsis thaliana*, overexpressing BREVIPEDICELLUS (BP) leads to excessive pedicel tissue growth, while loss of BP reduces its radius. When combined with a loss-of-function erecta (er), this reduction intensifies, causing radial constriction. In *Nicotiana tabacum*, knockdown of MADS-box gene NtSVP caused elongation in pedicels, while overexpression resulted in much shortened pedicels. These studies suggest the function of MADS-box transcription factors in plant pedicel development. In the current study we sought to identify and understand the genomic basis for control of apple pedicel length and diameter. Knowledge of Quantitative Trait Locus (QTLs) and genes that affect pedicel characteristics in apples have potential applications in apple breeding and fruit production. The identification and manipulation of these genes holds the promise of developing new apple varieties with improved pedicel traits i.e. ultimately fruit mass and enhanced fruit quality.

957T **The strength of weird ties: positive genetic interactions are impactful yet overlooked** Mengyi Sun Cold Spring Harbor Laboratory

Genetic interaction, the phenomenon that perturbing two genes simultaneously produces a phenotype deviated from the expectation given the effects of the individual perturbations, often reveals functional linkage among genes and pathways. Based on the sign of deviation, genetic interaction can be classified into positive or negative interactions. We hypothesize that, because positive interactions are more likely to involve genes from different pathways compared to negative interactions, they are more likely to generate impactful innovations. We verify our hypothesis by coupling large-scale genetic interaction data in yeast to the PubMed database, a prominent literature database in biology. Surprisingly, we find that despite their importance, positive interactions are at least 50% less likely to be studied compared to negative interactions. We provide evidence that this under-exploration can be partially explained by the bias inherent in human heuristic strategy in finding innovation. Finally, we demonstrate that interpretable machine-learning techniques can potentially alleviate the bias and inefficiency of human heuristic search. These results also provide insights into how to accelerate scientific research in general.

958T **To be or not to be an auxotroph - The curious case of MET15** Nelson Castilho Coelho[1], Sauin Parikh[1], Branden van Oss[1], Aaron Wacholder[1], Ivan Belashov[2], Sara Zdancenwicz[2], Manuel Michaca[2], Jiazhen Xu[2], Yun Kang[3], Nathan Ward[3], Sang Yoon[3], Katherine McCourt[1], Jake McKee[1], Trey Ideker[4], Andrew vanDemark[5], Gina DeNicola[3], Anne-Ruxandra Carvunis[1] [1]Computational and Systems Biology, University of Pittsburgh School of Medicine, [2]University of Pittsburgh, [3]Moffitt Cancer Center, [4]University of California, [5]University of PIttsburgh

Since its discovery in the 1970s, the homocysteine synthase Met15 (also known as Met17 and Met25) has been considered essential for inorganic sulfur assimilation in yeast. The *MET15* gene has served as auxotrophic marker for hundreds of experiments carried out in yeast, especially those using large collections like the yeast deletion collection, which have been of extreme impact in the foundation of eukaryote genetics and systems biology.

Here, we demonstrate through structural and evolutionary modeling, *in vitro* kinetic assays, and genetic complementation, that an alternative homocysteine synthase encoded by the previously uncharacterized gene YLL058W enables cells lacking Met15 to assimilate enough inorganic sulfur for survival and proliferation. We show that toxic accumulation of the gas hydrogen sulfide explains the failure for these cells to grow in patches or liquid cultures, unless provided with exogenous methionine or other organosulfurs. The addition of a hydrogen sulfide chelator to the culture media, and propagation as colony grids, allow cells without Met15 to assimilate inorganic sulfur and grow, and cells with Met15 to achieve even higher

yields.

Contrary to what has been assumed for decades, Met15 is not essential for inorganic sulfur assimilation in yeast. Instead, *MET15* is the first example of a yeast gene whose loss conditionally prevents growth in a manner that depends on local gas exchange.

959T **Quantifying gene by environment interactions in the activity of protein degradation pathways** Randi R. Avery, Mahlon A. Collins, Frank W. Albert Genetics, Cell Biology, and Development, University of Minnesota

Protein degradation by the ubiquitin-proteasome system (UPS) is an essential process that regulates protein abundance and removes misfolded and damaged proteins from cells. We recently showed that protein degradation is a genetically complex trait shaped by variation throughout the genome, often in a pathway-specific manner. UPS activity is highly environment-dependent, and gene-by-environment interactions (GxE) are pervasive in complex trait genetics. However, to what extent genetic influences on the UPS are modified by environmental factors is almost entirely unknown.
To comprehensively explore GxE in the genetics of the UPS, we mapped genetic influences on the activity of six UPS pathways in eight environments in the yeast *Saccharomyces cerevisiae*. We tested a standard growth condition and environments that cause large, well-defined changes in UPS activity, including nutrient deprivation, protein misfolding, and proteasome inhibition and activation. We used high-throughput reporters to measure UPS activity in millions of single cells. We mapped loci that contain variation affecting UPS activity using a statistically powerful method based on whole-genome sequencing of pools of phenotypically extreme recombinant progeny of a cross between two yeast strains.
We found 419 loci affecting UPS activity across the 48 pathway/environment combinations. In line with previous work, many loci affected UPS activity in a pathway-specific manner. To test for GxE, we examined 1) locus presence/absence and 2) changes in locus effect direction (*i.e.,* one allele increases UPS activity in one environment, but decreases it in another) across environments for each pathway. Of the average of 8 loci found across pathways in the standard medium, 88% were also found in at least one other environment. Of loci that were shared across environments, 17% had a change in effect direction. Thus, most genetic effects on UPS activity are consistent across environments, with modest amounts of GxE.
Some loci exhibited strong GxE. For example, 25% of the changes in effect direction across environments mapped to the *HAP1* gene. This locus showed the strongest change in effect direction of all loci detected. Here, the same allele increased UPS activity in nutrient deprivation but decreased UPS activity in other environments. This “hotspot” locus is known to affect the expression of thousands of genes in *trans*. Indeed, most (84%) loci with change in effect direction occurred within 25 kilobases of a known hotspot, which is significantly more than loci with consistent effect direction (67%; $p = 0.0014$). This suggests that *trans*-acting effects that modify cellular states are a source of GxE in the UPS. Our results reveal instances of strong GxE in UPS activity against a backdrop of remarkably stable effects across environments.

960T **Environment-specific hubs of genetic interaction modify the phenotypic effects of genetic perturbations** Ilan Goldstein, Joseph J Hale, Ian Ehrenreich Molecular and Computational Biology SectionDepartment of Biological Sciences, University of Southern California

Interactions between genetic perturbations and segregating loci can cause perturbations to show different phenotypic effects across genetically distinct individuals. In addition, interactions between a genetic perturbation and segregating loci may vary across environments. To study these complex interactions on a genome scale, we used combinatorial DNA barcode sequencing to measure the fitness effects of 8,013 CRISPRi perturbations targeting 1,721 distinct genes in 169 yeast cross progeny (or segregants) grown in two environments (respiratory and fermentable media). We identified ~600 genes whose perturbation show different effects across segregants in at least one environment. Only 271 (%45) of these genes were found to have background dependent effects in both environments. To understand the interactions giving rise to background dependent effects within and between environments, we mapped ~700 loci that modify the phenotypic effect of one or more perturbation. Six ‘hub’ loci were found to modify the effect of many genetic perturbations. Only one of these hub loci was found to modify a large number of phenotypic effects in both environments. These results suggest that an individual’s response to perturbations is shaped by a network of perturbation-locus interactions that cannot be measured by approaches that examine natural variation on its own or perturbations in singular genetic backgrounds. Furthermore, these networks of genetic interaction may differ dramatically between environments.

961T **A neural network based framework for systematically modeling genotype-phenotype relationships** David G Mets[1,1], Ryan York[2], Prachee Avasthi[2] [1]Genetics, Arcadia Science, [2]Arcadia Science

Modern methods for predicting phenotypes from genotypes often assume genetic influences on phenotypes combine additively and independently despite extensive documentation of gene-gene and gene-environment interactions. Here, we present an artificial neural network-based modeling framework for predicting phenotypes from genotypes (and vice versa) that captures non-linear relationships and can model many phenotypes simultaneously. In simulated and empirical data we find

accurate phenotypic predictions (5-20 mean average percentage error) based on genotypes. The accuracy of these predictions relies both on capturing gene-gene interactions and on simultaneously modeling multiple phenotypes suggesting that establishing genotype-phenotype maps that model the systematic relationships among genes, environments, and phenotypes can better capture the underlying biology thant mappings that treat the factors driving phenotypic variation as independent.

962F **Master regulators of biological systems in higher dimensions** Holger Eble[1], Michael Joswig[1], Lisa Lamberti[2], Will Ludington[3,4] [1]TU Berlin, [2]ETH Zurich, [3]Carnegie Institution for Science, [4]Johns Hopkins University

A longstanding goal of biology is to identify the key genes and species that critically impact evolution, ecology, and health. Network analysis has revealed keystone species that regulate ecosystems and master regulators that regulate cellular genetic networks. Yet these studies have focused on pairwise biological interactions, which can be affected by the context of genetic background and other species present, generating higher-order interactions. The important regulators of higher-order interactions are unstudied. To address this, we applied a new high-dimensional geometry approach that quantifies epistasis in a fitness landscape to ask how individual genes and species influence the interactions in the rest of the biological network. We then generated and also reanalyzed 5-dimensional datasets (two genetic, two microbiome). We identified key genes (e.g. the rbs locus and pykF) and species (e.g. Lactobacilli) that control the interactions of many other genes and species. These higher-order master regulators can induce or suppress evolutionary and ecological diversification by controlling the topography of the fitness landscape. Thus, we provide a new method and mathematical justification for exploration of biological networks in higher dimensions.

963F **Stable genotype-to-phenotype mapping in an evolving population** Jessica Rhodes[1], Mark Bitter[2], Skyler Berardi[3], Jack Beltz[3], Hayes Oken[3], Lauren McIntyre[4], Dmitri Petrov[2], Paul Schmidt[3] [1]Genetics, Stanford University, [2]Genetics, Stanford, [3]Biology, University of Pennsylvania, [4]Molecular Genetics & Microbiology, University of Florida

Genome-wide association studies are widely used to infer the genetic basis of a range of complex traits across species. Yet, it is unknown how stable the resulting genotype-phenotype-map is throughout the evolutionary process. Specifically, polygenic changes in allele frequency may shift the epistatic landscape and increase or decrease the association of variants with the phenotype of interest. In this study, we leverage a highly replicated, outdoor mesocosm system of *D. melanogaster* populations to directly test the stability of the genotype-phenotype map throughout evolution. We mapped abdominal pigmentation – a classical, well-studied trait, with a known core biochemical network and associated variants from several previous GWAS studies. Our goal is to assess both how the genotype-to-phenotype map shifts while the population undergoes a seasonal shift in pigmentation and how well it predicts the underlying seasonal allele frequency changes.

The trait mapping of the outbred populations from both outdoor and indoor cages (N=10 for each treatment) at two timepoints revealed that the genotype-to-phenotype map was broadly conserved across replicate cages and timepoints. As expected, the average abdominal pigmentation decreased from spring to fall in outdoor cages. While outdoor populations exhibited much greater phenotypic shifts than indoor populations, the large effect size loci were conserved between them with a few notable exceptions – most prominently the *yellow* gene peak that only appears in the outdoor populations. Furthermore, our trait mapping is consistent with the largest hits of previous GWAS in other populations and we identified SNPs near the key pigmentation genes *tan*, *ebony*, and *bab*. However, when we tested whether these loci exhibit systematic shifts in allele frequencies associated with the overall pigmentation evolution from spring to fall, we found shifts at only one of the large-effect size loci identified during mapping (*bab*). We hypothesize that the muted impact of most mapped genes on the evolution of the trait may be driven by their pleiotropic effects. Overall, we find that the genotype-to-phenotype map is remarkably stable and similar between populations, but is not necessarily a robust predictor of which variants will be responsible for the phenotypic responses to selection.

964F **Let's talk about bruno: Uncovering genetic variants causative of differences in dysgenic sterility in Drosophila melanogaster.** Lorissa Full Saiz, Natalie Copeland, Julia Gorman, Emilio Espinosa, Oscar Full Olbera, Hasan Nooruddin, An Bui, Caycel Desales, Sydni Marsh, Bryan Salinas, Erin S Kelleher Biology and Biochemistry, University of Houston

Transposable elements (TEs) are genetic parasites that proliferate in the germlines of organisms to ensure their transmission to offspring. While TEs are predominantly vertically transmitted from parent to offspring, they can invade new host genomes via horizontal transfer between species. The unrestricted transposition of newly invaded TEs can reduce the fertility and fitness of their host. Although TE repression mechanisms evolve rapidly, it is not instantaneous, so standing variation in host populations with respect to TE fertility and fitness effects are predicted to be major targets of selection following TE invasions.

The P-element invasion of Drosophila melanogaster is a modern example of a novel TE invasion and provides us with

an opportunity to identify standing variation in the fitness effects of TEs. In the absence of host repression, P-elements cause germline DNA damage that leads to a sterility syndrome called hybrid dysgenesis. Contemporary populations of D. melanogaster evolved piRNA-mediated silencing of P-elements, in which maternally transmitted piRNAs suppress transposition and dysgenic sterility in offspring. However, P-element naive mothers derived from pre-invasion natural populations do not produce P-element piRNAs and are not able to transmit them to offspring. These offspring are then typically sterile. Therefore, differences in the frequency of dysgenic sterility between offspring of different naive female genotypes reveal the presence of host genetic variation in fertility costs.

Through quantitative trait locus (QTL) mapping, our lab identified the bruno locus as a likely source of natural variation in dysgenic sterility. However, the causative variant behind these fertility differences remains unknown. I am performing fine-scale, marker-assisted mapping to narrow the QTL window, then determining the exact causative variant(s) of the phenotypic differences in dysgenic sterility by performing CRISPR-Cas9 mediated allele swaps. Identifying the causative variants will allow us to determine how dysgenic sterility is reduced, and ultimately if this reduction was beneficial following P-element invasion. Although evolutionary biologists often localize natural variation through QTL mapping, it is rare to isolate the exact causative variant that determines a trait of interest. My research will complete the progression from QTL to causative variation, thereby expanding our understanding of the molecular genetic basis for trait variation.

965F **Genetic correlations associated with body coloration, aggression, and activity levels in *Drosophila melanogaster*** Paulina Montes Mendez, Samuel Miller, Katelyn McCaffery, Sarah Ruckman, Kimberly Hughes Florida State University

One long standing question in evolutionary biology is whether single genes that control multiple traits (pleiotropy) results in limitations on adaptive evolution. If it does, then our ability to predict adaptation (e.g., in the face of changing environments) is compromised. We are using a much-discussed correlation between body coloration and aggressive behavior as a system to address this question. Having found the predicted genetic correlation between cuticle color and aggressive behavior in *Drosophila melanogaster* using artificial selection (unpublished data), we then asked if any other behaviors co-evolved under selection on cuticle color. For example, the dopamine synthesis pathway is plausibly related to color, aggression, and other behaviors, such as activity level. We therefore measured activity level of flies (*D. melanogaster*) selected for darker and lighter cuticle color. Results suggest that activity level is higher in the dark-selected lines, suggesting that genetic correlations do constrain the independent evolution of cuticle color and behavior. The next step in this study to identify candidate genes underlying the correlation and test for pleiotropic effects using transgenic approaches.

966F **Genetic and morphological contributions to natural variation in pup isolation calls in deer mice** Maya L Woolfolk[1,2,3], Nicholas Jourjine[1,2,3], Sade McFadden[1,2,3], Hopi E Hoekstra[1,2,3] [1]Organismic and Evolutionary Biology, Harvard University, [2]Molecular and Cellular Biology, Harvard University, [3]Museum of Comparative Zoology, Harvard University

Neonatal vocalization is a behavior critical for eliciting care from parents across vertebrates and in many mammals, vocalizations also serve to establish social bonds between parents and offspring. While neonatal vocalization varies between species in both quantity and content, the proximate mechanisms underlying this variation are largely unknown. Deer mice (genus *Peromyscus*) are a group of closely related but behaviorally diverse rodents that offer an opportunity to study natural variation in pup vocal behavior. Previously, we identified significant interspecific differences in temporal and acoustic features of pup cries, several of which evolved repeatedly between species. To further investigate the genetic basis of this behavioral variation, we performed quantitative trait locus (QTL) mapping with 881 F2 individuals generated by intercrossing two sister species: *P. maniculatus* and *P. polionotus*. We first found acoustic features of different vocalization types are uncoupled in F2 hybrids, suggesting that they are under separate genetic control, and we identified several loci significantly associated with species-specific differences in pup vocal behavior. One likely cause underlying the acoustic variation between species is different laryngeal morphology. Therefore, in conjunction with our genetic approach, we also targeted the mechanistic basis of vocal variation by utilizing microCT-generated data and performing morphometric analyses of three cartilages in the primary vocal organ, the larynx. We found that *P. maniculatus* has larger thyroid cartilages and greater total larynx cartilage volume than *P. polionotus*. Both features are hypothesized to play an important role in acoustic structure and vocal production, which suggests there are potential contributions of differential laryngeal morphology to interspecific variation in acoustic features such as average frequency/pitch. We are following up this initial work by analyzing these laryngeal features in F2 hybrids, with which we can identify a causal relationship between structural variation and variation in acoustic structure. In this system, we are uncovering mechanisms underlying natural variation in pup vocal behavior to identify genetic and morphological bases of behavioral evolution.

967F **Haplotype reconstruction using low-pass whole-genome sequencing in genetically diverse mouse populations** Samuel J Widmayer[1], Lydia K Wooldridge[2], Michael C Saul[2], Laura Reinholdt[2], Beth L Dumont[2,2], Daniel M Gatti[2] [1]Computational Sciences, The Jackson Laboratory, [2]The Jackson Laboratory

The Diversity Outbred mouse population (DO) is a premier resource for powerful quantitative trait locus mapping and systems genetics. However, access and genotyping cost remain a barrier to entry for DO experiments. DO mice are typically genotyped using the Giga Mouse Universal Genotyping Array (GigaMUGA), which contains roughly 140,000 markers and costs $100 per mouse. GigaMUGA data demonstrate an estimated 12.2 crossovers per generation have accumulated between generations 21 and 36, which is roughly half the expected rate. This disparity suggests that genotyping DO animals using GigaMUGA arrays lacks the required resolution to capture all recombination events, reducing its utility for genetic mapping. We describe an accurate, cost-effective workflow for genotyping DO animals using low-pass whole-genome sequencing. We prepared 96 samples using two different sequencing approaches: double-digest restriction site–associated DNA sequencing (ddRADseq) and low-coverage whole genome sequencing (lcWGS). These samples were split between two populations: 48 DO animals (Generation 41) and 48 animals derived from an advanced intercross between four wild-derived strains (4WC) of *Mus musculus musculus* and *M. m. castaneus*. We constructed reference haplotypes for each population and used QUILT to impute SNPs for each sample. We then derived chromosome-specific genotype and allele probabilities from a filtered subset of these imputed SNPs using R/qtl2. Founder allele probabilities were on average over 95% concordant with GigaMUGA-derived allele probabilities in both populations for either library preparation method. We achieved comparable concordance even after downsampling the alignments to lower than 0.25X coverage, significantly reducing the cost of genotyping compared to the GigaMUGA. The observed number of crossovers in DO mice also closely approximates their expected frequency, suggesting that our workflow may improve the precision of haplotype reconstruction in complex mouse crosses. Hundreds of loci less than 0.1 Mb remain discordant from GigaMUGA, and ongoing work seeks to leverage recently published structural variant datasets and regions of identity-by-descent to characterize sources of noise in haplotype reconstructions. We aim to lower barriers to conducting DO mouse experiments by reducing genotyping costs and the computational expertise associated with obtaining accurate haplotype reconstructions.

968F **Trophic-level gut length divergence evolved under sexual conflict in Lake Malawi cichlids** Aldo Carmona Baez[1], Patrick J Ciccotto[2], Emily C Moore[3], Kaitlin P Coyle[4], Melissa S Lamm[5], Erin N Peterson[4], Natalie B Roberts[1], Rafael Guerrero[1], Reade Roberts[1] [1]Biological Sciences, North Carolina State University, [2]Warren Wilson College, [3]University of Denver, [4]Q2 Solutions, [5]Novogene

Variation in gastrointestinal morphology is associated with dietary specialization across the animal kingdom. Gut length generally correlates with trophic level, and increased gut length in herbivores is a classic example of adaptation to diets with lower nutrient content and a higher proportion of refractory material. However, the genetic basis of gut length variation remains understudied, partly due to the inaccessibility and plasticity of the gut tissue, as well as the lack of dietary diversity within traditional model organisms relative to that observed among species belonging to different trophic levels. Here, we confirm the genetic basis of gut length variation among recently evolved Lake Malawi cichlid fish species with various dietary adaptations. We then produce interspecific, inter-trophic-level hybrids to map evolved differences in intestinal length in an F2 mapping cross between *Aulonocara koningsi*, a carnivore with a relatively short gut, and *Metriaclima mbenjii*, an omnivore with a relatively long gut. We identify numerous candidate quantitative trait loci for evolved differences in intestinal length. These quantitative trait loci are predominantly sex-specific, suggesting an evolutionary history of sexual conflicts for the gut. We also identify epistatic interactions potentially associated with canalization and the maintenance of cryptic variation in the cichlid adaptive radiation. Overall, our results suggest complex, polygenic evolution of gut length variation related to trophic level differences among cichlids, including sexual conflicts and epistatic interactions that may be involved in evolutionary processes underlying other traits in cichlids.

969F **Toward whole-organism genetic mapping: The Arcadia Chlamydomonas Diversity Collection** Ryan York, Prachee Avasthi, Ben Braverman, Tara Essock-Burns, Galo Garcia, Jase Gehring, David Matus, Cameron MacQuarrie, David Mets Arcadia Science

How genomes give rise to organismal variation is a central problem in biology. Genetic diversity panels are powerful tools for this task, allowing diverse phenotypic measurements to be mapped to a common genomic background. In theory, measurements of a given diversity panel could be scaled to a point approximating the breadth of functions encoded by the genome, creating the potential for whole-organism genetic mapping. With this in mind, we created the Arcadia *Chlamydomonas* Diversity Collection (ACDC), a community resource for organism-level genotype-phenotype mapping. The ACDC consists of ~1,800 fully-sequenced, clonal F_2 strains generated from a cross between the unicellular algal species *C. reinhardtii* and *C. smithii. C. reinhardtii* and *C. smithii* display extensive morphological, behavioral, ecological, and physiological variation. Using high-throughput phenotyping tools, we have found that these differences are also reflected among the ACDC strains. Leveraging this, we have developed neural network-based genetic mapping approaches to jointly identify the molecular basis of many phenotypes at once. We have identified several principal axes of variation and their genetic correlates, providing an initial glimpse into the genomic underpinnings of *Chlamydomonas* organismal biology. We are excited to keep expanding the characterization of the ACDC and, as such, all strains, genotypes, phenotypes, and experimental tools

associated are publicly available and open source.

970F **Error rates in Q_{ST} vs. F_{ST} comparisons depend on genetic architecture** Junjian «Janis» Liu, Michael «Doc» Edge Department of Quantitative and Computational Biology, University of Southern California

Genetic and phenotypic variation among populations is one of the fundamental subjects of evolutionary genetics. One question that arises often in data on natural populations is whether differentiation on a particular trait might be caused in part by natural selection. For the past thirty years, researchers have used Q_{ST}-F_{ST} approaches to compare the amount of trait differentiation among populations on one or more traits (measured by the statistic Q_{ST}) with differentiation on genome-wide genetic variants (measured by F_{ST}). Theory says that under neutrality, F_{ST} and Q_{ST} should be approximately equal in expectation, so Q_{ST} much larger than FST is consistent with local adaptation, and Q_{ST} much smaller than F_{ST} is consistent with stabilizing selection. At the same time, in making this and similar statements, investigators have differed in their definitions of genome-wide F_{ST} (particularly regarding “ratio of averages” vs. “average of ratios” versions of F_{ST}) and in their definitions of the variance components in Q_{ST}. Here, we show that these details matter. The different versions of F_{ST} and Q_{ST} have different interpretations in terms of coalescence time, and comparing incompatible statistics can lead to elevated type I or type II error rates, with some typical choices leading to type I error rates as high as 15% when the nominal rate is 5%. Further, although the expectation of Q_{ST} does not depend on the number of loci influencing the trait, the distribution of Q_{ST} does, so the right choice of comparison distribution depends on genetic architecture. We discuss solutions and provide a guide to making Q_{ST}-F_{ST} comparisons that are theoretically coherent and empirically conservative.

971F **Like mother, like daughter? Phenotypic plasticity, environmental covariation, and heritability of size in a parthenogenetic wasp** Scott Monahan, Arun Sethuraman Biology, San Diego State University

Dinocampus coccinellae (Hymenoptera:Braconidae, Euphorinae) is a solitary, generalist Braconid parasitoid wasp that reproduces through thelytokous parthenogenesis, an asexual process in which diploid daughters emerge from unfertilized eggs, and uses over fifty diverse species of coccinellid ladybeetles worldwide as hosts. Here we utilized a common garden and reciprocal transplant experiment using parthenogenetic lines of D. coccinellae presented with three different host ladybeetle species of varying sizes, across multiple generations to investigate heritability, plasticity, and environmental covariation of body size. We expected positively correlated parent-offspring parasitoid regressions, indicative of heritable size variation, from unilineal (parent and offspring reared on same host species) lines, since these restrict environmental variation in phenotypes. In contrast, because multilineal (parent and offspring reared on different host species) lines would induce phenotypic plasticity of clones reared in varying environments, we expected negatively correlated parent-offspring parasitoid regressions. Contrary to expectations, our results indicate (1) little heritable variation in body size, (2) strong independence of offspring size on the host environment, (3) a consistent signal of size-host tradeoff wherein small mothers produced larger offspring, and vice versa, independent of host environment. Our study offers support for a constrained fecundity advantage model of Cope’s Law, wherein D. coccinellae maintains phenotypic plasticity in body size despite parthenogenetic reproduction.

972F **Co-mutation based genetic networks to infer temporal mutation dynamics in ancient human mitochondrial genomes** Rahul K Verma[1], Janna Fierst[2] [1]Biological Sciences, Florida International University, [2]Florida International University

The evolution of modern humans is a long and complicated process which started from their first appearance and continues to the present day. Various habitats have played a significant role in shaping the migratory paths in ancient times and stabilization of current sub-populations around the globe. Mitochondria is the chief cell organelle for responding to these habitats since it is involved in cellular metabolism and energy generation. The majority of human ancient DNA (aDNA) studies were focused mainly on mitochondrial DNA (mtDNA) due to the fact that mtDNA is present in cells in a higher copy number than the nuclear genome Studies have shown that mitochondrial DNA (mt-DNA) has acquired certain adaptations in response to human diet as well. To account for the role of genetic background with respect to variable sites in shaping the migratory and evolutionary path, the ancient mtDNA was analyzed as spatiotemporal co-mutation networks.

The human sub-populations are represented by mitochondrial haplogroups due to enrichment of variable sites geographically. Similarly, studies on ancient mtDNA revealed the dominance of haplogroup U in hunter-gatherer class and haplogroup H along with J and K in early farmer class of ancient humans. We employed a network-based approach to deduce the co-occurring variable sites to generate the weighted genetic interaction networks for the mtDNA sequences for six eras named Mesolithic, Neolithic, Copper, Bronze, Iron and Middle era. We found that Mesolithic era had highest percentage (6.8%) and the Middle era had least percentage (1.0%) of ancestral SNPs, which is consistent with the period of that era.

The haplogroup composition showed that, Mesolithic era is completely dominated by haplogroup U, in Neolithic and Copper eras haplogroups U, H and K are dominant. Haplogroup U has been associated with hunter-gatherer group and haplogroup H has been associated with farmer group. In Copper, Iron and Middle eras haplogroup H was found to be dominantly present

which supports the idea of agricultural developments during these periods.

The analysis of genetic interaction networks provided evidence for the significance of different genetic interactions in each era. In Mesolithic era ND5 with ND4 and CYB with ND4 genes, in Neolithic era, ND1 gene with CO3 and CYB genes and ND5 gene with multiple genes, in the Copper era CO1 gene with ND6 and ND2 with ND5, in Bronze era, ND4 with ND1 and ND6 with ND5 and CO1 with multiple genes, and in Iron era, ND6 gene with ND3, CYB and ND5, and CYB, ND4, ND1 and ND2 genes forming prominently high weight interactions.

Since the networks are purely temporal, we further sought to perform the phylogenetic studies on these mtDNA sequences to generate the spatio-temporal evolutionary relation among the sequences. This would help us to compare the network based temporal results with the geography-based phylogeny.

973F **The gall of an aphid : Novel secreted proteins hijack plant gene expression** Aishwarya Korgaonkar, David Stern, Clair Han HHMI Janelia Research Campus

In an extreme form of interspecies exploitation, insects hijack plant developmental pathways to induce novel plant organs called galls. These galls represent a dramatic reprogramming of plant cell biology resulting from the direct action of insects on host plants. One example are the cone-shaped galls induced by the aphid, *Hormaphis cornu,* on the leaves of *Hamamelis virginiana*.

We discovered that these aphids encode a large class (~500) of novel secreted, cysteine-rich proteins with no homology to any known proteins. These proteins are highly divergent other than a pair of widely spaced cysteine-tyrosine-cysteine (CYC) motifs, hence named *bicycle* proteins. Evidence for these proteins as gall effectors comes from our discovery that links a *bicycle* gene, *g16073*, to a naturally occurring variation in plant gall color. Furthermore, the aphid genotype at this genetic locus has a targeted and quantifiable effect on plant gene expression leading to the hypothesis that the transformation of leaf tissue into a gall is driven by the direct action of injected aphid bicycle proteins. Ongoing work is focused on functional characterization of aphid bicycle proteins in the host plant.

974F **Leveraging old data and new methods to illustrate the critical role of epistasis in genetics and evolution** Jorja Elliott[1], Maximos Chin[2], Brian E Fontenot[3], Sabyasachi Mandal[1], Thomas McKnight[1], Jeffery P Demuth[3], Heath Blackmon[1] [1]Texas A&M University, [2]University of California Davis, [3]University of Texas at Arlington

Much of evolutionary theory is predicated on assumptions about the relative importance of simple additive versus complex epistatic genetic architectures. Previous work suggests traits strongly associated with fitness will lack additive genetic variation, whereas traits less strongly associated with fitness are expected to exhibit more additive genetic variation. We use a quantitative genetics method, line cross analysis, to infer genetic architectures that contribute to trait divergence. By parsing over 1600 datasets by trait type, clade, and cross divergence, we estimated the relative importance of epistasis across the tree of life. In our comparison between life history traits and morphological traits, we found greater epistatic contributions to life history traits. Our comparison between plants and animals showed that animals have more epistatic contribution to trait divergence than plants. In our comparison of within-species versus between-species crosses, we found that only animals exhibit a greater epistatic contribution to trait divergence as divergence increases. While many scientists have argued that epistasis is ultimately of little importance, our results show that epistasis underlies much of trait divergence and must be accounted for in theory and practical applications like domestication, conservation breeding design, and understanding complex diseases.

975F **Coheritability and Coenvironmentability as Concepts for Partitioning the Phenotypic Correlation** Jorge Vasquez-Kool Health Human and Life Sciences, Shaw University

Central to the study of joint inheritance of quantitative traits is the determination of the degree of association between two phenotypic characters, and to quantify the relative contribution of shared genetic and environmental components influencing such relationship. One way to approach this problem builds on classical quantitative genetics theory, where the phenotypic correlation between two traits is modelled as the sum of a genetic component called the coheritability, which reflects the degree of shared genetics influences affecting the phenotypic correlation, and an environmental component, namely the coenvironmentability that accounts for all other factors affecting the observed trait-trait association. Here a mathematical and statistical framework is presented on this partition and describe visualization tools to analyze concurrently the coheritability, coenvironmentability and the phenotypic correlation. Examples of its application are presented.

976F **Exploiting natural variation in wild *Saccharomyces cerevisiae* strains to understand why certain individuals are more susceptible to alpha-synuclein (a-syn) toxicity** Julio A Molina Pineda[1], Manasa Veluvolu[2], Tara N Stuecker[2], Stephan N Witt[3],

Jeffrey A Lewis[2] [1]Cell and Molecular Biology, University of Arkansas, [2]Biological Sciences, University of Arkansas, [3]Biochemistry and Molecular Biology, LSU Health Shreveport

Parkinson's disease (PD) is a progressive neurodegenerative disorder affecting more than 5 million people worldwide. A hallmark of PD is dopaminergic neuronal cell death caused by cytotoxic aggregates of alpha-synuclein (a-syn). However, it is unclear why a-syn forms cytotoxic aggregates in some individuals but not others, and how these a-syn aggregates cause cellular toxicity. Understanding the genetic basis of variation in a-syn cytotoxicity in humans is challenging, so we turned to the budding yeast Saccharomyces *cerevisiae* as a powerful and tractable genetic model. a-Syn overexpression in yeast recapitulates the subcellular localization and cytotoxicity seen in neuronal cells, and, excitingly, we have identified wild yeast strains with either increased susceptibility or high resistance to a-syn overexpression. Thus, we have a new model for understanding the genetic basis of natural variation in a-syn susceptibility. Using a panel of strains with high or low a-syn susceptibility, we have performed global transcriptional profiling following over-expression of a-syn using two different promoter systems. Our results suggest that strains with natural resistance to a-syn over-expression have a more robust gene expression response, while also identifying candidate genes that protect against a-syn toxicity or exacerbate it. Overall, this work demonstrates the power of using natural variation combined with system genetics to identify novel genes and processes important for disease susceptibility.

977F **QTL Mapping of Yeast Mating Efficiency and Cell Cycle Progression** Dominick Costanzo[1], Dimitra Aggeli[1], Alex Nguyen Ba[2], Michael Desai[3], Gregory Lang[1] [1]Lehigh University, [2]University of Toronto, [3]Harvard University

Most phenotypes are complex, with contributions from many loci throughout the genome. Quantitative Trait Locus (QTL) mapping is a powerful strategy for uncovering the loci contributing to complex traits, including small-effect variants. We are using a mapping population of ~100,000 segregants from a cross between a laboratory strain and a vineyard isolate. Each segregant has been genotyped and uniquely barcoded. Using a bulk barcoded assay, we mapped loci underlying two traits: mating efficiency and cell- cycle progression. We are currently applying this technique to plasmid copy number and signaling through the mating pathway.

978F **Dissecting complex traits in yeast by saturation genome editing** Kevin R Roy[1,2], Justin D Smith[1], Shengdi Li[3], Sibylle C Vonesch[3], Michelle Nguyen[1], Wallace T Burnett[1], Kevin M Orsley[1], James E Haber[4], Robert P St.Onge[5], Lars M Steinmetz[1,2,3] [1]Genetics, Stanford University, [2]Stanford Genome Technology Center, Stanford University School of Medicine, [3]Genome Biology Unit, European Molecular Biology Laboratory, [4]Rosenstiel Basic Medical Sciences Research Center and Department of Biology, Brandeis University, [5]Biochemistry, Stanford University

Understanding how genetic variants give rise to complex traits remains one of the biggest challenges in genetics. We previously developed a high-throughput CRISPR guide/donor homology-directed repair (HDR)-based system for variant phenotyping termed ***Multiplexed Accurate Genome Editing with Short, Trackable, Integrated Cellular barcodes*** (MAGESTIC). To characterize the efficiency and fidelity of MAGESTIC at the genome scale, we introduced guide-donor libraries targeting natural single-nucleotide variants (SNVs) into the laboratory strain and characterized on- and off-target editing outcomes by whole-genome sequencing of thousands of clones. This work revealed four major challenges: (1) low efficiency guides leading to unedited clones, (2) repetitive regions prone to structural variant (SV) formation, (3) integration of donor plasmids at target sites, and (4) low representation of SNVs due to re-cleavage by SpCas9. To address the first two challenges, we developed a super-charged donor HDR system (MAGESTIC 3.0) combining three orthogonal methods: donor DNA recruitment with the FHA domain of yeast Fkh1p, single-stranded donor DNA synthesis with the bacterial retron system, and *in vivo* assembly of linearized donor plasmids. MAGESTIC 3.0 improved editing kinetics at low-efficiency targets and editing fidelity at SV-prone regions over each single system, completely abrogating aberrant SV formation in some cases. To address the third challenge, we developed an inducible SaCas9 system to cleave integrated plasmids and simultaneously recover correct edits with near 100% efficiency. To address the fourth challenge, we profiled a panel of engineered variants of SpCas9 and LbCas12a with enhanced fidelity and broadened target ranges for their ability to edit all SNVs across guide target regions. We identified several variants showing substantially improved SNV representation over wild-type SpCas9. We used this optimized MAGESTIC 3.0 system to screen all targetable natural variants residing in 112 quantitative trait loci (QTL) for 32 conditions, revealing a complex genotype-phenotype map of causal variants. As expected, causal variants were more likely to be missense variants. Surprisingly, a large fraction of QTL harbored more than one causal variant with implications for association-based studies. MAGESTIC 3.0 will enable the functional dissection of the genome at single-nucleotide resolution and inform attempts to improve HDR-based genome editing across organisms.

979F **Selection to combined antifungal drug stressors produces non-additive genomic responses in experimentally-evolved *Saccharomyces cerevisiae* populations** Megan A Sandoval-Powers, Molly K Burke Integrative Biology, Oregon State University

The role of additive versus non-additive genetic interactions on complex trait variation remains an open question in quantitative genetics. These interactions are often highly influenced by environmental perturbations; therefore, a deeper understanding of how quantitative trait loci respond to complex stressful environments is needed. Here, we used an evolve-and-resequence (E&R) framework to study the genomic and phenotypic responses associated with antifungal drug resistance, a human health-relevant complex trait. Outbred *Saccharomyces cerevisiae* populations were evolved under a single antifungal drug environment (caspofungin acetate [Cas] or clotrimazole [Clo]) or a combined drug environment (Cas+Clo) for ~50 asexual generations. By comparing changes in populations evolved to the combined drug treatment with the single drug treatments, we assessed the extent to which responses were driven by additive effects (predicted by individual stressors) versus non-additive effects (unique from individual stressors). Phenotypic changes in evolved populations suggest that the combined-drug populations increased the greatest in fitness relative to the ancestral population. Pooled-population genome sequencing of evolved replicates revealed ~40K high-coverage single-nucleotide polymorphisms (SNPs) to investigate within and between treatments. We used linear models to identify candidate SNPs, those with the greatest and most consistent change in frequency over time, and little overlap was observed across treatments when comparing single-drug and combined-drug populations. Candidate SNPs often implicated different genes and regions, most notably when compared between Cas and Cas+Clo treatments. A significantly differentiated SNP in the Cas treatment occurred within chromosome 15 in the *PDR5* gene encoding a pleiotropic drug resistance factor, and SNPs in this gene were not significant in the Clo or Cas+Clo treatments. Distinct genomic changes in the combined drug-treatment indicate that polymorphisms can contribute non-additively to the drug resistance trait. This finding suggests that genetic interactions may be more complex than predicted by simple additivity, at least in the context of antimicrobial drug resistance. This has important implications for our understanding of how variation arises and evolves in complex traits associated with human health and disease.

980S **Mapping the Genetic Underpinnings of Natural Variation in Mutagen Tolerance in *Drosophila melanogaster*** Llewellyn Green, Erin Kelleher Biology and Biochemistry, The University of Houston

Organisms are continuously under attack by numerous mutagens in the environment. If this damage is not repaired correctly, it can result in increased mutation and genomic instability. Apart from these obvious direct effects on DNA damage and mutation, many of these mutagenic agents can also exert other harmful physiological effects on the organism, including death. Consequently, mutagen tolerance, the ability to withstand and promptly repair DNA damage, is a fundamental determinant of organismal fitness.

Genetic screens in individual strains provide limited biological insight into how natural populations respond to mutagen exposure. Despite its relative importance, little is known about the genetic factors that contribute to natural variation in mutagen tolerance. To address this gap, we used the Drosophila Synthetic Population Resource (DSPR) to perform an extreme quantitative trait locus (QTL) mapping strategy to map mutagen tolerance in *Drosophila melanogaster.*

We chose to focus on two common environmental mutagens, ionizing radiation (X-rays) and UV-B radiation. These mutagens differ significantly in their variance and prevalence in the environment. Higher-energy ionizing radiation predominantly causes double-stranded breaks (DSBs), while UV-B radiation causes more variable types of damage that may involve separate repair pathways. We predict that due to these differences in exposure, there will be a wider range of genetic variation for UV-B tolerance to act upon than for ionizing radiation.

Our third instar screen on ionising radiation identified a single locus that spans the third centromere, while the UV-B screen on embryos identified three loci that have not been previously associated with the trait. The lack of overlap between the two stressors suggests that different DNA repair and stress response pathways are acting in each case. While a small number of genes familiar to DSB repair have been identified under the ionising radiation QTL, very few familiar candidates have been found under the mapped UV-B loci; a potential indication that the genes contributing to tolerance in natural populations of *D. melanogaster* are much broader than previously characterised.

We anticipate that with the addition of functional genetic analysis of candidate genes under mutagen tolerance QTLs, coupled with SV analysis of founder haplotypes, will be used to identify the genetic underpinnings of natural variation in mutagen tolerance in *D. melanogaster* and provide new insights into the evolution of stress response mechanisms.

981S **The genetic basis of the non-monotonic response to atrazine in *Drosophila melanogaster*** Pamela C Lovejoy Biology, St. Joseph›s University New York

Atrazine is one of the most widely used herbicides in the United States. Even though atrazine has agricultural benefits, it has been shown to have a variety of negative effects on non-target organisms. In *Drosophila melanogaster*, atrazine causes reductions in lifespan, alterations to development time, decreases in reproductive fitness, and changes in expression of

proteins involved in response to oxidative stress. Within several of these traits, non-monotonic dose response curves have been observed, such that intermediate concentrations of atrazine have the strongest effects, while low and high concentrations of atrazine have minimal effects. In this study, I investigated the effect of atrazine on the trait of egg laying preference. Flies given the choice of five different atrazine concentrations lay the most eggs on food containing the highest and lowest concentrations and the least eggs on food containing intermediate concentrations. This creates a non-monotonic "U-shaped" curve when number of eggs laid is graphed. The goal of this research is to identify and investigate the genes affecting this non-monotonic response. To do this, I have performed a genome-wide association study (GWAS) using the *Drosophila* Genetic Reference Panel (DGRP). The GWAS returned 138 genetic variants that are associated with the non-monotonic response to atrazine. The candidate genes associated with these variants are currently being investigated with RNAi. This research was integrated into the BIO 290 Modern Genetics course at St. Joseph's University New York (SJNY) over several years to provide the students with a course-based undergraduate research experience (CURE) during their sophomore year. Students assisted with data collection for the complete GWAS and performed their own smaller GWAS with the subset of data they collected during the course, identifying candidate genes and common gene ontology terms. Students presented posters with their results at the SJNY Undergraduate Research Symposium, gaining a valuable experience that will enhance their CVs going forward. This research will help elucidate the non-monotonic effects of atrazine and increase college student retention and future success through its integration into the classroom.

982S **Evolutionary Constraints Associated with Color and Aggression in *Drosophila melanogaster* and *D. simulans*** Sarah Ruckman, Kimberly Hughes Florida State University

One long standing question in evolutionary biology is whether single genes that control multiple traits (pleiotropy) result in limitations on adaptive evolution. If it does, then our ability to predict adaptation (e.g., in the face of changing environments) is compromised. We are using a much-discussed correlation between body coloration and behavior as a system to address this question. Aggression and pigmentation are hypothesized to be genetically correlated in many organisms because the same biochemical pathways (e.g., dopamine) are used in color synthesis and the production of molecules that modulate behavior, including aggression. We used two species of fruit flies, *Drosophila melanogaster* and *D. simulans* to test this hypothesis. By focusing on two species, we assessed the repeatability and similarity in genes underlying genetic correlations. To test for genetic correlation, we first selected for darker (and lighter) body color and then tested for aggressive behavior periodically. Our results suggest that dark-selected flies evolved to be more aggressive, suggesting that genetic correlation does constrain the independent evolution of cuticle color and behavior. The next step in this study to identify candidate genes underlying the correlation and test for pleiotropic effects using transgenic approaches.

983S **Genetic dissection of variation in heavy metal susceptibility in *Drosophila melanogaster*** Stuart Macdonald Molecular Biosciences, University of Kansas

Environmental toxicants present considerable risk to human health, and among the most concerning are compounds containing heavy metals. Due to broad industrial use and historically broad incorporation into common products, there is widespread metal contamination of drinking water, food, and soil. Even extremely low levels of exposure to certain metals can yield deleterious consequences for human health. However, there is also considerable variation in an individual's response to any given toxic compound. Understanding the genetic and molecular pathways underlying the response to toxic metals, and the nature of differential metal susceptibility, will enable more accurate prediction of the risks associated with exposure. Detailed, population-based studies in humans are challenged by the inability to control the dose to which individuals are exposed. Genetically-tractable model systems such as *Drosophila* offer considerable advantages; Exposure levels can be precisely controlled, powerful genetic mapping experiments can be executed, and candidate susceptibility genes can be functionally validated using a sophisticated genetics toolkit. Additionally, there is broad gene conservation between humans and flies, including many known metal response and detoxification genes. Thus, studies in flies can provide fundamental insight into toxicity variation in humans. We exposed adult flies from >500 different inbred strains from the *Drosophila* Synthetic Population Resource (DSPR) to toxic levels of 5 metal salts (cadmium chloride, lead acetate, lead nitrate, manganese chloride, and mercury chloride). The DSPR is a powerful multi-parental population framework enabling the genetic dissection of trait variation. QTL mapping led to the identification of QTL for all metals, some of which positionally overlapped across treatments, implying they have common genetic effects on susceptibility to different metals. This is supported by positive correlations in strain lifespan across all exposure treatments, strong correlations in the founder haplotype effects at coincident QTL, and the recapitulation of 4 multi-metal loci following QTL analysis of a composite phenotype resulting from principal components analysis of all metal response traits. Mapped QTL implicate several plausible candidate genes that we are functionally testing via RNAi and genome editing. For instance, *GstS1* (encoding a glutathione S transferase detoxification protein), *Gss1* and *Gss2* (glutathione synthases that are also involved in xenobiotic detoxification), and *ZnT41F* (a zinc transporter). In combination with ongoing expression QTL studies in DSPR strains under both naive and metal-exposed conditions, our work will lead to the identification of loci and mechanisms contributing to variation in a series

of key environmental and industrial metal toxicants.

984S **Increasing power in inbred strain association mapping by recognizing variance heterogeneity** Marissa C Ashner[1], Teresa M McGee[2], Robert W Corty[2], Jialiu Xie[1], William Valdar[3] [1]Department of Biostatistics, University of North Carolina at Chapel Hill, [2]Curriculum in Bioinformatics and Computational Biology, University of North Carolina at Chapel Hill, [3]Department of Genetics, University of North Carolina at Chapel Hill

Modern quantitative trait locus (QTL) mapping in panels of inbred strains uses a linear mixed model (LMM) to test for SNP-phenotype association while accounting for a random effect of population structure. A decade of mathematical tricks has mitigated the computational expense of repeatedly fitting this complex model for genome-wide applications. Existing procedures, however, assume that the phenotype of each strain (or individual) is known with equal precision. In reality, this assumption often does not hold: individuals from some strains are intrinsically more variable than others, and ignoring this can lead to false positives and missed QTL signals. We propose a method, weighted Inbred Strain Association Mapping (wISAM), that accounts for heteroscedastic residual variance in the study population using a weighted regression technique and makes use of variance shrinkage methods to stably estimate these weights. We compare wISAM to existing methods through simulation, demonstrating that it can provide additional statistical power for GWAS, and in real data applications on using the Hybrid Mouse Diversity Panel (HMDP) and panels of inbred strains in other organisms. We also consider how to accommodate potentially problematic features of some datasets, including phenotypic distributions with zero-inflation or experimental designs where some strains have only a single biological replicate.

985S **Exploring evolutionary forces shaping the genetic architecture of complex disease** Kellen Riall[1], Jeremy Berg[2] [1]he Department of Human Genetics, The University of Chicago, [2]The Department of Human Genetics, The University of Chicago

Genome-wide association studies (GWAS) have shed light on the genetic basis of complex diseases, but the role of evolutionary forces in shaping genetic variation of disease phenotypes remains unclear. Despite the presumed fitness cost of disease and strong evidence for selection against functional mutations, evidence for sustained directional selection against complex disease phenotypes is limited. Motivated by this puzzle, we propose a model for a highly polygenic disease evolving at mutation-selection-drift balance (MSDB). Our model assumes that complex disease variants are subject to a combination of directional selection against a disease phenotype and stabilizing selection on related pleiotropic quantitative traits, and predicts that our ability to learn about directional selection against disease from GWAS data depends on our assumptions about the source of mutational pressure. If the mutational pressure conforms to long-term evolutionary equilibrium, where mutations predominantly increase disease risk, directional selection is easily detectable, but the predicted patterns of variation are inconsistent with the data. In contrast, if mutations are equally likely to raise or lower disease risk, the ability to detect directional selection depends on the strength of stabilizing selection. When stabilizing selection is weak relative to directional selection, the allele frequency distribution of risk increasing alleles is indistinguishable from that obtained under neutrality, and contains no information about the strength of directional selection against on the disease. However, this symmetry can be broken if we know whether the risk increasing alleles are derived or ancestral. In contrast, when stabilizing selection is strong, this relationship is reversed: the derived versus ancestral identity of risk increasing alleles is relatively uninformative, but directional selection creates an excess of risk increasing alleles at high frequencies relative to low frequencies. Our analysis suggests that a systematic characterization of the impact of sustained directional selection on disease phenotypes will require that we can determine whether individual risk increasing causal variants are derived or ancestral. To determine if this is feasible, we study the concordance of derived versus ancestral status among putative causal variants within fine mapping credible sets for several UK Biobank traits.

986S **Contemporary evolution of complex traits in the plant fungal pathogen Zymoseptoria tritici** Camille Maurin[1], Marc-Henri Lebrun[2], Cyrille Saintenac[1], Anne Genissel[1] [1]INRAE, [2]CNRS

How pathogens evolve new virulence remains a important question for Health and Agriculture. Microbes, especially fungi, have a high potential for rapid adaptation, with excessive levels of genetic diversity. Here we study the ascomycete fungus *Zymoseptoria tritici*, the causal agent of Septoria Tritici Blotch, a major disease of wheat across the world.

Beyond doubt the arms race between host and pathogen is shaping the fungal genome, evolving against the host immune system. However the overall view on the genetic basis of rapid adaptation of fungal populations remains unclear. A recent resistance breakdown in the field against the resistance gene Stb16q thus provides a unique opportunity to study contemporary evolution of ecologically relevant phenotypes. Towards this goal we sampled a panel of 109 natural fungal isolates. To seek loci conveying adaptation to host resistance, we carried out a thorough study combining phenotyping in the laboratory, NGS sequencing of 109 natural isolates, together with pacbio sequencing of several virulent isolates.

Here we provide empirical evidence using GWAS and QTL mapping approaches that several loci are involved, with polymorphism arising from standing genetic variation or *de novo* mutations. The relative contribution of both types of variants is discussed in our study by comparing empirical data to forward-in-time simulations. Candidate loci are currently under functional survey, by producing gene knockout and allele replacement. In addition, we found that both coding and regulatory variants contribute to the phenotypic variation. To further investigate the role of non-coding *cis*-regulatory mutations and explore the nature of gene regulatory networks involved in this adaptation, we collected samples during infection of wheat isolines in presence or absence of the resistance gene in the laboratory. Gene expression measurements using 3'sequencing is currently ongoing.

Altogether, our results demonstrates the high complexity of this ecologically relevant and recent adaptation still ongoing in the field.

987S **The effect of Neanderthal introgression on human complex traits** Leqi Tian, David Lu, April Wei Cornell University

Early modern humans interbred with Neanderthals after migrating out of Africa approximately 50,000 years ago, resulting in around 1-4% of the genomes of present-day non-African descendants being derived from Neanderthals. Recent studies have shown that the remaining introgressed variants in present-day humans generally exhibit reduced phenotypic effects and per-SNP trait heritability compared to variants originated in humans, but the evolutionary models to explain the reduction remain elusive. Previous evolutionary studies of Neanderthal introgression have focused on purifying selection against deleterious mutations by modeling direct fitness costs; this approach does not provide much insight into how Neanderthal introgression influences human complex traits. Here, we examine Neanderthal introgression through the lens of complex trait evolution to gain a more comprehensive understanding of this process. We implement a forward-in-time simulation model that is specifically designed for the evolutionary history of introgression and complex traits evolution which incorporates a human exon annotation map from the UCSC Genome Browser and the deCODE recombination map. Tree-sequence format is used to encode the whole-genome data during simulations, which allows us to quantify the impact of introgression on the phenotypes of modern humans as well as the distribution of Neanderthal ancestry across the entire genome accurately and efficiently. A vast parameter space encompassing polygenicity, the distribution of effect sizes, and modes of selection on phenotypes is simulated to investigate more realistic models for explaining the observed data. We are also testing whether stabilizing or directional selection could better explain the distribution of Neanderthal ancestry in human genomes and the reduced influence of the remaining introgressed variants on human complex traits. These results will provide new insights into the impact of Neanderthal introgression on human complex traits evolution.

988S **A novel method for computing population summary statistics** Ziqing Pan[1], Drew DeHaas[2], April Wei[2] [1]Computational Biology, Cornell University, [2]Cornell University

Population level summary statistics, such as allele frequency, linkage disequilibrium and SNP association effect, are essential in comprehending the population history, natural selection, and disease mechanisms. Methods for computing population-level summary statistics are predominately implemented on genotype matrices, which do not take advantage of the correlation among samples or SNPs. Furthermore, the computation complexity via matrix algebra can sometimes increase quadratically with sample size or number of SNPs. As a result, existing computational frameworks often fail to afford large-scale complicated computations with large datasets. Here, we propose a novel alternative method for computing whole-genome summary statistics by leveraging a new data structure genotype representation graph (GRG) developed in our group. Like variant call format (VCF) and ancestral recombination graph (ARG), GRG can encode whole-genome polymorphism data losslessly, but it is more compact. The radical reduction in size comes from capturing the shared sample list across mutations with shared paths in the graph such that each node represents a unique subset of samples that share mutations. Given the graph representation of genomic data, we reformulate the traditional population summary statistics computation (e.g., matrix-matrix multiplication) as arithmetic along graph traversals. Leveraging the hierarchical structure, we further reduce the computational complexity by reusing the computed nodes to avoid repeated calculation. Several simple first-order summary statistics including allele frequency and association effect have been computed for the whole-genome with the novel algorithm, achieving the same order of time as the current state-of-the-art methods. Moreover, we anticipate graph traversal on GRG will promise better scalability for more complex and higher order statistics that are currently unsolvable with the traditional methods, such as genome-wide linkage disequilibrium. The GRG-based computation will open up new avenues for efficient and scalable genomic computation in the era of large biobanks.

989S **Testing for differences in polygenic scores in the presence of confounding** Jennifer Blanc, Jeremy J Berg University of Chicago

Polygenic scores have become an important tool in human evolutionary genetics, enabling the prediction of individual phenotypes from their genotypes. Understanding how the pattern of differences in polygenic score predictions across

individuals intersects with variation in ancestry can provide insights into the evolutionary forces acting on the trait in question. However, because most polygenic scores are computed using effect estimates from population samples, they are susceptible to confounding by both genetic and environmental effects that are correlated with ancestry. The extent to which this confounding drives patterns in the distribution of polygenic scores depends on patterns of population structure in both the original estimation panel and in the prediction panel. Here, we use theory from population and statistical genetics, together with simulations, to study the procedure of testing for an association between polygenic scores and axes of ancestry variation in the presence of confounding. We use a general model of genetic relatedness to describe how confounding in the estimation panel biases the distribution of polygenic scores in a way that depends on the degree of overlap in population structure between panels. Using the understanding gained from this analysis, we develop a method that leverages the patterns of genetic similarity between the two panels to guard against these biases, and show that this method can provide better protection against confounding than the standard PCA-based approach in certain situations. We then use the UK Biobank to further test our approach and explore how various parameters, such as sample size and number of loci, impact both PCA and our procedure. Finally, we apply our approach to re-analyze several cases of reported polygenic selection in humans utilizing state-of-art GWAS and polygenic score construction methods that maximize the predictive power of the polygenic score while controlling for stratification bias.

990S **QTL-mapping using the ancestral recombination graph** Vivian Link, Charleston W. K. Chiang, Nicholas Mancuso, Michael D. Edge University of Southern California

Understanding the genetic basis of complex phenotypes is a central pursuit of human medical genetics. Our recent method finds associations between phenotypes and genetic loci by using the Ancestral Recombination Graph (ARG). The ARG encodes the evolutionary history of all individuals in a sample, and can be seen as a series of marginal coalescent trees. Conditioned on the ARG, we calculate local expectations of the Genetic Relatedness Matrix (eGRM), which we test for association in a variance components framework using Restricted Maximization Likelihood (REML).

Our simulation results show that the eGRM efficiently captures untyped variation and that our method is especially beneficial for phenotypes with multiple causal alleles in the same locus (allelic heterogeneity). However, our method does not scale well to sample sizes that are larger than a few thousand individuals. Here, we present strategies for making our method faster, including approximating the eGRM and approximating the REML algorithm. We further assess how the approximations affect our power to find associations.

991S **Muskox genetics: How does genotype affect complex wool fiber phenotypes?** Dominique N Wagner[1,2], Victor N Roman[1,2], Evon Delisle[1], Clayton N Allex-Buckner[1,2], Amber N Braddock[1,2], Sanaz N Farajollahi[1,2], Patrick B Dennis[1], Blake W Stamps[1], Heather J Huson[3], Nancy Kelley-Loughnane[1] [1]Biomaterials Branch, Air Force Research Laboratory, [2]Biological and Nanoscale Materials, Eqlipse Technologies, [3]College of Agriculture and Life Sciences, Cornell University

Understanding the link between genotype and phenotype is critical for the understanding of any trait. However, this link becomes increasingly difficult to discern with complex traits, which often involve dozens or hundreds of genes. Muskox (*Ovibos moschatus*) wool, known as qiviut, is hypothesized to have greater thermal insulative properties than other natural or synthetic fibers. However, due to the relatively low number of commercial producers and low individual fiber yield (usually <4kg/year), availability of qiviut is extremely limited. As such, there is significant interest in understanding the genetic basis for fiber quality and yield, with the eventual goal of increasing production and integrating fiber assembly into a synthetic biological framework. To understand the link between genotype and the complex qiviut fiber phenotype and materials chemistry of muskox keratin proteins, we generated a reference genome and performed whole genome sequencing on 20 individuals collected from The Musk Ox Farm (Palmer, AK) with a range of wool fiber quality and production quantity. We performed a genome-wide association study to identify single nucleotide polymorphisms (SNPs) that are significantly associated with both fiber quality and yield. To address the likelihood that multiple genes/SNPs contribute to these complex phenotypes, we also performed a random forest analysis that identified which ensemble set of genomic features is most likely to contribute to the phenotypes of interest. These analyses will help us understand which genomic features are likely to be important to qiviut fiber quality and production, and will advance our ability to integrate the portions of the biological fiber production mechanism into a synthetic framework.

992S **Experimental evolution of mating system in M. guttatus** Sharif Tusuubira, John Kelly KU

We apply experimental evolution to Mimulus guttatus (yellow monkeyflower) to replicate populations in three different treatments: fully outcrossing, mixed mating, and fully selfing. Replicate populations were allowed to evolve in response to selection pressures imposed by their respective mating system treatments for 10 generations. We then grew seed from the ancestral population alongside the final generation of each experimental population to measure trait divergence. We show

that allele frequency changes at QTLs and changes in overall homozygosity (an immediate affect of mating system differences) are both responsible for differing trait means among populations. Distinguishing these causes, we find that numerous traits responded to selection to increase the efficiency of self-fertilization whenever it was a major component of reproductive success. Whole genome sequencing applied to the evolved populations reveals a signature of selection on individual loci as well as the broad effects of mating system differences on molecular evolution via linked selection.

993S **The genetic architecture of adherence in a clinical isolate of the budding yeast *Saccharomyces cerevisiae*** Hita Yalla[1], Atari Abundo[1], Brendan Woodworth[1], Helen Murphy[2] [1]Biology, William & Mary, [2]William and Mary

Biofilms are communities of microbes that have enhanced resistance to environmental stressors. They are characterized by an extracellular matrix, attachment to a surface, and cell-to-cell adherence. Biofilms can pose a threat in medical settings due to the challenges of eradicating them. Some *Saccharomyces cerevisiae* strains isolated from natural and clinical environments are able to form biofilms when induced in nutrient limiting conditions. We investigated the genetic architecture of adherence to a plastic surface, the first step in biofilm formation, in a highly heterozygous clinical isolate that contained ~40,000 SNPs when originally isolated. The fluorescent protein mCherry was incorporated into the genome, which allowed for a high-throughput fluorescence-based assay to measure adherence in an F_5 mapping population. Using bulk segregant analysis (BSA-seq) on pools of highly adherent and non-adherent segregants, we found 5 major loci that contribute to variation in plastic adherence. Of particular interest was natural allelic variation in *TPK2*, one of the catalytic subunits of PKA. Allele replacement in a highly-adherent segregant verified the role of a single SNP contributing significant variation to plastic adherence. These findings suggest that allelic variation that effects cAMP-PKA signaling is a major source of variation in plastic adherence, as it is for other filamentous phenotypes, such as invasive growth and biofilm colony formation in yeast. Our results also suggest that environmental isolates harbor genetic variation in major signaling pathways that can contribute to pathogenic and virulence traits.

994S **(co)Evolution of GAPDH genes following duplication in yeast** Mohammad Siddiq[1,1], Nick Brown[2], Hannah Kania[3], Patricia Wittkopp[4] [1]Ecology and Evolutionary Biology & Molecular, Cellular, and Developmental Biology, University of Michigan, [2]University of Pennsylvania, [3]Duke University, [4]Department of Ecology and Evolutionary Biology, University of Michigan

Evolutionarily related copies of genes formed from historical duplication events, called paralogs, are present in almost all known genomes. Paralogs are initially redundant in function following gene duplication, and this redundancy enables them to evolve and functionally diversify in ways that were previously inaccessible. Despite this diversification, proteins encoded by paralogous genes often retain the capacity to carry out some common ancestral functions. Whether this functional overlap plays a role in the subsequent evolution of paralogs is not well understood. We investigated how three paralogous genes that encode *GAPDH*s in *Saccharomyces cerevisiae—TDH1*, *TDH2*, and *TDH3*—diversified during historical evolution and evaluated whether these genes exert coevolutionary pressures on each other in the present day. We found that the paralogous *TDH* genes have evolved to contribute differently to growth, and that this divergence is largely explained by evolved differences in the genes' cis-regulatory sequences. Further, our results suggest that the conserved ancestral capacity of all *TDH* genes to provide *GAPDH* activity continues to intertwine their evolutionary fates such that the evolution of variation at one gene is contingent on the level of activity being provided by others. The propensity of evolutionarily related genes to retain functional overlap and coevolve may enable the net output of a metabolic step to be maintained by stabilizing selection while the relative contributions of the underlying genes change. This phenomenon, akin to observations in developmental pathways, may allow the architecture of metabolic steps to drift over time and provide a simple explanation for why similar metabolic reactions are carried out in different ways across evolution.

995S **Investigating the Evolution of Duplicated Genes Using Conditional Complex Genetic Interaction Analysis** Brittany M. Greco, Rohan Dandage, Soyeon Cho, Elena Kuzmin Biology, Concordia University

Whole-genome duplication (WGD) events have played a pivotal role in shaping the genomes of organisms across the tree of life. *Saccharomyces cerevisiae* underwent WGD approximately 100 million years ago which corresponds to the time of the emergence of angiosperms (and their fruit) and has since retained around 18% of its paralogs. The factors influencing the retention and functional evolution of specific duplicates remain poorly understood. In this study, we use a systematic analysis of conditional complex genetic interactions to unravel the impact of metabolic changes in the environment on the retention of paralogs resulting from the WGD event. We quantitatively scored the fitness of 79 double and corresponding 158 single gene deletion mutants of WGD paralogs, which have previously shown to exhibit sparse digenic and trigenic interaction profiles under standard growth conditions, across a range of metabolic environmental conditions comprising nine carbon and five nitrogen sources for a total of 45 carbon-nitrogen combinations. We have also considered alternative metabolic conditions that simulate the emergence of fruity plants which have been shown to illicit a phenotypic response in our

paralogs of interests. Conditions which led to a growth defect of the most mutant strains contained monosodium glutamate combined with either raffinose or sucrose, proline with ribose, urea with glucose and allantoin with fructose, while urea with ribose affected the least. Each paralog pair showed a growth defect in at least one condition. By mapping conditional trigenic interactions of WGD paralogs, we aim to measure their degree of functional divergence and redundancy and reveal their functional roles. This study will provide insight into the evolutionary forces that shape genomes.

996S **Fine-mapping causal polymorphisms underlying differential protein expression in *Saccharomyces cerevisiae*** Minh Phan[1], Maggie Barry[2], Winter A Yi[1], Daniel Pollard[1] [1]Biology, Western Washington University, [2]University of Oregon

The central dogma outlines the flow of genetic information from DNA to mRNA to protein, underscoring the influence of genetic variation on observable traits in organisms. Genetic variants can exert their effect on observable phenotypes by changing the function, localization, and importantly, abundance of mRNA and protein. Previous research largely focused on mRNA abundance and used it as a proxy for protein abundance. However, there are processes independent of mRNA abundance like protein synthesis and degradation can have significant effects on protein abundance. Thus, how genetic variation affects protein abundance and the molecular mechanisms underlying this process presents itself as an under-explored yet crucial aspect in the story of gene expression.

To answer this question, a dynamic system will be modeled with the eukaryotic organism *Saccharomyces cerevisiae* (baker's yeast) and its easily inducible mating pheromone response pathway. To decode the genetic basis of trait variation, a key step is to identify the genetic variants associated with the phenotypic trait. While the current bulk segregant analysis (BSA) method efficiently maps causal quantitative trait loci (QTLs), there has yet to be a method to fine-map the specific single nucleotide polymorphism (SNP) within QTLs responsible for phenotypic traits. Our project aims to address this gap with a novel fine-mapping method that integrates BSA with a recombination selection scheme. Iterative selections for recombinants with specific marker combinations will ensure that genetic recombination has occurred between each SNP, overcoming the resolution limitation of the classic BSA QTL mapping method and facilitating the identification of individual causal SNPs. This fine-mapping method will be developed using the case study of a two-gene, CAM1 and DIG1, locus that has been previously shown to be a trans-acting QTL affecting the protein expression of the pheromone-responsive gene, FIG1. An efficient, high-throughput fine-mapping method will further bridge the gap between genetic variation and protein expression and potentially uncover molecular mechanisms underlying this process.

997T ***egg-7,* an ortholog of human phosphoglucomutase 3 is required for fertility in *C. elegans*** Katherine Maniates[1], Kendall Flanagan[2], Andrew Singson[2] [1]Rutgers University, [2]Waksman Institute, Rutgers University

Fertilization and the activation of gametes are precise events that require cell-cell adhesion, binding, fusion, signaling, and recognition. Despite the importance of fertilization for all sexually reproducing organisms, many of the genes and molecules involved in generating the fertilization synapse are still unknown. In particular, many fewer genes and molecules on the egg have been identified as being involved in fertilization. The asymmetry between known sperm and egg components required for fertilization is seen across many organisms including mice, flies, worms, and fish. Identification of these genes required in the egg for fertilization has been challenging due to both biological and technical reasons, among these reasons are redundancy, pleiotropy, and the complexity of these processes. Many of these challenges are not unique to identifying genes involved in fertilization, but also in any field that encounters sterile or lethal mutant phenotypes.

We have developed a forward genetic screening approach using recently developed balancer chromosomes to identify new genes required for fertilization. The benefits of this screen include generating stable balanced lines of candidate mutations that are sterile or lethal following EMS Mutagenesis for further analysis. This approach will be valuable for researchers across fields that are searching for sterile or lethal mutants. Preliminary rounds of this screen have identified many candidate mutations. One mutant that we identified is a premature stop codon in F21D5.1, now called *egg-7,* an ortholog of mammalian phosphoglucomutase 3 (PGM3). PGM3 is an enzyme involved in glycosylation and synthesis of GPI anchors. Mutants in this gene are egg-specific sterile, hermaphrodite animals have normal morphology and germline development. However, these mutants are sterile, and fertility is unable to be recovered after mating with males. EGG-7 is localized in the oogenic germline and early embryos. We hypothesize that *egg-7* is required for glycosylation and synthesis of GPI anchor proteins on the oocyte's surface for fertilization.

998T **Investigating the role of optimal apoptosis levels in maintaining progeny fitness and fertility under temperature stress** Kristen Quaglia, Hannah N Lorenzen, Samantha H Oswald, Lisa N Petrella Marquette University

As surface temperatures rise due to global warming, organisms from rice to flies to nematodes face extinction solely due to the inherent temperature sensitivity of fertility. We investigated how germline apoptosis may be a mechanism that can preserve fertility under temperature stress. In the pioneer species *C. elegans*, we use both genetically diverse wildtype strains

and mutants that affect the level of apoptosis to investigate this question. Under non-stress conditions, approximately 50% of oogenic nuclei in the germline undergo apoptosis to remove low-quality nuclei and/or to supply more cytoplasm to remaining oocytes in the N2 wildtype strain. It has been shown that as temperature increases and fertility decreases, apoptosis in the germline increases over baseline levels. To understand how progeny fitness and fertility may be impacted by apoptosis, we are investigating how the level of apoptosis correlates with fertility and progeny fitness measured by oocyte size and embryonic lethality. We found that genetically diverse wildtype strains showed a range in levels of apoptosis, fertility, and progeny fitness metrics at elevated temperature, but that the rate of apoptosis did not directly correlate with the level of fertility or progeny fitness. However, all strains were able to increase apoptosis during temperature stress, suggesting that it may be the ability to change apoptosis levels that is important. Therefore, we tested fertility and progeny fitness traits in mutants that had no apoptosis or elevated levels of apoptosis under non-stress conditions. We found that mutants with no apoptosis had lower fertility, smaller oocytes, and higher embryo lethality at all temperatures compared to the N2 wild type. We also found that mutants with high apoptosis had lower fertility, smaller oocytes, and higher embryo lethality than N2 wild type at higher temperatures, but the same as N2 wild type at non-stress temperatures. Our results indicated that there may be an optimal range of apoptosis in the *C. elegans* germline. Both no apoptosis, and high apoptosis lower fertility and progeny fitness at elevated temperatures compared to most wild strains. Apoptosis within an optimal range may function under a moderate temperature stress to maintain fertility and ensure fit progeny.

999T **The role of SPE-21, a palmitoyltransferase in sperm activation.** Saai Anugraha Tiruchendurai Suryanarayanan, Amber Krauchunas, Dawn Chen, Andrew Singson Rutgers, The State University of New Jersey

Spermatids undergo post-meiotic differentiation to gain polarity, become motile and fertilization competent. In *C. elegans*, this process, also known as sperm activation, transforms round spermatids to motile, amoeboidal spermatozoa. These spermatozoa have pseudopods that help them crawl to the oocytes. Additionally, during sperm activation, Golgi-derived vesicles called membranous organelles (MOs) fuse with sperm plasma membrane and release their contents to the membrane and extracellularly. This process is analogous to mammalian acrosomal reaction. Using forward genetics, we identified a mutation in s*pe-21* also designated as *dhhc-5*, *spe-21(as41ts)*. We also generated a genetic null, *dhhc-5(syb4299)*, using CRISPR. *spe-21* is on chromosome III, and it encodes a palmitoyl acyltransferase (PATs). This is only the second identified mutation of the 15 predicted PAT encoding genes in *C. elegans*. We observed the following phenotypes in the *spe-21* mutant worms: Both *spe-21* mutant hermaphrodites and males are sterile. Their sperm fail to activate *in-vitro* and *in-vivo* and do not produce pseudopods. SPE-21 localizes to the MOs. Using split-ubiquitin membrane yeast -2-hybrid, we have data suggesting potential interactions of SPE-21 with other proteins involved in spermatogenesis, sperm activation and fertilization. Our discovery will be pivotal in underscoring the importance of palmitoylating enzymes in making fertilization competent sperm in *C. elegans* and other species.

1000T **SPE-13 is a sperm membrane protein involved in the fertilization synapse complex function during fertilization in C. elegans** Yamei Zuo[1], Amber Krauchunas[2], Andrew Singson[1] [1]Rutgers University, [2]University of Delaware

Fertilization is a process where two gametes recognize and fuse to form a zygote that would later develop into an embryo. However, the underlying genetic mechanisms for fertilization are still not well understood in all species. spe-13 has been identified as a “spe-9 class” gene that contributes to the fertilization process in C. elegans. Mutations in this gene class cause animals to produce sperm with normal morphology and motility that cannot fertilize wild-type oocytes after contacting oocytes in the spermatheca. Loss of function spe-13 mutant hermaphrodites are sterile, and their fertility can be rescued by N2 males, suggesting that spe-13 is required in the sperm during fertilization. Like all spe-9 family mutants, spe-13 mutants undergo normal spermatogenesis and spermiogenesis (sperm activation). Mutants’ sperm accumulate in the spermatheca, yet still fail to fertilize the oocytes. To determine the spe-13’s gene sequence, we recently cloned spe-13 using Whole Genome Sequencing and found out that spe-13 is R06A10.5. SPE-13 is a small protein containing 130 amino acids with a predicted transmembrane domain and a large cytoplasmic tail. Our gene expression data showed that SPE-13 is exclusively expressed in sperm, indicating that SPE-13 is likely located on the sperm membrane required for fertilization. Through CRISPR/Cas9, we generated SPE-13-GFP strain to visualize the subcellular localization of SPE-13. Our finding confirmed our hypothesis that SPE-13 localizes to the cell membrane in the activated spermatozoa. Furthermore, by using a membranous organelles (MO) marker SPE-38, we conclude that SPE-13 localizes to the MOs in the spermatids. Finally, we found that for SPE-13 to correctly localize to the MOs in the spermatids and cell membrane in the spermatozoa, four other spe-9 class genes, spe-45, spe-9, spe-36, and spe-38, are required for these two separate steps, with spe-45 being required for the first step and the rest being required for the second step. Together, our results lead to the findings that SPE-13 is located on the sperm surface, playing a role in building the fertilization synapse complex on the sperm membrane for successful fertilization. In conclusion, our work identifies an additional component in the fertilization synapse in C. elegans and helps us better understand the complexity of the fertilization synapse. Similarly, small proteins have been identified in other species playing an essential role during fertilization, such as FIMP in mammals and Bouncer in zebrafish. Therefore, studying SPE-13 could also shed light on the roles

small proteins may play during fertilization.

1001T **The role of NUC-1 in apoptotic cell corpse clearance** Jonathan Pickett, Niccole Auld, Lathan Lucas, Omar Peña-Ramos, Xianghua Liu, Zheng Zhou Baylor College of Medicine

Approximately 300 billion cells die and need to be replaced in our bodies, daily. Degrading such vast amounts of cellular content, in addition to foreign material such as that of bacteria, requires the coordinated activity of specialized enzymes and subcellular compartments. One of the most important enzymes in this process, Deoxyribonuclease-2 (DNAse-2), is also responsible for preventing unnecessary immune responses to DNA. *nuc-1* is the *Caenorhabditis elegans* (*C. elegans*) gene that encodes the DNAse-2 enzyme. NUC-1 is primarily localized to lysosomes where the acidic environment allows this enzyme to function at its peak efficiency. We have developed a time-lapse imaging-based assay for monitoring the degradation of apoptotic cell corpse DNA in *C. elegans* embryos. Here, we show that NUC-1 acts in engulfing cell phagolysosomes to degrade apoptotic cell corpse DNA. The engulfment of apoptotic cells and lysosomal fusion to phagosomes, but not NUC-1 activity prior to engulfment, is necessary for NUC-1-mediated apoptotic cell corpse DNA degradation.

1002T **VAB-3/PAX6 regulates gonad morphogenesis in *C. elegans*** Victor Stolzenbach[1], Priti Agarwal[2], Ronen Zaidel-Bar[2], Erin Cram[1] [1]Biology, Northeastern University, [2]Cell and Developmental Biology, Tel Aviv University

The *C. elegans* gonad and distal tip cell (DTC) is a well characterized model of migration driven organogenesis. As the organ develops the DTC guides the proliferating germ cells pushing from behind as it elongates away from the body center along the ventral side, performs a 180 degree turn, and continues to elongate toward the body center along the dorsal side before finally becoming immobile as the organ takes its final shape. To better understand the genes involved in the latter part of this process, specifically the cessation of migration, a novel RNA-seq dataset was generated from DTC's isolated at L4 and early adult stages. Analysis of this data identified *vab-3*, an ortholog of the human PAX6, as a highly expressed gene in the L4 phase. Inhibition of *vab-3* via RNAi causes the gonad to continue to elongate well into adulthood resulting in a variety of swirl-like phenotypes. The cascade by which *vab-3* causes this to occur is unknown. Here we show that expression of *hlh-12*, a bHLH type transcription factor crucial for proper DTC migration, declines ~72 hours post egg laying. This coincides with the period of time when the DTC begins to halt migration as the organ finishes developing. In a *hlh-12* GFP model, expression of GFP is prolonged and increased significantly in *vab-3* RNAi conditions. These results suggest that *hlh-12* is central to maintaining the migratory programming of the DTC since loss of its expression correlates with cessation of migration.

1003T **Genetic evidence that the Pumilio-family proteins PUF-3 and PUF-11 repress SPN-4 translation in oocytes to prevent premature CCR4-NOT-mediated maternal RNA destabilization in *C. elegans*** Erika Tsukamoto[1], Micah Gearhart[2], Caroline Spike[2], David Greenstein[2] [1]Genetics, Cell Biology and Development, University of Minnesota, [2]University of Minnesota

Purified LIN-41-containing ribonucleoprotein complexes contain several different RNA-binding proteins, including the nearly identical and functionally redundant Pumilio-family RNA-binding proteins PUF-3 and PUF-11 (Tsukamoto et al., 2017). LIN-41 and PUF-3/11 promote the 3'UTR-mediated translational repression of the Rbfox-related RNA-binding protein SPN-4 in oocytes (Hubstenberger et al., 2012; Tsukamoto et al., 2017). Interestingly, the maternal-effect embryonic lethality caused by null mutations in *puf-3/11* is partially suppressed by mutations in *spn-4*. These observations suggest that SPN-4 over-expression in oocytes contributes to *puf-3/11* embryonic lethality. To understand the origin of *puf-3/11* maternal-effect lethality more completely, we screened 28,498 EMS-mutagenized haploid genomes for dominant suppressors of *puf-3/11* lethality and identified 24 strains in which *puf-3/11* lethality was suppressed enough to permit backcrossing. Whole genome sequencing was used to identify candidate suppressor mutants in each strain. As expected, we identified a new allele of *spn-4*; one of the strains was heterozygous for a maternal-effect-lethal allele of *spn-4* with a premature stop codon. More intriguingly, nine of the suppressed strains carried independent mutations in two different genes that encode essential subunits of the CCR4-NOT mRNA deadenylase complex: *let-711/*Not1 (8 strains) and *ccf-1/*Caf1 (1 strain). Most of these mutations were heterozygous in the suppressed strains and likely to be strong loss-of-function alleles. We have confirmed that other, independently-generated alleles of *let-711* and *ccf-1* dominantly suppress *puf-3/11* maternal-effect embryonic lethality. To test for more suppressors, we independently generated mutations in two of the other components of the CCR4-NOT complex: *ntl-2* and *ccr-4*. Our preliminary results suggest that mutations in *ccr-4* suppress *puf-3/11* maternal-effect embryonic lethality. Our current model suggests that the SPN-4 RNA-binding protein plays an important role in targeting specific mRNAs for deadenylation and decay during the oocyte-to-embryo transition. According to this model, in *puf-3/11* null mutants, SPN-4 is precociously expressed in proximal oocytes and causes premature clearance of maternal mRNAs with which it associates. We are currently trying to determine whether SPN-4 selects mRNAs for degradation by virtue of specific high-affinity RNA binding.

1004T **A Sperm–Oocyte Protein Complex as an Actin Regulator Required for Egg Activation in *Caenorhabditis elegans*** Tatsuya Tsukamoto[1], Ji Kent Kwah[2], Naomi Courtemanche[1], Andy Golden[3], David Greenstein[1], Aimee Jaramillo-

Lambert[2] [1]Department of Genetics, Cell Biology, and Development, University of Minnesota, [2]Department of Biological Sciences, University of Delaware, [3]National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health

Fertilization triggers the completion of female meiosis and launches the oocyte-to-embryo transition. *C. elegans spe-11* is one of a few paternal-effect lethal genes. We report that SPE-11 forms a protein complex with an oocyte protein, OOPS-1 (Oocyte Partner of SPE-11), and that the complex is required for many post-fertilization events, including the proper completion of meiosis, the block to polyspermy, and eggshell formation. We discovered *oops-1* as an mRNA target of the oogenic LIN-41 and OMA-1 RNA-binding proteins. Tandem affinity purification (TAP) of OOPS-1 followed by mass spectrometry identified SPE-11. Likewise, SPE-11 TAP identified OOPS-1. Expression of both proteins in *E. coli* yields a stable complex, which we purified. Consistent with this molecular interaction, we determined that *oops-1* and *spe-11* exhibit apparently identical null phenotypes—approximately half of the mutant embryos display meiotic arrest in meiosis I or meiosis II, with the spindle drifting away from the cortex; whereas the other half display a phenotype in which meiotic chromosomes segregate at anaphase I and II but fail to form polar bodies. McNally and McNally (2005) noted that *spe-11* mutant embryos exhibit similarities to embryos treated with the F-actin inhibitor Latrunculin. Thus, we tested whether the OOPS-1–SPE-11 complex modulates actin assembly. Our experiments show that the complex binds F-actin in the absence of other proteins and inhibits formin-mediated actin assembly *in vitro*. Thus, the OOPS-1–SPE-11 complex may function in part by mediating key meiotic roles of F-actin. We are currently exploring this possibility using live-cell imaging. We isolated new mutations that suppress a temperature-sensitive *spe-11* mutant at the non-permissive temperature. Analyses of these new extragenic suppressor mutations might provide information on the mechanisms by which the OOPS-1–SPE-11 complex promotes the oocyte-to-embryo transition. We replicated the result that SPE-11 promotes embryonic development when ectopically expressed in the maternal germline (Browning and Strome, 1996). This finding raises the question of why evolution has separated OOPS-1 and SPE-11 into separate gametes. A potential answer is suggested by the observation that strains expressing SPE-11 in both male and female gametes exhibit transgenerational low fertility and slow growth phenotypes, indicating a potential role in paternal epigenetic inheritance.

1005T **The role of the HSP-90 co-chaperone SUGT-1 in GLP-1/Notch signaling and germline development in *C. elegans*** Jonathan C. Bastick[1], Eleanor M. Maine[2], James Lissemore[1] [1]Biology, John Carroll University, [2]Biology, Syracuse University

Activation of the GLP-1/Notch transmembrane receptor on the surface of the germline is required for germline stem cell maintenance and a number of other functions in *C. elegans*, including oocyte development and embryonic cell fate decisions. We have shown previously that the molecular chaperone HSP-90 promotes GLP-1/Notch signaling in the germline of *C. elegans.* In other systems, it has been shown that HSP-90 requires the assistance of a number of co-chaperones to conduct its protein-folding function. *C. elegans* encodes orthologs of ~17 HSP-90 co-chaperones, raising the question of which, if any, of these co-chaperones function in the GLP-1/Notch signaling pathway. We have been investigating the possible roles of HSP-90 co-chaperones in GLP-1/Notch signaling using RNA interference (RNAi) by feeding to knockdown expression of co-chaperone genes in N2 (wildtype) and *glp-1(bn18ts)* worms. *glp-1(bn18ts)* provides a sensitized background with reduced GLP-1/Notch signaling to reveal possible genetic interactions between GLP-1/Notch and HSP-90 co-chaperones. The SUGT-1 co-chaperone, encoded by the *D1054.3* gene, plays a role in kinetochore assembly and microtubule function in other systems, but there are little data on its function in *C. elegans*, and its possible role in GLP-1/Notch signaling has not been explored.

We have examined the effect of RNAi knockdown of *D1054.3* expression in N2 and *glp-1(bn18ts)*. Specifically, we have measured brood sizes and embryonic/larval lethality and have used DIC and fluorescence microscopy (with DAPI) to examine the germlines of adult worms. With respect to brood sizes, in N2 worms *D1054.3* knockdown had a variable effect with some animals producing broods of normal size (~250-300 embryos) and others being sterile. Sterility was low penetrance, ~25%. In contrast, knockdown of *D1054.3* had a stronger effect in *glp-1(bn18ts),* with ~75% sterility and no worms producing normal size broods. DIC and fluorescence microscopy revealed that, regardless of background, reduction of SUGT-1 function caused defects in oogenesis (oocyte shape and position), spermatogenesis (uncompacted sperm), and chromosome morphology in pachytene nuclei. Furthermore, in the *glp-1(bn18ts)* background, reduction of SUGT-1 function caused, in some animals, endomitotic DNA replication in oocytes (Emo phenotype), possible polyploid embryos, and large numbers of embryos retained (Egl phenotype). Taken together, our results suggest that SUGT-1 plays important roles in germline function and in GLP-1/Notch signaling in oogenesis.

1006T **The EBAX-type Cullin-RING E3 ligase promotes Linker Cell-type Death, a conserved non-apoptotic developmental cell death program.** Lauren Bayer Horowitz, Shai Shaham Laboratory of Developmental Genetics, Rockefeller University

Programmed cell death is essential for animal development and homeostasis, and its disruption is associated with many

disorders including neurodegeneration and cancer. Apoptosis is a prominent cell death form, however mutations in key apoptotic regulators cause only minor developmental defects in vertebrates. Non-apoptotic programs also exist, but their molecular basis remains poorly understood. Linker Cell-type Death (LCD) is a conserved non-apoptotic and caspase-independent cell death program that operates in *C. elegans* development. The Ubiquitin Proteasome System (UPS) is a key effector of LCD. The heat shock factor HSF-1 activates transcription of the E2 ubiquitin-conjugating enzyme LET-70/Ube2D2, which stimulates proteasome activity and effects LCD. The proteolytic targets of the UPS during LCD, however, and how their degradation triggers linker cell demise are unknown. In a screen for additional LCD regulators, we found that the conserved E3 ligase BC-box protein, EBAX-1, is required for LCD. EBAX-1 was previously shown to function as the substrate recognition subunit of Cul-2 based E3 ligases and to promote degradation of misfolded proteins. We hypothesize that EBAX-1 functions similarly during LCD to target specific substrates for ubiquitination. EBAX-1 is expressed in the linker cell throughout its lifetime and functions cell autonomously to promote LCD. We also show that EBAX-1 acts downstream of HSF-1 and LET-70 during LCD, suggesting that EBAX-1 functions with the UPS. To identify candidate substrates that EBAX-1 targets for degradation during LCD, we screened previously identified substrates of EBAX-1 and its homologs. Intriguingly, reduced expression of either of the homologs of the human argonaute AGO2, *alg-1* or *alg-2*, is sufficient to restore cell death to *ebax-1* mutant linker cells. Thus, ALG-1 and ALG-2 may be targeted for ubiquitination to promote LCD. In contrast to apoptosis where caspase effectors only transiently bind their targets, UPS E3 proteins can stably interact with substrates, providing an opportunity to identify the key cellular processes that are dismantled during cell death. The mechanisms we discover may, therefore, unearth general mechanisms of cellular destruction that also function during apoptosis and in disease.

1007T **Role of Dicer methylation during oocyte-to-embryo transition in *C. elegans*** Nick Newkirk[1], Shin-Yu Chen[2], Ryan Bell[3], Hongyuan Li[4], Mark Bedford[5], Andrew Z Fire[6], Swathi Arur[4] [1]MD Anderson UTHealth Graduate School of Biomedical Sciences, [2]Department of Genetics, MD Anderson, [3]Stanford University, [4]Department of Genetics, MD Anderson Cancer Center, [5]Department of Epigenetics and Molecular Carcinogenesis, MD Anderson Cancer Center, [6]Department of Genetics and Pathology, Stanford University

Dicer, a small RNA processing protein, is critical for regulation of gene expression. Misregulation of Dicer results in various diseases, infertility and developmental defects. Complete loss of Dicer, in worms and mice, while pleiotropic, results in failed oocyte formation and complete sterility. Due to its critical role in fertility and development, Dicer's activity is tightly controlled through post-translational modifications. While performing mass spectrometric analysis of human Dicer proteins, we identified a novel Arginine methylation site in the helicase domain of Dicer. *In vitro* methylation confirmed that this Arginine methylation is conserved from human to *C. elegans* Dicer. The goal of this study is to determine the effect of Dicer methylation, *in vivo*, using the model organism *C. elegans,* with a focus on its role in development and fertility. Using the combination of CRISPR mediated edits, live imaging, and biochemical analysis, we identify a specific role for Dicer methylation in completion of anaphase I of meiosis I during the oocyte-to-embryo transition. Defects in this process result in non-viable embryos rather than developing zygotes. Ongoing work to define the small RNA populations affected by this modification, and its methyl domain reader, will help define the molecular mechanism through which methylation of Dicer, on a conserved Arginine residue, regulates oocyte-to-embryo transition.

1008T **PP1cβ associated with two myosin phosphatase-targeting subunits protects against rupture during embryo elongation** Neha Varshney[1], Rebecca Green[1], Sindy Chavez[1], Pablo Lara-Gonzalez[2], Karen Oegema[1,3], Arshad Desai[1,3] [1]Department of Cell & Developmental Biology, University of California, San Diego, [2]Department of Developmental and Cell Biology, University of California, Irvine, [3]Department of Cellular and Molecular Medicine, University of California, San Diego

Protein phosphatase 1 (PP1) dephosphorylates a diverse set of biological targets to regulate several essential cellular processes in cells and tissues. The mechanisms that regulate PP1 specificity for different targets at distinct times and spatial locations is an active area of research. Here, we investigate the regulation of PP1 during embryonic development of *C. elegans*, when two catalytic isoforms, PP1cβ^{GSP-1} and PP1cα^{GSP-2}, are active. These two isoforms are ~90% identical, are expressed at similar levels, and function redundantly during early embryonic divisions. Double depletion of both isoforms leads to severe defects in the one-cell embryo. Despite redundant function in early embryonic divisions, depletion of PP1cβ^{GSP-1}, but not PP1cα^{GSP-2}, results in embryonic lethality, indicating that PP1cβ^{GSP-1} performs specific essential functions during the later stages of embryonic development that cannot be compensated for by PP1cα^{GSP-2}. Using a high-content imaging approach, we show that PP1cβ^{GSP-1} is essential for proper head enclosure and elongation during development. To investigate if PP1cβ^{GSP-1}-specific target subunits are also required for embryonic development, we screened candidate subunits from the myosin phosphatase (MYPT) family. Depletion of the myosin phosphatase targeting subunit 1 (MYPT1) homolog, MEL-11, phenocopied the effect of PP1cβ^{GSP-1} depletion. Surprisingly, knockdown of the *C. elegans* MYPT3 homolog GFI-2 also resulted in a similar, albeit less penetrant, rupture phenotype. Yeast 2-hybrid analysis indicates that MEL-11 and GFI-2 interact preferentially

with PP1cβ^{GSP-1} over PP1cα^{GSP-2}. To address which tissue and developmental processes require PP1cβ^{GSP-1}-MYPT activity, we are developing the means for inducible and efficient degradation in the skin, intestine, and body wall muscle. In addition to revealing how a specific PP1c isoform contributes to a key morphogenetic event during embryonic development, these efforts have the potential to provide mechanistic insight into the origins of a rare human congenital disease, Noonan-like syndrome, which is associated with mutations in PP1cβ.

1009T **Understanding the roles of a sperm-oocyte protein complex (SPE-11-OOPS-1) in *C. elegans* egg activation** Ji Kent Kwah[1], Tatsuya Tsukamoto[2], David Greenstein[2], Andy Golden[3], Aimee Jaramillo-Lambert[1] [1]University of Delaware, [2]University of Minnesota, [3]National Institutes of Health

The cornerstone of sexual reproduction is fertilization, where one sperm and one oocyte fuse, triggering embryonic development. In many animals, the sperm provides a haploid genome, a pair of centrioles for the first mitotic division, and the signal for egg activation. Mutants lacking these factors are known as paternal-effect embryonic lethal (PEL). In *C. elegans*, *spe-11* is the only known strictly PEL gene. Oocytes fertilized by sperm lacking SPE-11 have defects in egg activation and the egg-to-embryo transition resulting in embryonic lethality. The mechanism of SPE-11 in egg activation remains elusive. We identified a gene encoding an interacting partner of SPE-11 that is expressed in the oocyte; *oops-1* (oocyte partner of SPE-11). We found that OOPS-1 is localized to the cortex of oocytes. Characterization of a whole open reading frame (ORF) deletion mutant of *oops-1* [*oops-1(tn1898Δ)*] showed that, similar to *spe-11* mutants, *oops-1(tn1898Δ)* produces a severely reduced number of viable progeny. We imaged oocyte meiosis *in vivo* in wild-type, *spe-11(hc90)* [W191Stop], and *oops-1(tn1898Δ)* strains. Similar to previously published data, the chromosomes of *spe-11(hc90)* mutant embryos segregate at anaphase I and II but fail to form polar bodies. However, *oops-1(tn1898Δ)* mutants show various meiotic phenotypes with approximately half arresting at either meiosis I or II and the remaining mutant embryos displaying a *spe-11*-like phenotype. Like the *spe-11* mutants, polar body formation of the *oops-1* mutant is disrupted in examples that exit meiosis I. As previous genetic results suggested that *spe-11(hc90)* is a hypomorphic allele, we also analyzed *spe-11(tn2059Δ)* whole ORF deletion null mutants and found *spe-11(tn2059Δ)* had meiotic defects similar to *oops-1(tn1898Δ)* null mutants. In addition to meiosis, we are investigating the role of SPE-11 and OOPS-1 in the formation of the eggshell, which is essential for prevention of polyspermy and embryonic development. Both *spe-11(hc90)* and *oops-1(tn1898Δ)* mutants display similar defects in eggshell integrity. We found that *oops-1(tn1898Δ)* have defects in chitin formation similar to previous work in the *spe-11(hc90)* mutant. Analysis of strains harboring fluorescently labeled proteins involved in chitin layer formation in the eggshell (CBD-1 and CHS-1) and the egg-to-embryo transition (MBK-2), shows that the localization and expression of these proteins remain unchanged. Thus, the source of the eggshell defects when OOPS-1 and SPE-11 are compromised is still under investigation.

1010T **A sensory cilium mediates specific neuron-glia attachment** Leland Wexler[1], Max Heiman[2] [1]Genetics, Boston Childrens Hospital, [2]Harvard Medical School

Glial cells form specialized attachments with specific neuronal partners, but how such precise cell-cell pairings occur remains unknown. Here, we show that a sensory cilium mediates the highly stereotyped attachment of a single *C. elegans* neuron, called URX, to its partner glial cell, called ILso. The URX neuron offers a remarkable example of specificity in neuron-glia pairing. Its dendrite is positioned in the dorsal sensory bundle of the head and makes a “jump” across the nose tip to attach to a specific glial partner (ILso) in the lateral sensory bundle. Although 36 different glial endings are present at the nose tip, the URX dendrite recognizes and makes exclusive stereotyped attachments to the lateral ILso glial cell. We found that this specific neuron-glia pairing occurs by a multistep process. First, in early embryos, the URX dendrite anchors to a different glial guidepost, via the adhesion protein SAX-7 and the scaffolding protein GRDN-1, such that the dendrite is stretched out to its full length during embryo elongation. Mutants that disrupt dendrite anchoring result in severely shortened URX dendrites that fail to reach the nose tip. Second, in late embryos, we find that the URX dendrite ending jumps across the nose to form its mature attachment to the ILso glial cell. Using three-color imaging of URX, a cilia marker, and the ILso glial cell, we find that this attachment is mediated by a sensory cilium. By examining mutants that cannot form cilia, we find that the URX dendrite fails to attach to the lateral ILso glia, showing that the sensory cilium is strictly required for this neuron-glia attachment. Through a candidate screen we found that the loss of the conserved SPARC family protein TEST-1 results in the sensory cilium failing to attach to the glial partner. Importantly, vertebrate SPARC family proteins are secreted by glia and regulate adhesion at synapses, suggesting cilia-glia pairing may resemble pairing of dendritic spines and glia at vertebrate synapses. Finally, we used an unbiased forward genetic screen for mutants with defects in URX-ILso attachment and isolated several mutants that severely disrupt cilia-glia attachment. Together, our results show that, in addition to their canonical role in sensory signaling, cilia can mediate cell-cell adhesion including in the context of specific neuron-glia pairing.

1011T **The genetic interaction between *unc-33* and *hmp-2* in embryonic epidermal morphogenesis of *Caenorhabditis elegans*** Grace Gottschamer, Stephanie Maiden Biology, Truman State University

The embryonic epidermis in *Caenorhabditis elegans* is a simple genetic model to understand epithelial cell structure and

movement during development. Epidermal morphogenesis involves the intercalation of the dorsal-most cells, epiboly of ventrally-migrating cells, and epidermal elongation. These processes require the cadherin/catenin complex, specifically HMR-1/cadherin, HMP-2/β-catenin, and HMP-1/α-catenin proteins, to maintain cell-cell contacts and tissue integrity. In epidermal enclosure and elongation, α-catenin binds to actin, strengthening cell adhesions. Through drug treatments with microfilament and microtubule inhibitors, actin and microtubules have both been shown to be required for epidermal morphogenesis. More research has been conducted on the role of actin and its binding proteins than on microtubule binding proteins in epidermal morphogenesis. The *unc-33* gene encodes a microtubule regulator known for its role in neuronal development. Mutations in *unc-33* cause an abundance of microtubules and irregular axon outgrowth, which results in uncoordinated animal movement. We previously showed that knockdown of *hmp-2*/β-catenin by feeding RNA interference (RNAi) in homozygous *unc-33(e204)* animals results in 65.3% of embryos that failed to hatch compared to 17.9% in wildtype animals. Using differential interference contrast microscopy, we found that feeding *hmp-2(RNAi)* resulted in 100% of wildtype and 80% of homozygous *unc-33(e204)* embryos developing a humpback phenotype, and 0% of wildtype and 60% of homozygous *unc-33(e204)* embryos with rupturing of internal cells between ventral enclosure and two-fold body elongation. This suggests the epidermal contractions through actin tore the epidermal sheet that was not properly formed. Future experiments looking at participating microtubules and actin with fluorescent confocal microscopy would shed light on the genetic interaction between *unc-33* and *hmp-2*. The active muscle could also be putting further strain on the developing epidermis in *unc-33(e204);hmp-2(RNAi)* embryos, but this would require future analysis.

1012T **The role of phosphorylation of ZIPT-7.1 on *Caenorhabditis elegans* sperm maturation** Trace Ackley, Stephanie Maiden Biology, Truman State University

Spermatogenesis is the process by which germ line stem cells divide into haploid cells and differentiate into functional gametes. The latter portion of this process is sperm maturation, which is a rapid, multi-step pathway that leads to the motility of sperm cells. *Caenorhabditis elegans* has been used as a model organism to help understand the molecular mechanisms involved in this maturation process. *C. elegans* sperm maturation is a change in shape from a round immotile spermatid into a spermatozoa that contains a pseudopod which allows the sperm to crawl. For males, this rapid change in cell shape occurs when the seminal fluid is mixed with the spermatids during ejaculation. Although the entire process of sperm maturation has yet to be elucidated, a few steps have been determined essential for the process to occur. A large influx of zinc ions into the cytosol of the spermatid has been found to cause the formation of the pseudopod. In C. elegans, the process of moving zinc through the cell occurs through the ZIPT-7.1 transporter, which is a transmembrane protein found within membranes of certain vesicles that rapidly transport zinc ions from vesicles into the cytosol of the cell. The present project focuses on how ZIPT-7.1 may be activated via phosphorylation. Various bioinformatic tools were used to determine the possible phosphorylation sites of ZIPT-7.1. First, the protein sequence was plugged into the Net-Phos online computing system, which gives the mathematical probability of which amino acids may be phosphorylated. Then, the amino acid sequences of homologous ZIPT-7.1 proteins of mice, humans, zebra fish, and fruit flies were compared to the *C. elegans* sequence through a multiple sequence alignment tool, T-COFFEE. The amino acids with both the highest probability of phosphorylation and high conservation between homologs were chosen for targeted gene editing: Ser198Ala, Ser236Ala, Thr347Ala. Unlike serine and threonine, alanine cannot be phosphorylated. The genetic mutations in *C. elegans* will be introduced via CRISPR-Cas9 ribonucleoprotein complexes, and then sperm activation will be tested in stable lines. Thus far, control trials have indicated an 81% activation of wildtype spermatids using Pronase. If the mutated sperm do not activate as well as the wildtype, then the evidence would suggest that ZIPT-7.1 is regulated at those amino acids via phosphorylation.

1013T **Epidermal protein synthesis inhibition cell non-autonomously triggers organism-wide growth quiescence in C. elegans** Qiuxia Zhao, Rekha Rangan, Shinuo Weng, Cem Ozdemir, Elif Sarinay Cenik Molecular Biosciences, The University of Texas at Austin

Interorgan communication is crucial for multicellular organismal growth, development, and homeostasis. Here, we employed the auxin-inducible degradation system in C. elegans to temporally and spatially modulate protein translation, through depletion of essential factors (RPOA-2, GRWD-1, or TSR-2) for ribosome biogenesis. Our findings reveal that embryo-wide inhibition of ribosome biogenesis induces a reversible early larval growth quiescence, distinguished by a unique gene expression signature that is different from starvation or dauer stages. When ribosome biogenesis is inhibited in volumetrically similar tissues, including body wall muscle, epidermis, pharynx, intestine, or germ line, it results in proportionally stunted growth across the organism to different degrees. We show that specifically inhibiting ribosome biogenesis in the epidermis is sufficient to trigger an organism-wide growth quiescence. Epidermis-specific ribosome depletion leads to larval growth quiescence at the L3 stage, reduces organism-wide protein synthesis, and induces cell non-autonomous gene expression alterations. Furthermore, we find that UNC-31 and IDA-1, two dense-core vesicle (DCV) pathway components, play a significant role in epidermal ribosome biogenesis-mediated growth quiescence. Our tissue-specific knockdown experiments reveal that

the organism-wide growth quiescence induced by epidermal-specific ribosome biogenesis inhibition is suppressed by reducing unc-31 or ida-1 expression in the epidermis. Finally, we observe an overall increase in DCV puncta labeled by IDA- 1 when epidermal ribosome biogenesis is inhibited, and these puncta are present in or near epidermal cells. In conclusion, these findings suggest a novel mechanism of nutrition-independent multicellular growth coordination initiated from the epidermis tissue upon ribosome biogenesis inhibition.

1014T **SPE-54 is required for proper pseudopod shape and function in *C. elegans* sperm** Jack E Howell[1], Corinne S Vanella[2], Matthew Ragle[3], Lynn Zavada[2], Samuel Pasman[2], Zoe Johnson[3], Jordan Ward[3], Shantá Hinton[2], Diane C Shakes[2] [1]Biology, William & Mary, [2]William & Mary, [3]UC Santa Cruz

Unlike their flagella powered counterparts, nematode sperm crawl via pseudopod-based cell motility. Furthermore, in a distinct counterpart to actin-based motility systems, nematode sperm crawl via the polymerization/depolymerization dynamics of the Major Sperm Protein (MSP). Within the sperm's pseudopod, MSP assembles into non-polar filaments whose assembly dynamics are thought to be regulated by the worm's many sperm-specific phosphatases and kinases. Here we investigate the function of a non-receptor tyrosine phosphatase SPE-54, whose catalytic domain diverges from the canonical sequence. *spe-54* knockout mutants have dramatically reduced male fertility; males successfully inseminate females, but their sperm fail to migrate to the site of fertilization. Hermaphrodite self-fertility is partially impaired, with knockouts laying fewer embryos and higher numbers of unfertilized oocytes. As in wildtype males, *spe-54* males make spherical, haploid spermatids which activate to form polarized spermatozoa. During *spe-54* sperm activation, both membranous organelle (MO) fusion and MSP localization to the nascent pseudopod occur normally. However, the pseudopods of *spe-54* spermatozoa are both abnormally short and broad. Preliminary results reveal a reduction in pseudopod treadmilling rates that suggests a lowered activity of MSP depolymerization. To determine whether SPE-54's non-canonical catalytic domain impacts its phosphatase activity, we are testing eukaryotic-expressed SPE-54 for phosphatase activity. Further characterization of *spe-54* sperm motility defects and SPE-54's molecular function are ongoing

1015T **Exploring the role of SCF ubiquitin ligase in synaptonemal complex disassembly** Ailin Zhou, Yumi Kim Biology, Johns Hopkins University

Meiosis is a specialized cell division process essential for sexual reproduction. Unique to meiosis is its prolonged prophase, during which chromosomes pair and recombine with their homologous partners to ensure proper segregation. In most eukaryotes, this pairwise alignment between homologous chromosomes is mediated by a proteinaceous scaffold called the synaptonemal complex (SC). The SC forms a tripartite structure, consisting of two parallel chromosome axes and a central region that links the paired chromosomes. Our recent work identified the complete set of the SC central region components in *C. elegans*. Intriguingly, the final missing SC components are two Skp1-related proteins (SKR-1 and SKR-2), which are essential adaptors of the Skp1-Cul1-F-box (SCF) ubiquitin ligase that targets substrates for polyubiquitination-mediated protein degradation. The co-option of SKR proteins as SC subunits raises the possibility that the SC structure might protect its components from SCF-mediated polyubiquitination and subsequent degradation. However, it is unknown whether SCF targets SC proteins for proteolysis at the end of pachytene to allow its rapid disassembly. Here, we show that the levels of SC proteins are significantly reduced when they are not integrated into the SC due to the absence of one of its subunits. The stability of SC proteins is restored upon depletion of the RPN-3 subunit of the proteasome, indicating that SC proteins are subject to proteasome-mediated proteolysis when they are not part of the SC. Currently, we are investigating whether the degradation of SC proteins depends on the SCF activity and will present our latest findings.

1016T **Germline versus somatic stem cells: metabolism of distinct lineages composing the *Drosophila* ovary** Emily M Wessel[1,2], Daniela Drummond-Barbosa[1,2] [1]Genetics, University of Wisconsin- Madison, [2]Morgridge Institute for Research

Stem cells and their differentiating progeny have different metabolisms according to their distinct cellular states and functions. Few studies have examined the specific metabolic requirements along stem cell lineages in the context of whole living organisms, where complex tissues can house multiple stem cell types. In the *Drosophila* ovary, two very different stem cell lineages - derived from germline stem cells and somatic follicle stem cells - closely interact and are nutritionally regulated at various steps. Progeny of the germline stem cells undergo drastic differentiation to form a large mature oocyte while the follicle cells follow a more traditional somatic lineage. In this study, we examined the cell-autonomous requirements for fatty acid oxidation versus glycolysis in this model system using FLP/*FRT*-mediated genetic mosaic analysis. Remarkably, we found that fatty acid oxidation is not required in either germline stem cell or follicle stem cell lineages under normal conditions. By contrast, glycolysis is required for the maintenance of germline stem cells, for survival of follicle stem cells and their earliest progeny, and for the proliferation of more differentiated mitotically dividing follicle cells. Glycolysis is also required at later stages in the germline for egg chamber growth and survival, and also for normal nuclear development in both the germline and follicle cells. Surprisingly, the proliferation of germline stem cells and their early daughter cells does not require glycolysis,

suggesting an unusual metabolic state. Future studies will address the mechanistic basis for these specific requirements, and what alternative metabolic requirements are at play.

1017T **Looking for stress pathways modulated by heat stress during *Drosophila melanogaster* oogenesis** Ana Caroline Gandara[1,2], Daniela Drummond-Barbosa[1] [1]University of Wisconsin-Madison, [2]Morgridge Institute for Research

Temperature influences fertility across organisms; however, how suboptimal temperatures affect adult gametogenesis remains understudied despite the current climate crisis. We recently reported two in-depth analyses of how chronic exposure to suboptimal temperatures affects adult gametogenesis using *Drosophila melanogaster*. Male fertility was drastically reduced at 29°C (but not 18°C) due to low sperm abundance and quality. In females maintained at 18°C or 29°C, egg production was reduced (relative to 25°C control) through distinct cellular mechanisms: 29°C increased early germline cyst and vitellogenic follicle death and decreased oocyte quality, whereas 18°C slowed follicle growth. Surprisingly, germline stem cell (GSC) behavior and follicle growth were not affected in females at 29°C, raising the possibility of mechanisms partially protecting the germline. We are currently investigating the mechanisms responsible for female germline protection at 29°C using a combination of candidate and unbiased approaches. These studies will provide new insight into how temperature-dependent factors impact the female germline in a key model insect. Further, they will provide a foundation for a broader understanding of the effects of climate change on the reproduction of a wide range of species.

1018T **Innexins proteins regulate the breaking and making cell-cell interactions during collective cell migration** Guangxia Miao biological science, Florida State University

In the study of cell movement, much of the attention has been focused on observing how cells traverse from one location to another. However, there remains a substantial gap in the understanding of how cell collectives break away from their initial neighbors in the process of delamination. Even less is known about how cells make new connections upon arrival at their ultimate destination. To be concise I name this process neolamination.

I have established an *in vivo* model using the border cells in the *Drosophila* ovary to study both delamination and neolamination. Utilizing the powerful tools of *Drosophila* genetics, coupled with newly emerged optogenetics techniques and high-resolution live imaging, I have delved deep into the intricacies of collective border cell migration. In prior research, I investigated mechanisms by which border cells separate from the follicular epithelium in the process of delamination and how they make new connections upon reaching the oocyte, a process of neolamination. This research led to the identification of key stages and the regulatory genes involved in each process.

A standout discovery was the crucial role of innexins proteins, responsible for forming gap junctions between cells. These proteins facilitate the diffusion of ions and small molecules between cells. Intriguingly, we observed that during the neolamination process, innexins function in a channel-independent manner, partially through the regulation of microtubule (MT) abundance and its post-translational modifications. In this work, I will exploit our newly-developed live imaging to study the border cell MT dynamics to uncover how innexins regulate MTs. Innexins are also essential for delamination and I will compare and contrast their contributions to these two processes.

1019T **Investigating the roles of kinases and phosphatases in meiotic biorientation and spindle assembly** Madeline Terry[1], Janet Jang McKim[2], Manisha Persuad[2], Kim McKim[2] [1]Genetics, Waksman Institute of Microbiology, [2]Waksman Institute of Microbiology

During female meiotic cell division, the interactions between the kinetochores and the spindle are responsible for the correct segregation of chromosomes, independent of centrosomes. Correct genome partition relies on the chromosomes and their kinetochores establishing proper end-on attachments connected to microtubule fibers stemming from opposite spindle pole ends. The capture of spindle microtubules to kinetochores is error prone, which can lead to incorrect segregation of chromosomes. Unequal distribution of chromosomes can ultimately lead to spontaneous abortions, birth defects, and infertility. We are interested in determining the mechanisms for how kinases Aurora B, Aurora A, and Mps1 regulate error correction and end-on attachments to ensure the accurate biorientation of chromosomes during meiosis. Kinetochore subcomplex NDC80, recruited by SPC105R, is associated with the conversion of lateral to end-on attachments and is a target of Aurora B kinase during error correction. Aurora B, Mps1 and Aurora A localize to the central spindle, kinetochores and spindle poles respectively. Protein phosphatase 2A (PP2A) antagonizes the kinases and is necessary for NDC80 to establish stable end-on interactions with microtubules. How the kinases and PP2A interact to regulate biorientation, is not known. To better understand the relationship between the kinases and the shifting of attachments from lateral to end-on, we intend to confirm NDC80's ability to regulate end-on attachments through phosphomimetic and phospho-null mutants. To determine the mechanisms behind the kinases and their roles in spindle assembly, we intend to manipulate their locations by targeting the various kinases to either the spindle poles, central spindles, or the chromosomes, as well as generate knockdowns of spindle

assembly regulators. We will examine these phenotypes through confocal microscopy. We predict that NDC80 regulates end-on attachments and the kinases in three different locations are responsible for mediating correct microtube-kinetochore attachments.

1020T **The helicase activity of Me31B/DDX6 in *Drosophila* germline development** Evan Kara, Yousef Nammari, Raheem Mansoor, Deep Govani, Abraham Fielder, Brynn Nylin, Ming Gao Indiana University Northwest

Me31B (Maternally Expressed at 31B) is a putative ATP-dependent, RNA helicase essential for *Drosophila* female germline development. Our recent findings showed that mutations in Me31B's helicase domain led to female sterility in a dominant manner. However, the mechanistic role of the protein's helicase activity is not clear. In this study, we use Me31B-helicase-domain mutations (*me31B*^{E208A} and *me31B*^{DVLAAAA}) to investigate the role of the protein's helicase activity in the context of *Drosophila* germline. Previous research suggested that Me31B relies on its helicase domain to post-transcriptionally regulate germline RNA stability, translation, and decay. Therefore, we screened the two mutants for phenotypes in transcriptome (by mRNA/small RNA sequencing), proteome (by mass spectrometry), and translation of representative germline proteins (including Osk, Nos, Tral, Cup, and Me31B itself). The experiments revealed the mutants' phenotypes in oogenesis, embryogenesis, germ cell formation, protein localization, and so on. Our study indicates that Me31B's helicase activity is an integral part of Me31B protein function and plays an important role in *Drosophila* germline development.

1021T **Functional Role of Molecular Regulators in Determining Neuronal Morphology and Neurotransmitter Identity of TmY14 Subtypes in the Developing Drosophila Visual System** Maisha S Jacy, Claude Desplan, Yu-chieh D Chen Biology, New York University

The central nervous system has tremendous neurodiversity with different molecular and morphological distinct neuronal types. The molecular regulators controlling morphological features of different neuronal types remain to be elucidated. Combining a wide array of genetic toolkits and the whole brain EM connectome, the developing Drosophila visual system has been an excellent model system to address this important developmental question. Recent single-cell RNA sequencing (scRNAseq) data from the Desplan lab provides a comprehensive transcriptomic atlas for all optic lobe neurons of Drosophila throughout development. There are ~250 clusters, presumably 250 different cell types, identified by the scRNAseq analysis.

Although there are available genetics tools for target genetic manipulation in Drosophila, there is a lack of highly cell-type-specific targeting distinct cell types throughout development in the fly visual system. I firstly generated cell-type-specific split-GAL4 lines to label a transmedullatory neuronal (Tm) type throughout development: TmY14. Upon further examination of TmY14 neuronal morphology, I found two morphological subtypes with distinct lobula and brain projection patterns. I further examined the recently published EM connectome dataset and identified these two morphological subtypes of TmY14 with distinct neurotransmitter identities: one TmY14 subtype is predicted to be glutamatergic with projection to the central brain while another TmY14 subtype is predicted to be GABAergic without central brain projection. I aim to understand the molecular regulators underlying differences in the morphological and neurotransmitter differences in these two subtypes. Using the scRNAseq data, I will identify candidate genes differentially expressed in these two TmY14 subtypes and investigate their roles in regulating their morphological differences. Using the cell-specific split-GAL4 tool combining with Vglut-flp or Gad1-flp transgenes, I aim to knock down the differential expressed genes between glutamatergic and GABAergic TmY14 Cells and examine their roles in regulating subtype-specific neuronal features. The results of my project will shed light on the mechanisms underlying neuronal differentiation and allow further investigation of genetic regulation of neuronal morphological and functional features during development.

1022T **ex-vivo cultivation of Drosophila imaginal wing discs to study the mechanisms that determine whether cells live or die after radiation-induced caspase activation** Sarah I Colon, Tin Tin Su Molecular, Cellular and Developmental Biology, University of Colorado

Cells can survive after activation of apoptotic caspases, but what determines whether a cell lives or dies after caspase activation remains poorly understood. Taking advantage of a published reporter for past caspase activity (Ding et al., eLife, 2016; Sun et al., Nat Comm., 2020), we were able to visualize cells that survived caspase activation specifically after exposure to ionizing radiation in Drosophila larval wing discs. We found that cells with X-ray-induced past active caspases (XPAC) do not arise at random, but are born at specific locations within the developing imaginal wing discs of Drosophila larvae. Our data shows that the apoptotic signaling pathway is needed to induce XPAC cells as knocking down key components of the apoptotic pathway decreases XPAC number. Yet, XPAC cells appear in stereotypical patterns that do not follow the pattern of IR-induced apoptosis, suggesting additional controls at play. Functional testing identified the contribution of wingless (Drosophila Wnt1) and Ras signaling pathways to the prevalence of cells that activated caspases but did not die. To further study the influence of these two pathways in XPAC cells, ex-vivo cultivation of Drosophila imaginal wing discs has been conducted. Preliminary

data gathered shows that imaginal wing discs can remain alive in ex-vivo cultivation for 12 hours after exposure to radiation. However, tissues appear hypoxic at 12h post cultivation so further protocol optimization is needed. An ex-vivo system will allow us to test pharmacological inhibitors, such as inhibitors of Wnt and Ras signaling, and further understand how these pathways influence IR-induced caspase activity.

1023T **Investigating the role of the Ecdysone Receptor in germline to somatic cell communication** Lindsay Swain, Allison Simmons, Lauren Jung, Elizabeth Ables East Carolina University

Oogenesis requires complex coordination between both somatic and germ cell populations, relying on systemic signals such as hormones for proper oocyte production and formation. *Drosophila melanogaster* is an excellent model organism to explore how signaling from germ to somatic cells is required for viable egg production. *Drosophila* oogenesis utilizes steroid hormones such as ecdysone to facilitate many aspects of oocyte development such as germline stem cell proliferation, egg chamber growth, and border cell migration**.** Ecdysone function relies on reception by the heterodimeric complex, Ecdysone Receptor (EcR) and Ultaspiracle (Usp), that in turn activate transcriptional targets. EcR and Usp are expressed in both germline and somatic cell populations, but the role that ecdysone signaling plays in germ cells to control egg chamber development is unclear due to lack of suitable reagents to block ecdysone signaling specifically in germ cells. Here, we use novel reagents to deplete EcR levels or block transcriptional activation specifically in the germline. We find that depletion of EcR in germ cells results in a variety of somatic phenotypes. These include: an increased number of germaria with germ cell “collision” events, where cysts were not separated by follicle cells; shorter distance between cysts; and cysts with a longer aspect ratio. These phenotypes were accompanied by increased numbers of abnormal egg chambers, quantified as alterations in the number of oocytes per follicle, and slowed egg chamber growth. There was also a significant decrease in follicle cell proliferation, suggesting that EcR is needed to stimulate proliferation of overlying somatic cells. We also find that depletion of EcR in germ cells results in mild border cell migration phenotypes, such as delayed timing, cluster detachment, and altered cell number. Overall, these data suggest that in addition to its well-characterized roles in somatic follicle cells, EcR is necessary in the germline to promote timely egg chamber assembly and development.

1024T **Tnpo-SR promotes microtubule dynamics and fusome morphogenesis in *Drosophila* germline stem cells** Amanda Powell[1], Anna Williams[2], Lauren Anllo[1], Elizabeth Ables[2] [1]Biology, East Carolina University, [2]East Carolina University

Germline stem cells (GSCs) play a pivotal role in maintaining fertility across species as the precursors to oocytes and sperm, and also serve broadly as a model for how stem cells maintain their stemness. In *Drosophila* females, GSCs undergo asymmetric divisions that yield differentiating cystoblasts while maintaining the stem cell pool. The orientation of each asymmetric mitotic division is crucial for stem cell maintenance, yet the underlying molecular mechanisms governing this remain unresolved. One likely contributor to this establishment is the fusome, a cytoskeletal organelle with a tubulin-based core and endoplasmic reticulum-like membranous exterior. The fusome serves as a central hub for intracellular trafficking and facilitates GSC-cystoblast connectivity. We hypothesize that the fusome plays a functional role in re-establishing GSC polarity at each cell cycle. Interestingly a beta-importin, Tnpo-SR, seems to coordinate the maintenance of germline stem cells via the reorganization of microtubules. Loss of Tnpo-SR not only causes microtubule disorganization, mitotic misalignment, and fusome fragmentation but also leads to a loss of GSCs over time. We propose that by promoting proper microtubule dynamics, Tnpo-SR also promotes the intracellular movement of core fusome proteins back to the anterior pole of the stem cell, re-setting polarity at each division. This research highlights the significance that microtubules and cytoskeletal polarity play in maintaining stem cell self-renewal and identifies Tnpo-SR as a potential regulator of this process.

1025T **Coordination of cell cycle and morphogenesis during organ formation** Jeffrey Matthew, Vishakha Vishwarkarma, Thao P Lee, Ryan A Agsunod, SeYeon Chung Biological Sciences, Louisiana State University, LSU

Organ formation requires precise regulation of cell cycle and morphogenetic events. Using the Drosophila embryonic salivary gland (SG) as a model, we uncover the role of the SP1/KLF transcription factor Huckebein (Hkb) in coordinating cell cycle regulation and morphogenesis. The hkb mutant SG exhibits defects in invagination positioning and organ size due to abnormal death of SG cells. Normal SG development involves distal-to-proximal progression of endoreplication (endocycle), whereas hkb mutant SG cells undergo abnormal cell division, leading to cell death. Hkb represses the expression of key cell cycle and pro-apoptotic genes in the SG. Knockdown of cyclin E or cyclin-dependent kinase 1, or overexpression of fizzy-related rescues most of the morphogenetic defects observed in the hkb mutant SG. These results indicate that Hkb plays a critical role in controlling endoreplication by regulating the transcription of key cell cycle effectors to ensure proper organ formation.

1026T **Chondroitin sulfate is required for proper control of *Drosophila* intestinal stem cells** Collin Knudsen, Hiroshi Nakato University of Minnesota

Chondroitin sulfate (CS) and heparan sulfate (HS) are evolutionary conserved glycosaminoglycans found in most animal

species, including *Drosophila*. CS and HS exist as proteoglycans (PGs) in which the sugar polymers are covalently attached to core-proteins. While there have been substantial amounts of research conducted on the functions of *Drosophila* HSPGs, roles of CSPGs in *Drosophila* development remain to be elucidated. To investigate the function of CS in development and regeneration, we generated mutants for *Chondroitin sulfate synthase* (*Chsy*), which encodes the *Drosophila* homologue of mammalian Chondroitin synthase 1, a critical CS biosynthetic enzyme, via CRISPR-Cas9 mutagenesis. In the midgut, the loss of *Chsy* resulted in elevated levels of intestinal stem cell (ISC) division during homeostasis, leading to an abnormally increased thickness of the midgut. *Chondroitin polymerizing factor* (*Chpf*) was investigated during midgut homeostasis, with *Chpf* mutants also showing increased ISC division and midgut thickness. Chpf in mammals is known to bind to Chsy, helping to synthesize elongated CS. Additionally, the longitudinal visceral muscle of the midguts in *Chsy* mutants was altered, with significant increases in muscle discontinuity and sprouting in comparison to wild-type. The source of CS in the midgut was found to be from local visceral muscle and enterocytes. Using a regeneration model, we found that *Chsy* mutant ISCs failed to properly downregulate mitotic activity at the end of regeneration. These data showed that CS is required for proper control of the ISC mitogenic activity during midgut homeostasis and regeneration, and a loss of CS results in disrupted midgut morphology.

1027T **_Sar1_, a GTPase involved in COPII vesicle trafficking, is critical for _Drosophila_ oogenesis** Makayla C Gomperts, Julie A Merkle Biology, University of Evansville

The process of cell fate determination is a major question in developmental biology, and the current understanding of mechanisms by which it occurs is very limited. In *Drosophila melanogaster*, oogenesis, or egg production, begins with the division of germline stem cells, eventually leading to the formation of a cyst composed of 16 cells. From here, one is selected to become the future egg, while the other 15 become supporting nurse cells. An EMS mutagenesis genetic screen in *Drosophila* identified several mutations in genes that lead to defects in oocyte determination, ultimately leading to a loss of eggs and fertility. *Sec24CD*, which forms the inner part of the vesicle coat involved in COPII anterograde trafficking, was identified from this screen. Since this was the first known role for COPII trafficking in oogenesis, we were interested in investigating whether other COPII components were also involved in oogenesis. *Sar1* is the GTPase needed for coat assembly of COPII vesicles. To study and analyze the role of *Sar1* in oocyte determination, RNAi knockdown of *Sar1* was performed using a variety of germline-specific Gal4 drivers. This resulted in rudimentary ovaries lacking recognizable germaria or egg chambers, demonstrating that *Sar1* is required early in oogenesis. However, given the dramatic phenotype observed, investigation of *Sar1* in oocyte identity could not be assessed. Using *Gal80^{ts}* to restrict RNAi knockdown to limited windows during oogenesis, intermediate defects have been obtained, wherein egg chambers are made but lack oocytes. Available CRISPR alleles were also utilized to determine loss of function phenotypes of *Sar1* by employing the TRiP-KO and WKO systems. Co-IP experiments have been used to determine the interactions of *Sar1* with COPII vesicle components *Sec24CD* and *Sec23.* Preliminary data confirm interaction of *Sec24CD* and *Sec23* in ovary lysates. Altogether, investigating the role of *Sar1* and COPII vesicle trafficking will allow for better understanding of the molecular mechanisms that control oocyte fate determination in *Drosophila*.

1028T **Nucleoporin107 is a critical determinant of soma-germline communication, essential for ovarian development and function** Merav Yaffa Gold[1], Tgst Levi[1], Tikva Shore[1], Tzofia Bialistoky[1], Shira Leebhoff[1], Girish Deshpande[2], Offer Gerlitz[1] [1]Developmental Biology and Cancer Research, The Hebrew University, [2]Department of Molecular Biology, Princeton University

In earlier studies aimed at uncovering novel components of ovarian development, we identified a novel missense mutation in Nucleoporin107 (Nup107; D447N), an essential component of the nuclear pore complex, as the cause of XX-Ovarian Dysgenesis, a rare disorder characterized by underdeveloped and dysfunctional ovaries. We have employed Drosophila to model the specific human mutation. Either the expression of a mutant isoform or specific knockdown of Nup107 in the gonadal soma resulted in female-specific infertility due to aberrant ovarian development, which to a large extent mimicks the human phenotype. Our data demonstrated that Nup107 regulates essential soma-germline interactions in both larval and adult stages essential for ovarian differentiation and function. Comparative transcriptomic analysis on Nup107 mutant and control larval gonads identified 82 differentially regulated genes including the transcription factor *doublesex* (*dsx*), known for its critical role in sex-specific differentiation. Either loss or gain of Dsx in the gonadal soma is sufficient to mimic or rescue the phenotypes induced by *Nup107* loss, thus establishing Dsx as the primary target and effector of Nup107. Further analysis revealed the primary larval and adult somatic cell types in which the activity of Nup107 is necessary and have begun to elucidate the affected signaling pathways and their involvement in germline–soma communication. Our data thus demonstrate that a sex- and tissue-specific regulation of Dsx by a 'housekeeping' nuclear envelope protein Nup107 is crucial for the ovarian development and function. Given the impressive conservation of Nup107 and the similar phenotypes associated with the mutation, many of our findings will be relevant to human health and hopefully will advance our understanding and treatment of conditions pertaining to female infertility.

1029T **The T-box transcription factor Org-1 is required to establish the *Drosophila* testis niche.** Tynan Gardner[1], Patrick Hofe[2], Kirklan Naumuk[2], Stephen DiNardo[1], Lauren Anllo[2] [1]Cell and Developmental Biology, Perelman School of Medicine at the University of Pennsylvania, [2]Biology, East Carolina University

Stem cells are required for tissue homeostasis and regeneration. Accomplishing such tasks often requires intimate association between stem cells and their cellular microenvironment, or niche. Unfortunately, we know little about how niches are initially established within tissues during organogenesis. We use the developing *Drosophila* testis as a model to study the genetic control of niche formation. Before niche assembly, the spherical gonad contains an interwoven mix of somatic cells encysting germ cells. A subset of these somatic cells is specified as pro-niche cells by Notch signaling prior to gonad coalescence (Kitadate & Kobayashi, 2010; Okegbe & DiNardo, 2011). Our imaging revealed that pro-niche cells extend protrusions to pull themselves out to the gonad periphery, where they migrate along extracellular matrix toward the anterior. We found that anterior assembly of the niche requires signaling from adjacent visceral muscle (Vm). In response to signaling, niche cells express the transcription factor *islet*, which is also required for positioning the niche (Anllo & DiNardo, 2022). Identifying regulators of *islet* expression would identify key intermediaries involved in niche assembly. To this end, we have shown that a minimal element from the *islet* enhancer containing Org1 binding sites is sufficient to drive gene expression in niche cells. *org1* is a T-box transcription factor with a known role regulating *islet* to specify embryonic muscles (Boukhatmi et al., 2014). Here, we show *org1* expression in embryonic niche cells, and significantly reduced Islet in the absence of *org1,* suggesting that Org1 mediates *islet* expression in the testis niche. Like *islet* mutants, *org1* mutant niche cells fail to form a single organized cluster at the anterior and are instead dispersed throughout the gonad. In addition, expression of certain key adhesion proteins is disrupted without *org1*: significantly fewer niche cells express N-cadherin, and all niche cells fail to express Fas3, suggesting additional function for *org1* in the forming niche beyond inducing *islet*. Future experiments will identify whether *org1* plays a dual role in regulating niche specification along with anterior cell movement. This work will enlighten our perspective of mechanisms that initially establish a compartmentalized stem cell niche during organogenesis.

1030T **Over-expression of the Ecdysone Receptor promotes an undifferentiated transitional state during germline stem cell differentiation** Lauren Jung, Alexandria Warren, Elizabeth Ables Biology, East Carolina University

The *Drosophila* ovary requires a tightly regulated network of signals to coordinate the division of their stem cells and differentiation of their daughter cells to produce viable oocytes. The steroid hormone ecdysone is known to be involved in germline stem cell (GSC) self-renewal, however its direct and autonomous role in the germline has not been evaluated. Ecdysone elicits a diverse array of transcriptional responses by binding to a heterodimeric complex composed of Ecdysone Receptor (EcR) and Ultraspiracle (Usp). To illuminate whether EcR facilitates autonomous reception of ecdysone in the germline, we built germline-compatible genetic tools to manipulate EcR levels and/or activity. We find that over-expressing either EcR.A or EcR.B1 isoforms in germ cells results in undifferentiated germ cell tumors and decreased numbers of BMP-responsive GSCs. Germ cells over-expressing EcR remained mitotic, failed to form cysts, and aggregated into egg chambers, reminiscent of cells with over-active BMP receptors or depleted *bam* levels. In tumorous ovaries, stem cell-like cells were also identified outside of their normal stem cell niche, suggesting that these cells remain competent to respond to BMP signals. We demonstrate that the tumor phenotype is dependent on ecdysone, as over-expression of an EcR.B1 transgene that cannot bind ligand suppresses tumor development. Moreover, restricting over-expression of EcR to more differentiated germ cells in 8- and 16-cell cysts failed to produce the tumor phenotype. These data suggest that EcR is required in the GSCs and their immediate daughters for the differentiation of cystoblasts and demonstrate that the low levels of EcR expressed in GSCs are sufficient for ligand-dependent activation of an ecdysone-responsive transcriptional program.

1031T **Cytokine Dynamics in Polyploidization During Drosophila Hindgut Regeneration** Paulo Belato, Donald Fox Pharmacology and Cancer Biology, Duke University

The ability to repair an injured tissue is a crucial part of survival for any organism. Although we usually think of regeneration through the lens of hyperplastic proliferation of tissue specific stem cells, many adult tissues lack these multipotent cells. As a result, one newly appreciated mechanism by which post-mitotic tissues can repair themselves after injury is by becoming polyploid. Polyploidy serves to create more genome copies and enlarge the cell, and thus can play an important role in tissue injury recovery. The fly pylorus is an excellent model to study wound-induced polyploidization because this diploid tissue lacks stem cells and relies on hypertrophic regeneration by endocycles (S-phases without M-phases). Incredibly, the remaining pyloric cells that survive injury are able to restore the tissue's cellular ploidy to match the number of genomes in the tissue pre-injury, irrespective of the injury severity (Cohen et al, 2018). As a clue to how polyploidy is tuned during pyloric regeneration, the Fox Lab has identified the JAK/STAT cytokine *upd3* as the molecular cue that signals injury and prompts remaining cells to engage with the endocycle. How *upd3* dynamically controls the regeneration program under various degrees of injury is poorly understood. To further this work, we are conducting high resolution quantitative imaging of an *upd3* reporter during pyloric regeneration. In preliminary experiments, we have observed that differences in pyloric injury

severity influence both *upd3* signal duration and amplitude in regenerating cells. In addition, we have also observed that the positional identity of pyloric cells along the anterior-posterior axis also affects the amplitude and duration *upd3* signaling in response to injury. Uncovering how regeneration-specific signaling dynamics start, monitor, and stop endocycling will reveal the factors involved in wound-induced polyploidization. Broadly, these findings can deepen our understanding of regeneration in tissues without constitutively active stem cells.

1032T **Dilp8 functions as a mature follicle sensor to prevent excessive accumulation of mature follicles in *Drosophila* ovaries.** Rebecca Oramas, Katarina Yacuk, Baosheng Zeng, Jianjun Sun Physiology and Neurobiology, University of Connecticut

Excessive accumulation and prolonged storage of mature follicles in *Drosophila* female ovaries leads to an unnecessary energy expenditure and oocyte aging, which affects the oocyte's quality and consequently decreases offspring hatching rates. As such, the number of mature follicles in *Drosophila* ovaries are tightly controlled. Each ovary is comprised of ~16 ovarioles and each ovariole contains 1-2 mature follicles, regardless of female's mating status. The mechanism by which the ovary counts the number of mature follicles remains a mystery. Previous work, and our recent RNAseq and antibody analysis, demonstrated that *Drosophila* insulin-like peptide 8 (DILP8) is specifically expressed in follicle cells of mature (stage-14) follicles but not in younger follicles. Contrary to previous findings, we found that mature follicle DILP8 is not essential for mating-induced ovulation and egg laying in an optimal condition. In contrast, we are surprised to find that DILP8 mutant females accumulate excessive mature follicles in their ovaries when the condition is not optimal, particularly when they are virgins. This also occurs when DILP8 is only knocked down in follicle cells. Considering the expression of DILP8 in mature follicle cells, we propose that DILP8 functions as a mature follicle sensor to regulate the number of mature follicles in the ovaries of virgin females. Further analysis indicates that DILP8 is required to induce ovulation and egg laying in virgin females to prevent excessive accumulation of mature follicles and oocyte aging. This mechanism may be very important in the wild, where females do not always have access to a male partner to cause mating-induced ovulation. The DILP8-mediated control of mature follicle number will ensure female maintain high quality oocytes all the time before the next mating.

1033T **Determining the requirement for PIP2 in *Drosophila melanogaster* sperm head-tail coupling** Marynelle S Icmat[1,2], Negar Nasirzadeh[1,2], Julie A Brill[1,2] [1]Department of Molecular Genetics, University of Toronto, [2]Cell Biology Program, The Hospital for Sick Children

The production of mature sperm from an undifferentiated germ cell is a highly regulated process involving dramatic morphological changes to form sperm heads and tails. The process by which the sperm tail is attached to the head, known as "sperm head-tail coupling", is an important phenomenon during sperm development. Since the development of fly and mammalian sperm is similar, we study this process using *Drosophila melanogaster*. In both mammalian and fly systems, sperm head-tail coupling requires the basal body, a specialized centriole that templates the sperm tail and functions as a microtubule organizing centre to promote nuclear elongation. A crucial step is anchoring of the basal body to the nuclear envelope, a process aided by centrosomal proteins. Flies with reduced levels of the lipid phosphatidylinositol 4,5-bisphosphate (PIP2), which is synthesized by the PIP5-kinase Skittles (Sktl) in Drosophila, are male sterile. Exactly how Sktl and PIP2 regulate sperm development remains unclear. In PIP2-depleted sperm, the basal body is initially anchored to the nuclear envelope. This attachment is lost as the nuclei continue to elongate, resulting in malformed sperm heads and sperm decapitation. Interestingly, reduced PIP2 levels result in altered recruitment and localization of centrosomal proteins known to be important for this process. These defects are rescued by over-expression of Sktl, indicating essential roles of Sktl and PIP2 in these processes. Furthermore, by combining mass spectrometry with BioID, a proximity-dependent labelling technique, we have discovered putative Sktl protein interactors during sperm development. Ongoing experiments will uncover regions of Sktl important for sperm development as well as identification of novel protein interactors that, through direct or indirect interaction with Sktl, mediate sperm head-tail coupling and other processes of sperm development.

1034T **Asperous, an EGF-Repeat Protein, Orchestrates Compartment-Specific Regenerative Growth in Drosophila Wing Discs** Si A Cave, Robin E Harirs Molecular Sciences, Arizona State University

Regeneration is a fundamental process that allows organisms to renew and replace damaged tissues. In this study, we utilize the *Drosophila* wing imaginal disc as a model system to unravel the mechanisms of an uncharacterized protein specifically involved in tissue regeneration.

Through RNA-sequencing, we identified *asperous* (CG9572) as a gene significantly upregulated during the regenerative process. Asperous (ASPR) presents a distinctive structural composition, featuring a signal peptide and repeating epidermal growth factor (EGF) domains that collectively form a WD40 structural motif. This structural arrangement prompts the hypothesis that ASPR is conceivably involved in intercellular signaling and the coordination of multi-protein complexes.

To decipher the specific function of ASPR, we employed Duration and Location (DUAL) Control, a novel genetic ablation system that induces cell death via apoptosis or necrosis while concurrently manipulating neighboring tissue. Our results demonstrate the indispensability of ASPR in regeneration following apoptotic cell death. Remarkably, reducing ASPR expression in the surrounding tissue after necrotic damage enhances regeneration, revealing a diverse role dependent on the nature of the tissue ablation.

Furthermore, ectopic expression of ASPR surprisingly hindered growth in a compartment-specific manner. Assessments of both the imaginal wing discs and wings following ablation revealed diminished anterior growth upon ASPR overexpression. Additionally, the restoration of anterior-specific markers observed during regeneration was notably absent in the presence of elevated ASPR levels, indicating a possible role in modulating cell identity post-ablation.

The expression levels and localization of ASPR appear to be critical determinants, influencing whether ASPR promotes or impedes regenerative growth.

This research underscores the importance of elucidating ASPR's compartment-specific role in different regenerative contexts. Its dual nature, dependent on the cell death type and spatial context, positions ASPR as a compelling target for future research. With its multifaceted role in tissue regeneration, ASPR promises valuable insights into the intricate mechanisms governing this fundamental biological process, with potential applications in advancing the understanding of compartment-specific growth patterns in regenerative biology.

1035T **Role of Malvolio, the *Drosophila* ortholog of human NRAMP2 metal ion transporter, in salivary gland morphogenesis** Rajprasad Loganathan[1], Srihitha Akula[2], Aditi Kulkarni[2], Tony Zhu[2], Rika Maruyama[2], Deborah Andrew[2] [1]Biological Sciences, Wichita State University, [2]Cell Biology, Johns Hopkins University

Malvolio (Mvl) is the Drosophila ortholog of the mammalian Solute Carrier Protein Slc11a2, which transports divalent metals, including iron. Mvl shows Fkh-dependent expression during embryonic salivary gland (SG) morphogenesis. *Mvl* zygotic loss has no effect on viability although a developmental delay was observed in $Mvl^{exc1}/Df(Mvl)$, with adults eclosing 48 – 72 hours later than their balancer-carrying siblings. Zygotic loss of *Mvl* also resulted in mild SG abnormalities and occasional small gaps in the denticles. Combined maternal and zygotic loss led to pronounced defects in SG morphology and high frequency denticle gaps. We also observed a loose assemblage of CrebA+ embryonic cells in the anterior region of the *Mvl* homozygotes that may be crystal cells (a subpopulation of Drosophila immune cells). Collectively, these results demonstrate varying degrees of developmental defects with the loss of *Mvl* during embryogenesis. Imaging of *Mvl* null embryos revealed that although the levels and localization of the adherens junction protein E-cadherin and polarity marker Bazooka were comparable to wild-type SGs, the levels of the apical polarity determinant Crumbs were notably decreased. To learn where Mvl localizes in SG cells and is likely to function, we generated Mvl antiserum and costained SGs with anti-Mvl in combination with several organelle-specific markers. These experiments revealed Mvl localization to Golgi, early, and late endosomes. We are testing a working hypothesis that the cell morphogenetic defects in *Mvl* loss-of-function are linked to defective endomembrane trafficking that affects Crb localization and recycling at the sub-apical domain. We are currently assaying the requirements for iron versus proton transport in *Mvl* function.

1036T **Effects of Developmental Alcohol Exposure on Parkinson's Disease models in Drosophila melanogaster** Navneet Sanghera Department of Biological Sciences, San Jose State Univeristy

We have established a Drosophila model of Fetal Alcohol Spectrum Disorder (FASD), a highly variable disorder that results from the consumption of alcohol during pregnancy. Exposing fetuses to alcohol during development can lead to effects including but not limited to developmental delays, low body weight, intellectual disabilities, behavioral changes, and reduced brain size. We have replicated most of these effects in Drosophila exposed to alcohol during development.

We carried out a large-scale genetic screen for mutations that alter the sensitivity of flies to developmental alcohol exposure (DAE). Through this screen, we found that mutations in the gene Dementin (Dmtn), which encodes the Drosophila ortholog of the Alzheimer Disease associated protein TMCC2, result in sensitivity to DAE. Using quantitative RT-PCR and locomotion assays, we showed that DAE results in changes in Dmtn expression, and that adult flies, after exposure to DAE, show climbing defects indicative of CNS dysfunction. Such climbing defects are also seen in fly models of neurodegenerative diseases (including Alzheimer's Disease).

Neurodegenerative diseases attack the central nervous system, which can lead to deficiencies in movement, power, senses, and cognition. We hypothesize that DAE causes neurodegeneration (and may target known pathways involved in neurodegeneration). Currently, we are surveying the interaction between DAE and Drosophila models of neurodegeneration specifically focused on mutants associated with proteins involved in Parkinson's Disease. We will present the results of rearing

Pink and Park mutant flies in ethanol. These two proteins work together in mitochondrial quality control by tagging damaged mitochondria with ubiquitin for further degradation. Interestingly, our results suggested an inverse relationship between these two mutants when exposed to alcohol during development. The park mutants were highly sensitive, while Pink1 mutants were resistant to the effects of alcohol exposure. In addition, we have performed climbing assays to test the health of the CNS system and our analysis indicates that DAE exacerbates climbing defects in young park mutants, but this effect does not worsen over time (suggesting an effect on CNS development).

We will also present data examining the interaction between DAE and climbing ability in Pink1 mutants results from survival assays on other Parkinson's disease associated mutants, and brain imaging to examine dopaminergic neuron degradation in Parkinson's Disease mutants reared on ethanol media.

1037T **Distant wound mediates gut homeostasis through blood cells in flies** Sveta Chakrabarti, Sandhya S Visweswariah Indian Institute of Science

Tissue damage triggers a complex response in animals, involving the activation of multiple pathways to repair the damage and protect against infection. This response relies on the detection of damage-associated molecular patterns, which signal cellular stress. Our recent study in flies has revealed that hydrogen peroxide, produced by blood cells, plays a critical role in the activation of immune pathways following injury. We also found that injured flies are better protected from infection with bacteria, suggesting that injury can train the immune system. Further research is needed to understand the molecular mechanisms by which hydrogen peroxide signals injury and activates immune responses. The gut plays a crucial role in immune function and nutrient absorption. Our current research demonstrates that blood cells relay injury signals to the intestine, stimulating stem cell proliferation and maintaining gut barrier integrity. We show here that the absence of hemocyte activation by ROS at the site of injury leads to a loss of adherence junctions in the gut leading to intestinal barrier dysfunction and increased lethality following injury. UPD3 produced from hemocytes activates STAT in the gut following injury, and chronic STAT activation in the intestine is required for the proper turnover of enterocytes post-injury and survival. Collectively, our results reveal that hemocytes remotely integrate signals to control intestinal homeostasis following an injury.

1038T **Investigating the effects of RNA binding protein interactions and RNAi knockdown phenotypes on *Drosophila* sperm development and mRNA localisation** Dana E Jackson, Sonia Lopez de Quinto, Helen White-Cooper Molecular Biosciences Division, School of Biosciences, Cardiff University

In *Drosophila melanogaster*, male germline cells advance through sperm development in a tightly regulated program of synchronised displacement, differentiation, elongation and individualisation.

While the bulk of spermatogenesis-specific transcription occurs in pre-meiotic primary spermatocytes, an exclusive subset of genes are also post-meiotically transcribed in mid-to-late elongating spermatids – at a point preceding the histone-transition protein-protamine switch. These genes express a number of asymmetrically-localised mRNAs that accumulate towards the distal tail-ends of growing spermatid cyst bundles; arranging in unusual localisation patterns of shooting speckled "comets" or U-shaped acorn "cups". Analysis of fluorescently tagged reporter constructs have revealed that this mRNA localisation precedes the formation of distinct protein gradients.

In addition to these localised mRNAs, we have also identified several RNA binding proteins (RBPs) enriched at the spermatid tail-ends. How and why do these non-uniform, subcellular mRNA distributions arise? What role do these RBPs play in regulating the active localisation, anchoring and translation of comet and cup mRNAs in spermatids?

We have used RNA-affinity pull-down assays to extract out bound fractions of comet and cup mRNAs with a pool of endogenous RBPs, including the highly-conserved IGF-II mRNA-binding protein (Imp). This revealed differential binding between 4 candidate RBPs and 11 comet and cup mRNAs *in vitro* – with binding affinities varying depending on the mRNA of interest. We are now in the process of optimising a modified Cl-AP protocol to precipitate whole, multi-RBP complexes (and their respective interacting RNAs) to re-verify these binding interactions in a more testis-authentic context, and to identify further co-localised mRNAs.

We have also performed a series of RNAi screens to investigate the functional roles of these RBPs in spermatids. We have found that a knockdown of *imp* leads to a variable spectrum of abnormal testis phenotypes, including mislocalisation of mRNA transcripts, loss of localised RNA and fluorescent protein reporter signals, and considerable disruption to spermatid elongation. By conducting HCR RNA-FISH and Lightsheet Fluorescence Microscopy, we have preliminarily determined that these RNAi-induced defects are detectable at both the level of translational dysregulation and at an earlier point of mRNA production, stability and/or localisation.

1039T **The Role of GATA Transcription Factor Serpent in Programmed Cell Death in *Drosophila* Ovaries** Baosheng Zeng, Haley Grayson, Jianjun Sun Physiology and Neurobiology, University of Connecticut

Programmed cell death (PCD) is a vital process for the survival of all living organisms. Recent research has revealed its essential roles in various stages of oogenesis, such as the degradation of mid-stage egg chambers and the developmental death of nurse cells in *Drosophila* ovaries. The GATA transcription factor Serpent (Srp) plays an important role in macrophage development and is crucial for phagocytosis in the embryo; however, its involvement in the cell death process within *Drosophila* ovaries has never been explored. In this study, we demonstrate that Srp is essential for proper cell death during oogenesis. Specifically, Srp becomes gradually upregulated in the follicle cells of degrading mid-stage egg chambers. *srp* knockdown results in premature death of follicle cells in degrading mid-stage egg chambers, leading to an incomplete clearance of dying germ cell debris. Molecular analysis indicates that *srp* knockdown leads to reduced expression of the engulfment receptor Draper (Drpr) in follicle cells and impairs the lysosomal activity in germ cells of degrading egg chambers. Our preliminary analysis indicates that Srp potentially acts downstream of the JNK pathway for the Drpr upregulation. Additionally, we found that Srp's role in cell death is not limited to mid-stage egg chambers, but also in the developmental death of nurse cells at the end of oogenesis. *srp* knockdown in follicle cells results in a lack of nurse cell acidification and persistent nurse cell nuclei (PNCN) defects in the stage 14 egg chambers. Overall, these findings reveal a novel role for Srp in regulating PCD in *Drosophila* ovaries and such a role may be conserved.

1040T **Interactions between *akirin* and *simjoang* during cardiac development** Armeta Hadjimirzaei[1], Scott J Nowak[2] [1]Molecular and Cellular Biology, KSU, [2]Molecular and Cellular Biology, Kennesaw State University

One of the most fundamental organs to form during the earliest stages of development is the heart. In the fruit fly (*Drosophila melanogaster*), many genes and proteins work together for the formation of a fully functioning heart. The conserved nuclear transcription cofactor Akirin has been identified as a key regulator of both the skeletal and cardiac myogenesis programs in *Drosophila.* The current model for Akirin function holds that this regulation of myogenesis by Akirin occurs through interactions with chromatin remodeling complex activity. Earlier work in the Nowak lab found that *akirin* works with the NuRD/CHD chromatin remodeling complex to facilitate proper expression of the cardiac gene program. For this study, we focused upon interactions between *akirin* and *simjoang* (*simj*), a key component of the NuRD/CHD complex. Using live confocal imaging, we recorded heartbeat patterns in a variety of combinations of single and double heterozygous embryos bearing mutations in *akirin* and *simj*. Our data indicates that interactions between these two loci are critical for the cardiac and skeletal muscle patterning process, strongly suggesting that NuRD/CHD activity through interaction with Akirin is a key regulator of these developmental programs.

1041T ***eEF1a2* has essential roles for a cytoskeleton homeostasis in aged fly muscles, which is independent from protein translations** Hidetaka Katow, Hyung Don Ryoo Cell Biology, New York University

The translation elongation factor eEF1α (eukaryotic elongation factor 1α) delivers aminoacyl-tRNAs to ribosomes during mRNA translation elongation. Many metazoan species have at least two eEF1α paralogs. In mammals and *Drosophila*, eEF1α1 is expressed ubiquitously, while eEF1α2 exhibits tissue-specific expression in neurons and muscle cells. Although eEF1α2 has been reported to be associated with certain neuronal diseases in humans and neuro degenerations in neuro muscular junctions, its role in muscle tissues remains poorly understood due to the short lifespan of mutant mice.

Therefore, we aimed to generate a novel eEF1α2 mutant using CRISPR/Cas9 gene editing, resulting in two loss-of-function mutants that remained viable for over a month.

In this study, we discovered that eEF1α2 plays an essential role in the cytoskeleton homeostasis of *Drosophila* indirect flight muscles. Specifically, eEF1α2 mutants exhibited thinner myofibrils in adult indirect flight muscles. With aging, these muscles showed uneven distribution of actin and myosin. Moreover, the mutant muscles developed actin- and myosin-rich structures ensheathing the trachea at >30 days after eclosion. These phenotypes were not rescued by eEF1α1, indicating that eEF1α2 functions in muscle cannot be substituted by its paralog. Notably, the mutant larval muscles did not exhibit adult-like phenotypes.

1042T **Investigating the nuclear requirement for Tnpo-SR in *Drosophila* germline stem cell self-renewal** Lovens Paul, Amanda Powell, Elizabeth Ables Biology, East Carolina University

Stem cells, with their unique capacity for self-renewal and differentiation into diverse cell types, are veritable engines driving tissue homeostasis, repair, and regeneration. Stem cell self-renewal has been extensively studied in *Drosophila* germline stem cells (GSCs), where stem cell function lays the foundation for the perpetuation of the germ cell lineage and the continuity of

life across generations. The intricate balance between self-renewal and differentiation that GSCs maintain is tightly regulated by a cadre of molecular actors, including the beta-importin Transportin-Serine/Arginine Rich (Tnpo-SR). Beta-importins are thought to promote nucleocytoplasmic trafficking; however, this class of proteins is also critical for moving mitotic spindle-associated cargo within the nucleus after nuclear envelope breakdown to promote mitotic spindle assembly. Here, we asked whether Tnpo-SR functions primarily in the GSC nucleus, cytoplasm, or both. First, we used a germline-enabled Tnpo-SR::HA transgene to track its intracellular localization across the phases of the cell cycle. We found that Tnpo-SR localizes to the nuclear membrane, nucleus, and cytoplasm, but moves to the chromatin during mitosis. Then, we aligned Tnpo-SR with human Tnpo3 and identified specific amino acids predicted to impact Tnpo-SR localization and cargo binding. Using this information, we designed a variety of germline-enabled UAS-containing transgenes that should alter Tnpo-SR localization or cargo binding in GSCs. These tools will allow us to pinpoint the exact cellular sites where Tnpo-SR is required for GSC regulation. Identifying the specific cargo molecules transported by Tnpo-SR is essential for comprehending the molecular signaling pathways and interactions that drive GSC fate decisions. Bridging these gaps in knowledge not only enhances our understanding of *Drosophila* GSC biology but also has broader implications for potential applications in human biomedical research, given the conserved nature of Tnpo-SR mechanisms across species.

1043T **Satellite DNA Regulation and the Mechanism of Segregation Distorter** Xiaolu Wei[1], Logan Edvalson[2], Amanda Larracuente[2] [1]Biomedical Genetics, University of Rochester, [2]Biology, University of Rochester

Meiotic drivers create genetic conflict by biasing their transmission to subsequent generations at a cost to the host organism. These conflicts arise in many taxa and may influence genome evolution, but little is known about how they exploit gametogenesis. Our lab studies the mechanism of the autosomal driver, Segregation Distorter (SD), in Drosophila melanogaster. SD is a sperm killer: SD/+ heterozygous males transmit SD to 95% of their offspring, whereas SD/+ females transmit SD fairly, to 50% of offspring. SD causes a chromatin condensation defect in wild type chromosomes during spermatogenesis through an unknown mechanism. The drive target is a large block of tandem satellite DNA repeats called Responder (Rsp). The role of the Rsp satellite in SD drive is unknown. Our earlier work showed that Rsp behaves as a dual-stranded piRNA cluster and is expressed early in spermatogenesis. Because piRNAs play a role in establishing silent chromatin, we hypothesized that the Rsp-derived piRNAs might be involved in drive. We combine cytological, genetic, and genomic approaches to test this hypothesis. We found that Rsp-derived transcripts, and particularly piRNAs, are reduced in SD/+ heterozygote testes. The abundance of Rsp transcripts correlates with the strength of drive. These data suggest that the mechanism of SD may involve dysregulation of Rsp RNA transcripts. Further study of SD may provide insights into drive mechanisms and how satellite DNAs are regulated during spermatogenesis.

1044T **Growth-critical Adipokines and their Role in Adipocyte to Ovary Signaling in *Drosophila melanogaster*** Chad Simmons, Tancia Bradshaw, Alissa R Armstrong Biological Sciences, University of South Carolina

Obesity, a longstanding health concern, contributes to the risk for several pathophysiologies including type two diabetes, cancer, and reproductive issues. In addition to adipose tissue accumulation, obesity disrupts the endocrine function of adipocytes, leading to altered inter-organ communication. Using *Drosophila melanogaster* as a model organism, our goal is to identify the fat-derived molecules that relay nutritional information to other organs. Recently, several adipokines have been shown to be critical for tissue growth during larval development. We set out to determine if these adipokines are also utilized for inter-organ signaling in adults. Since we know that nutrient sensing by the *Drosophila* fat body influences oogenesis, we focus on how these adipokines with known roles in larval development may mediate fat-to-ovary communication in adults.

Our study focuses on upd2, egr, ccha1, ccha2, gbp3 and sun; a group of adipokines that are critical to larval development, nutrient-availability signaling, and growth. Utilizing the Gal80^{ts}/Gal4/UAS system we knocked down individual adipokines in adult adipocytes. We have examined ovulation, germline stem cell (GSC) maintenance, and progression through vitellogenesis using whole mount immunofluorescence. Triglyceride content and adipocyte size were examined to determine the effects on the fat body. Knockdown of upd2 and egr in adult adipocytes does not affect GSC or cap cell numbers in the germaria; but disrupted vitellogenesis. Gbp3 knockdown in adipocytes also did not affect GSCs or cap cell counts, but did alter the adipocyte morphology, with fat bodies having lower triglyceride amounts and smaller cell size. In future experiments, we will examine how fecundity is affected by adipokine knockdown. Additionally, we will determine how dietary changes influence adipokine production and if they are relevant for maintaining adipokine to ovary signaling.

1045T **Investigating the role of *SRPK* in *Drosophila* germline stem cells** William G Outlaw, Amanda Powell, Elizabeth Ables Biology, East Carolina University

Oogenesis is defined as the creation of female gametes (oocytes). In *Drosophila*, this process begins in the germarium, where the germline stem cells (GSCs) are housed. Each GSC divides asymmetrically, producing a cystoblast that divides mitotically divides another four times. A single oocyte differentiated from within the resulting 16-cell cyst. Previous studies demonstrated

that the b-importin, *Transportin-Serine/Arginine rich* (*Tnpo-SR*), is necessary for GSC self-renewal and oocyte differentiation. Tnpo-SR is thought to bind cargo proteins and facilitate their movement across nuclear pores. In some cells, cargo recognition by Tnpo-SR requires the cargo to be phosphorylated prior to binding. *Serine/Arginine Protein Kinase* (SRPK) phosphorylates serine-arginine-rich proteins (SR proteins) in the cytoplasm to enable their intracellular transport into cell nuclei. Although roles for SRPK in meiotic spindle formation have previously been described, it has not been studied for a potential role in GSC self-renewal. We hypothesize that SRPK phosphorylates specific cargo, such as microtubule binding proteins, to promote the successful asymmetric division of GSCs. In support of this hypothesis, we find that SRPK is endogenously expressed in GSCs and localizes to the cytoplasm. We are currently testing whether GSC maintenance is impacted by depletion of *SRPK* specifically in germ cells. These localization and loss-of-function experiments will help to explain the potential molecular mechanisms by which Tnpo-SR promotes GSC self-renewal.

1046T **The Drosophila TENT5 homology is required for spermatid individualization** Abdulqater Al-nouman[1], Kyle Helms[2], Jennifer Curtiss[1] [1]Biology, New Mexico State University, [2]Neurology, Columbia University

The transcription factor Eyeless induces ectopic eyes when mis-expressed. We mis-expressed Eyeless in the wing and performed transcriptomics to identify upregulated eye specific transcripts. Another lab generated data from an Eyeless CHiP-seq experiment. The *CG46385* gene appeared in both data sets, suggesting that *CG46385* is a direct transcriptional target of Eyeless and plays a role in eye development. *CG46385* is predicted to encode a non-canonical polyA polymerase. Vertebrate orthologs of *CG46385* have polyA polymerase activity and physically interact with Smad transcription factors; some have been implicated in human male fertility. We used the CRISPR-Cas9 system to generate mutations in *CG46385*. None of these mutations have obvious effects on eye development; however, a mutation in the CG46385 catalytic domain renders homozygous males sterile. Individualization occurs after terminal differentiation during spermatogenesis in *Drosophila.* Before individualization, 64 elongated spermatids form a syncytium. During individualization, 64 actin cones assemble around each spermatid nucleus to form an individualization complex (IC). The IC forms a cystic bulge that travels down the axonemes of each spermatid laying down plasma membrane and stripping away unneeded organelles and cytoplasm until it reaches the distal end of the cyst. The IC pinches off into a waste bag and components are degraded via a non-apoptotic caspase cascade. Cleaved caspase-3 is active initially around the spermatid nuclei but is then restricted to the cystic bulge and the waste bags. As the IC travels down the spermatids active caspases are removed from the individualized regions. Immunofluorescence for actin and caspase-3 shows that *CG46385*$^{2\text{-}83}$ homozygous mutants have defects in spermatid individualization, as waste bags are absent and the actin cones that travel down the axonemes display a scattered configuration. Cleaved caspase-3 expression is also ubiquitous in cysts, rather than being restricted to the cystic bulge. *In situ* hybridization reveals that *CG46385* transcripts are present in elongating spermatids and localize in a “comet” expression pattern. Cup and comet genes are post-mitotically transcribed and localize to the distal ends of the elongating spermatids. Mutants for some of these cup and comet genes result in failure of spermatids to individualize. Together this work demonstrates that *CG46385* is essential during *Drosophila* spermatogenesis for spermatid individualization.

1047T **Exercise effects on the female germline stem cell lineage in *Drosophila melanogaster*** Sofia Bachmann[1,2], Emily M Wessel[1,2], Daniela Drummond-Barbosa[2,3] [1]University of Wisconsin Madison, [2]Morgidge Institute for Research, [3]Genetics, University of Wisconsin Madison

Exercise exerts a profound influence on human physiology and is popularly known as a ‘magic bullet’ for overall health. However, it remains unclear how regular physical activity affects adult stem cell lineages, which are pivotal for maintaining the structure and function of various tissues and organs. The *Drosophila melanogaster* female germline stem cell lineage has well-characterized responses to dietary and physiological factors, and *Drosophila* is also amenable to the study of exercise physiology. As a first step to test how germline stem cells are affected by exercise, we designed an improved exercise machine based on previous models that capitalize on the natural negative geotaxis response of *Drosophila*. To validate the efficacy of our new exercise machine, we analyzed *Drosophila* activity levels, fat stores, and muscle physiology of exercised compared to non-exercised control females. In the future, we plan to use our optimal exercise regimen to uncover if and how germline stem cells and their differentiating daughter cells respond to regular exercise.

1048T **CG14767: a novel regulator of the Hippo/Yki tumor suppressor pathway** Swastik Mukherjee, Alexey Veraksa Biology, University of Massachusetts at Boston

The Hippo/Yorkie (Yki) tumor suppressor pathway is an evolutionarily conserved system in metazoans that controls cell proliferation, differentiation, and cell death. The Hippo pathway is regulated by endosomal trafficking; however, the underlying mechanism is not well understood. In a screen for *Drosophila* Yki-interacting proteins, we identified a novel interactor, CG14767, that may be involved in endocytic regulation of Yki function. The mammalian orthologs of CG14767 belong to the lysosomal-associated protein transmembrane (LAPTM) family. They are localized in late endosomes and play multiple roles in

mammalian cells. However, the function of *Drosophila* CG14767 is unknown. The goal of this work is to uncover the molecular mechanisms by which CG14767 controls Yki activity at the level of endosomal trafficking. Using protein-protein binding assays, we have shown that the binding between CG14767 and Yki is mediated via the PPxY motif/WW domain interaction. Genetic tests have revealed that CG14767 is both required and sufficient for limiting the growth of adult *Drosophila* wings and suppressing Yki-induced overgrowth in adult *Drosophila* eyes. It is also required to limit the Yki-induced overgrowth in third instar larval wing discs. CG14767 and Yki colocalize in cultured *Drosophila* S2 cells, and further colocalization studies have revealed the involvement of CG14767 in the endolysosomal trafficking, where it likely recruits Yki. We hypothesize that CG14767 inhibits Yki activity either by sending it for degradation in the lysosome or by cytoplasmic retention. We are addressing this hypothesis by investigating the cellular and molecular mechanisms of CG14767 function using a combination of genetics and cell biological approaches. This research will expand our knowledge of the mechanisms of Yki regulation and will provide further insights into the regulation of Hippo signaling by the endolysosomal system.

1049T **Roles of the insulin producing cells and the fat body in nutrient-dependent neuroblast reactivation from quiescence** Susan E. Doyle, Sarah E. Siegrist Biology, University of Virginia

Precise control of cell growth and proliferation is crucial for normal tissue development and function and involves the integration of intrinsic cellular programs with extrinsic cues. In *Drosophila*, proliferating neural stem cells, called neuroblasts, enter a period of mitotic quiescence at the end of embryonic development and reactivate in response to extrinsic nutrient cues as larvae hatch and begin feeding. Both the insulin producing cells of the brain (IPCs) and the fat body, a key nutrient sensing organ, have been implicated in nutrient-dependent activation of the PI3K growth pathway and subsequent neuroblast reactivation. In the case of the IPCs this occurs through direct release of insulin-like proteins, while the fat body has been proposed to indirectly promote insulin release. Here, we examine the relative roles of the fat body and the insulin producing cells in nutrient-dependent neuroblast reactivation from quiescence. We describe the time course of fat body development during the first 24 hours of larval life and compare this to the time course of neuroblast reactivation. Using animals in which either the fat body or the IPCs have been ablated, we compare the effects of loss of each of these cell types on the timing of neuroblast reactivation. Lastly, we use cultured larval brain explants to explore a previous report that the fat body releases a mitogen capable of promoting neuroblast reactivation from quiescence. Our results suggest that the insulin producing cells promote neuroblast reactivation to a greater extent than the fat body; however, coordination of signaling between both tissues is required to ultimately achieve proper timing of nutrient-dependent neural stem cell growth and proliferation.

1050T **Zrf1 regulates the genome integrity of adult intestinal stem cells crucial for midgut regeneration** Joshua SS Li[1], Ying Liu[1], Jun Xu[2], Weihang Chen[1], Baolong Xia[1], Ah-Ram Kim[1], Yanhui Hu[1], Richard Binari[1], John M Asara[1], Norbert Perrimon[1] [1]Harvard Medical School, [2]Chinese Academy of Sciences

The *Drosophila* midgut has emerged as a powerful model to identify genes that regulate intestinal stem cell (ISC) proliferation. Previously, our lab used both RNA Pol II occupancy profiling and single cell transcriptomics to uncover genes distinctly expressed in specific cell types in the fly midgut. Building upon this, we sought to assess the function of transcription factors enriched in midgut progenitors. In an RNAi screen targeting DNA binding proteins, we identified *Zrf1* as a regulator of ISC proliferation. During homeostasis or in response to damage, Zrf1 loss-of-function decreases ISC proliferation independent of cell death. Epistasis analyses find that Zrf1 integrates multiple signaling pathways via Myc. Co-IP experiments find that Zrf1 physically associates with components of the RNA induced silencing complex. Interestingly, Zrf1 is not required for RNA interference. Instead, Zrf1 dominantly modifies position effect variegation and retrotransposon expression indicative of a role in chromatin silencing. Our findings emphasize the importance of maintaining the genome integrity of adult ISCs crucial for midgut regeneration.

1051T **Molecular insights from RNA-Seq analyses on the mechanisms governing shape and cohesion of collectively migrating border cells** Rehan Khan[1], Pralay Majumder[2], Jocelyn McDonald[1] [1]Division of Biology, Kansas State University, [2]Life Sciences, Presidency University, India

During development and in diseases such as cancer, many cells move as collectives, but the mechanisms are poorly understood. *Drosophila* border cells represent an excellent model for investigating how cell collectives migrate in vivo. In the ovary, 6-10 follicle cells form the border cell cluster, which moves collectively between large nurse cells towards the oocyte. Border cells need to stay cohesive while navigating this complex tissue microenvironment. We previously showed that Protein phosphatase 1 (Pp1) promotes border cell migration, cell shapes, and cluster cohesion. Loss of Pp1 activity disrupts actomyosin contractility and cell-cell adhesion, causing cluster disintegration into individual round cells. We also found that nurse cells, and the surrounding tissue, impose compressive forces onto border cells. Overexpression of RhoGEF2 in nurse cells led to RhoA GTPase-dependent activation of non-muscle myosin II (Myo-II), contraction of nurse cells, and compression of border cells. Here, we report our investigation to understand the molecular mechanisms of Pp1-mediated cluster cohesion and border

cell response to mechanical forces. We performed two RNA sequencing experiments using Pp1-inhibited border cells (cluster cohesion) and wild-type border cells from egg chambers with RhoGEF2-expressing nurse cells (mechanical compression). The RNA-seq results were compared to control unmanipulated border cells. Our subsequent analysis identified 160 differentially expressed genes upon Pp1 inhibition, with significant enrichment of gene ontology (GO) terms related to cell-cell adhesion. We found 1153 differentially expressed genes in border cells compressed by RhoGEF2-expressing nurse cells, with significant enrichment of GO terms related to DNA replication, cell division, and protein targeting to the ER. These analyses thus reveal new insights into how border cells and other cell collectives stay cohesive and respond to physical constraints in the tissue microenvironment.

1052T **The conserved RNA binding protein Orb2 regulates cell-type-specific responses to rare codon enriched transcripts within two distinct stem cell lineages** Rebeccah Stewart[1], Scott Allen[2], Pelin Volkan[3], Don Fox[3] [1]Pharmacology and Cancer Biology, Duke University, [2]University of North Carolina at Chapel Hill, [3]Duke University

Differences in gene/protein expression are foundational to differences in cell identity, such as between undifferentiated stem cells and their differentiated progeny. One process that is understudied for its effect on gene/protein expression during differentiation is codon bias. Codon bias occurs when certain codons are rarely used compared to their synonymous counterparts and is present throughout all forms of life. To begin to understand how codon bias impacts development and differentiation, we completed an animal wide, reporter-based screen in the model organism *Drosophila melanogaster*. This screen revealed cell type- and tissue-specific responses to codon bias. Specifically, we found the testis and brain are unique in their ability to express protein derived from rare-codon enriched reporters. In these tissues, we find robust protein expression from reporters enriched in rarely used codons, whereas the other tissues in the fly do not express such reporters. Upon further investigation in the brain, we found differential regulation of protein expression from rare-codon enriched transcripts within stem cell lineages. Neural stem cells are unable to express reporters or endogenous genes enriched in rare codons, while differentiated neurons do so robustly. To uncover molecular regulators that enable neurons to specifically express rare codons, we conducted a targeted genetic screen of 54 candidate regulators. This screen identified the conserved cytoplasmic polyadenylation element binding (CPEB) protein Orb2 and its translational coregulator CG4612 as specific regulators of rare-codon enriched transcript translation in neurons. Using both RNA FISH and RNA-seq we then identified endogenously expressed rare-codon-enriched mRNAs regulated by Orb2, including the G-protein coupled receptor mGluR. These rare-codon enriched mRNAs are linked to Orb2's function in long term memory in specific neuronal cell types. In the testes, there is increased translation of a rare-codon enriched reporter and endogenous rare-codon enriched genes during spermatid differentiation. We have also found a role for Orb2 in increasing translation of the rare-codon enriched reporter in spermatids. Orb2 has an already described role in localizing mRNAs to the axoneme of differentiating spermatids with a measurable impact on fertility. In both the brain and testes, we hypothesize rare codons are needed for gene expression regulation mediated by Orb2 during differentiation. Using our *Drosophila* model, we have uncovered critical regulation of rare-codon enriched transcript expression driven by Orb2. Our findings reveal dynamic central dogma regulation within defined stem cell lineages that drives cellular differentiation and function.

1053T **Function of *CG11180/Chigno* in adult and developing *Drosophila* ovaries** Cheng Yang[1], Pedro Massa[1,2], Natalie Luffman[1,3], Matthew J Wawersik[1], Oliver P Kerscher[1] [1]Biology, College of William & Mary, [2]Division of Pre-Clinical Innovation, National Center for Advancing Translational Science, National Institutes of Health, [3]Human & Molecular Genetics Department, Virginia Commonwealth University, School of Medicine

CG11180 or *Chigno* is a novel protein identified in *Drosophila melanogaster* which exhibits functions in regulating cell differentiation and maintenance in reproductive systems. Our lab has found that *Chigno* is expressed in germline and somatic cells within both testes and ovaries. In addition, somatic inhibition of *Chigno* in testes and ovaries disrupts stem cell regulation and causes infertility. Here we investigate the reasons for these effects, specifically in adult and developing fly ovaries. Data examining *Chigno* expression pattern in adult ovaries is presented, focusing on the germarium which houses two stem cell niches. *Chigno* expression during ovary development is also shown. Furthermore, we explored the impacts of *Chigno* inhibition on somatic and germ cell morphology, behavior, and fate. Our results suggest that *Chigno* is required in adult ovarian follicle stem cells (FSCs), FSC progeny, and in the germline. Somatic *Chigno* inhibition causes accumulating FSC-like cells and pre-follicle cells (pFCs), suggesting that *Chigno* normally acts to promote FSC and pFC proliferation and/or differentiation. *Chigno* may also have important roles in maintaining the extended morphology of escort cells (ECs) that regulate differentiation of germline stem cells (GSCs) and their progeny in the germaria. Moreover, *Chigno* inhibition in the germline cause germ cell loss and defects in development of the somatic ovary, suggesting that *Chigno* is essential for germ cell viability during development, which, in turn, ensures normal development of adjacent somatic cells. Additional data examining the potential mechanisms by which these defects manifest after somatic or germline *Chigno* inhibition is also presented. The human homolog of *Chigno*, *PINX-1*, is localized to the nucleolus and functions as a telomerase inhibitor and tumor suppressor in many vital tissues and organs including liver, lungs, mammary, and reproductive tissues. Its reduced expression in ovarian

epithelial cells is also associated with increased ovarian cancer severity and increased tumor metastasis. As a result, our analysis of *Chigno* function has implications for our understanding of *PINX-1*'s role in cancer, infertility, and stem cell regulation.

1054T **Organization of apical-cortical Actin in the primary pigment cells of the *Drosophila* pupal eye** Abhi Bhattarai, Emily W McGhie, Joshua Woo, Ruth I Johnson Biology, Wesleyan University

The pseudostratified epithelium of the *Drosophila* pupal eye consists of around 750 ommatidia. Each ommatidium is composed of four central cone cells and two primary pigment epithelial cells that sit on top and completely surround a cluster of eight photoreceptors. Secondary and tertiary pigment epithelial cells form a lattice that separates each ommatidium. We find that the primary pigment cells, in particular, become characterized by the dense accumulation of apical-cortical actin filaments, that become radially organized. We name these Apical Radial Actin Filaments (ARAFs). The ARAFs appear to traverse the entire width of primary pigment cells, and non-muscle myosin II (NMII) accumulates along their length, suggesting that the ARAFs are contractile. We have found that two formins, Diaphanous (Dia), and Dishevelled Associated Activator of Morphogenesis (DAAM) are mainly responsible for the nucleation of the ARAFs. Further, the *Drosophila* Villin-family protein Quail (Qua) accumulates in primary pigment cells and is essential for ARAF integrity, suggesting that Qua bundles and anchors ARAFs. A second bundling protein, α-Actinin (ACTN), is also crucial for ARAF structure. Our 3D imaging reveals that ARAFs are required to refine the shape of maturing primary pigment cells.

1055T **The serine-like protease *masquerade* (*mas*) plays an important role in tracheal tube formation** Victoria Kurdyumov, Alexa Oldenkamp, Afshan Ismat Biology, University of St. Thomas

The embryonic trachea is a convoluted series of epithelial tubes that provide oxygen to all cells and tissues in the embryo. Proper formation of these tubes involves several distinct cellular processes, including invagination, collective migration, and cell intercalation. *Masquerade* (*mas*) is a serine-like protease that is expressed in the embryonic trachea. In the absence of *mas*, we found individual tracheal metameres had missing dorsal trunk or dorsal branches while the rest of the trachea formed normally. Moreover, we found that, when the lumen was missing, tracheal nuclei were not present. Using btl-GAL4::UAS-myrGFP, which marks the entire cell membranes of tracheal cells, we found misshapen tracheal cells and uneven dorsal trunks. Currently, we are looking at cell-cell junction markers. We are also in the process of generating over-expression constructs of *mas* to see what happens in the trachea with too much Mas present. We also are in the process of looking at whether there is a link between mas and FGF signaling in the trachea. Overall, this work will be instrumental to our understanding of tracheal tube formation.

1056T **Bourbon and Mycbp function with Otu to promote the expression of Sxl in the Drosophila female germline** Marianne Mercer, Michael Buszczak Molecular Biology, UT Southwestern

In Drosophila ovaries, germ cells differentiate through several stages of cyst development before entering meiosis. This early differentiation program depends on both the stepwise deployment of specific mRNA translation regulatory mechanisms and on maintenance of germline sexual identity. The study of female sterile mutations that result in formation of germ cell tumors has been invaluable in identifying the molecular mechanisms that control these developmental events. We identified a germ cell enriched gene *bourbon* (*bbn*), null mutants of which cause the formation of cystic germ cell tumors. Loss of *bbn* causes inappropriate and overlapping expression of Nanos (Nos) and Bag-of-marbles (Bam). To attempt to better understand the function of Bbn, we performed proteomic analysis and found Bbn forms a complex with the Drosophila ortholog of cMyc binding protein (Mycbp) and Ovarian tumor (Otu), a protein previously linked with regulation of the sex determination factor S*ex lethal* (S*xl*). Loss of *Mycbp* results in the formation of cystic germ cell tumors, mimicking the differentiation defects observed in *Sxl*, *otu*, and *bbn* mutants. Bbn promotes the stability of Otu and fosters interactions between Otu and Mycbp. We find that germ cells from *bbn* mutants display a loss of Sxl expression specifically in the germline. Strikingly, transgenic expression of *Sxl* rescues the *bbn* sterile phenotype, indicating one of the primary functions of this complex is to promote cytoplasmic Sxl expression. Lastly, we find that the human ortholog of Otu, OTUD4, and Mycbp also physically interact. Together these data indicate that Bbn, Otu and Mycbp form a conserved complex that promotes the differentiation of Drosophila germ cells.

1057T **Detailing the functions of Cytokine/JAK/STAT signaling during *Drosophila* midgut regeneration** Xiaoyu Kang[1], Bruce Edgar[2] [1]Oncological Sciences, Huntsman Cancer Institute, University of Utah, [2]Oncological Sciences, Huntsman Cancer institute, University of Utah

Understanding cytokine/JAK/STAT signaling is crucial, as it plays central roles in immune and inflammatory responses, regeneration, wound healing, and human diseases such as auto-immune disorders, inflammatory bowel diseases (IBD), and cancers. While the human inflammatory response is intricate, involving numerous cell types and cytokines, the *Drosophila* system offers a simpler model, with only three cytokines, Unpaired 1, 2, 3 and a single gene encoding their

receptor, Domeless (Dome). It also has only one Janus Kinase (JAK; Hopscotch (hop)), and one known STAT transcription factor, STAT92E. Our previous research unveiled that *Drosophila* cytokines Unpaireds (Upds), functioning akin to human IL-6, are massively induced in response to gut epithelial damage. They, in turn, trigger gut epithelial regeneration through Jak/Stat signaling. However, it is still not known what specific roles cytokine signaling plays in the different gut cell types, or what the target genes of this pathway are in each cell type. To elucidate how Upds induce gene expression during stress-dependent gut regeneration, we plan to map the gene targets of the cytokine effector, STAT92E, in the different midgut cell types through the regeneration process by combining CUT&TAG (to map the DNA binding sites of STAT92E) with RNA-seq and multiplexed FISH (to catalog the transcriptional output of STAT92E). Following this mapping survey, our study will investigate selected STAT target genes to determine their roles in intestinal stem cell (ISC) activation and their functions in the other midgut cell types. Specifically, we aim to address the following questions: 1) How does cytokine/Jak/Stat modulate stem cell transcription to promote proliferation? 2) What is its specific function in differentiation in the ISC lineage? 3) How does it interact the EGFR signaling pathway? We believe our findings will offer a valuable model for epithelial regeneration with broader implications. For example, understanding the mechanism of how IBD promotes tumorigenesis.

1058T **Regulating Hippo signaling, planar cell polarity, and metabolism through the Fat intracellular domain** Cole Julick[1], Nattapon Thanintorn[1], Yi Qu[2], Yonit Tsatskis[3], Helen McNeill[1] [1]Developmental Biology, Washington University School of Medicine in St. Louis, [2]Lunenfeld-Tanenbaum Research Institute, [3]The Hospital for Sick Children

Development requires sophisticated signal transduction systems to coordinate organ and tissue growth, metabolism, and cellular orientation and patterning. Fat (Ft) and Dachsous (Ds) are a pair of large, evolutionarily conserved cell adhesion molecules that act as a ligand-receptor system which regulates and coordinates these processes. In *Drosophila*, Ft functions at the cell surface where it preferentially binds to Ds in a heterophilic fashion. The interaction between these two cadherins initiates bidirectional signaling mediated by their intercellular domains (ICD) to regulate growth by influencing Hippo signaling and morphogenesis by regulating Planar Cell Polarity (PCP). The ICD of Ft contains multiple mitochondrial targeting signals that, when cleaved, release a fragment that is imported into mitochondria where it binds to and stabilizes Complex I suggesting mitochondrial signaling may also act to direct PCP. The ICD of Ft consists of 6 regions that are conserved between *Drosophila* to human. However, the complete function of these conserved regions isn't fully understood. We take advantage of the simplicity and accessibility of *Drosophila* larval wing imaginal discs to identify genes that play crucial roles in development. To understand the mechanisms by which Fat-ICD regulates Hippo signaling and PCP, we utilized CRISPR to make targeted deletions of the 6 conserved blocks of amino acid. We characterized each CRISPR line via RNA sequencing and were able to identify different gene expression profiles for the various lines. This allows for thorough examination of the role each conserved region plays in growth, development, and patterning. We identify mutations within the conserved regions in the Ft-ICD that impair Fat-Hippo signaling and PCP. Specifically, we find variation in wing size, shape, and symmetry along with PCP and gene expression. Our research provides further insight into the endogenous role of the conserved regions within the ICD.

1059T **Synergistic activation by Glass and Pointed promotes neuronal identity in the *Drosophila* eye** Hongsu Wang[1], Komal Kumar Bollepogu Raja[2], Kelvin Yeung[2], Carolyn Morrison[1], Antonia Terrizzano[1], Celine Tran[1], Alireza Khodadadi-Jamayran[3], Cornelia Fritsch[4], Simon Sprecher[4], Graeme Mardon[2,5], Jessica E Treisman[1] [1]Cell Biology, NYU Grossman School of Medicine, [2]Pathology and Immunology, Baylor College of Medicine, [3]Applied Bioinformatics Laboratories, NYU Grossman School of Medicine, [4]Universite de Fribourg, [5]Molecular and Human Genetics, Baylor College of Medicine

Progenitor cells can be directed to differentiate into distinct cell fates by a combination of extrinsic signals and intrinsic transcription factors. In the eye imaginal disc, the Glass (Gl) transcription factor is expressed in photoreceptors as well as non-neuronal cone and pigment cells, and acts autonomously in each cell type to promote its normal differentiation. Single-cell RNA-Seq analysis of *gl* mutant eye discs revealed that the differentiation of all cell types is disrupted. The first photoreceptor to form, R8, is the least affected, but few of the later-differentiating cell types are observed. R8 induces other photoreceptors to differentiate by activating Epidermal Growth Factor Receptor (EGFR) signaling, which is transduced by the transcription factor Pointed (Pnt). To understand how Gl and EGFR signaling interact in the absence of upstream retinal determination factors, we ectopically expressed Gl and/or the EGFR pathway activator Ras^{V12} in the wing disc. The combination of both factors, but neither alone, induced the expression of many genes associated with neuronal differentiation. This synergy required *pnt*, indicating that it occurs at the transcriptional level. We used targeted DamID to profile Gl and Pnt binding sites in eye disc cells at the onset of differentiation and in committed photoreceptors. We found that many enhancer regions were bound by both transcription factors in one or both conditions, including enhancers for some genes that were synergistically induced in the wing disc. Motif analysis suggested that each factor is able to recognize less optimal binding sites in co-bound regions, potentially due to cooperative binding. The genes directly bound and co-regulated by Gl and Pnt include both transcription factors and downstream effector genes, suggesting that Pnt and Gl promote neuronal identity through a multi-layered transcriptional network. We also found that Gl can directly activate the transcription of genes specific to non-neuronal retinal cells, independently of Pnt. These results shed light on the interactions between signal-regulated and intrinsic

transcription factors that enable a pool of equivalent progenitor cells to differentiate into multiple cell types.

1060T **Investigating the role of the Drosophila PI 4-kinase Four wheel drive during spermatocyte cytokinesis** Catherine Q.F. Zhang[1,2], Anastasia Fexa[1,2], Yonit Tsatskis[2], Julie A. Brill[1,2] [1]Molecular Genetics, University of Toronto, [2]Cell Biology Program, The Hospital for Sick Children

During sperm development, successful meiotic cytokinesis is essential to prevent multinucleate cells that can lead to infertility. Using the model of Drosophila melanogaster spermatogenesis, the phosphatidylinositol (PI) 4-kinase III β (PI4KIIIβ) "Four wheel drive" (Fwd) was identified as essential for meiotic cytokinesis. However, the mechanistic role of Fwd's lipid product, PI4P, during meiotic cytokinesis is not fully understood. In addition, the regulators that control the localization of Fwd at the Golgi during spermatogenesis are unknown. Using high-resolution time-lapse live imaging, markers to visualize the centralspindlin complex, spindle microtubules, actomyosin ring, plasma membrane, and membrane trafficking will be used to pinpoint the primary defect in *fwd* mutants during meiotic cytokinesis. To identify regulators of Fwd, analysis of putative interactors of Fwd by co-immunoprecipitation revealed a conserved interaction between Fwd and the Drosophila orthologs of mammalian proteins ARMH3 (CG8379) and ACBD3 (CG14232), which regulate PI4KIIIβ. Both proteins localized to the Golgi in Drosophila S2 cells and will be characterized as candidates that may recruit Fwd to the Golgi during spermatogenesis. In addition, novel interactors and putative regulators of Fwd will be identified using proteomics methods including AP-MS and BioID. Overall, uncovering the role of Fwd during meiotic cytokinesis will allow for insight into conserved mechanisms regulating this universal process.

1061T **Identifying polarity factors of Crumbs-induced neoplastic tissue growth** Max Shcherbina, Parama Talukder, Ulrich Tepass Cells & Systems Biology, University of Toronto

Crumbs (Crb), an apical transmembrane protein, plays a pivotal role in regulating epithelial polarity and influences tissue growth through its interactions with the Hippo and JNK pathways. Both in mammals and Drosophila, the Crb protein has been implicated in tissue growth regulation and tumour development. Notably, Crb overexpression in Drosophila imaginal disc epithelia induces neoplastic overgrowth. We are interested in exploring which factors are required for neoplastic tumourigenesis when Crb is overexpressed.

Moderate Crb overexpression activates the Hippo pathway effector, Yorkie, alongside the JNK pathway, leading to over-proliferation and neoplastic transformation of the epithelium. Surprisingly, high-level Crb overexpression switches JNK's role from promoting proliferation to inducing apoptosis, thereby reducing tumour size. Reducing JNK activity in this context seemingly restores full neoplastic growth, suggesting that high-level Crb overexpression triggers enhanced JNK activation, thus offsetting Crb's pro-proliferative effects.

Our focus has expanded beyond JNK signalling to include components of the epithelial polarity machinery in the context of Crb-induced neoplastic development. Testing Crb constructs with modified cytoplasmic domains, we discovered that removing either the C-terminal PDZ domain or the juxtamembrane FERM domain noticeably diminished the Crb-induced neoplastic phenotype. This finding emphasizes the significance of Crb's domain binding partners in facilitating Crb-induced neoplastic growth.

Building on these experiments, our current investigations are directed toward assessing the roles of known Crb binding partners and other components of the epithelial polarity machinery. We are screening their contributions to neoplastic development, alongside other key elements of the epithelial polarity complex. This approach aims to unravel the intricate network of interactions that facilitate Crb's role in epithelial tissue regulation and its potential aberration in neoplastic processes. Our goal is to investigate the precise molecular mechanisms through which these polarity factors influence Crb-mediated neoplastic transformation.

1062T **Function of the RhoGEF Cysts in imaginal disc morphogenesis and tumorigenesis** Ming Yu Cao, Milena Pellikka, Ulrich Tepass Cell and Systems Biology, University of Toronto

Rho1 is a small signalling G protein that regulates diverse cellular processes such as cytoskeletal organization, cell movements, and cell division. The key regulators of Rho1 protein activity include Guanine nucleotide-exchange factors (GEFs) and GTPase-activating proteins (GAPs). In Drosophila, RhoGEFs like RhoGEF2 and RhoGEF64C , as well as RhoGAP like Cumberland GAP, have been reported to exert context-dependent control over Rho1 signaling. Nevertheless, the specific mechanisms through which GEFs and GAPs govern the spatiotemporal activity of Rho1 during wing imaginal disc morphogenesis remain largely elusive.

Our laboratory has recently characterized the RhoGEF Cysts (mammalian orthologs p114 RhoGEF,p190 RhoGEF, AKP-13,

GEF-H1) in Drosophila embryos, demonstrating its adherens junction associated activation of the Rho1–Rok–myosin II pathway, thereby promoting epithelial integrity during gastrulation. The present study aims to examine Cysts' function in the regulation of wing disc tissue growth. Our results indicate that Cysts is recruited to the apical cortex of wing disc cells by the polarity proteins Crumbs and Bazooka. Here, it plays essential roles in regulating tissue folding and cell viability as loss of Cysts led to excessive epithelium folding at the hinge region and cell death. Furthermore, when apoptosis is inhibited with the p35 baculovirus protein, Cysts knockdown led to "microtumour" formation. Those "microtumours" have upregulated Yorkie and JNK signalling and show defects in epithelial polarity. We then further analyzed Cysts role during tumour development and found that Cysts knockdown accelerated overgrowth of the wing disc and delayed larval pupariation time consistent with increased neoplastic differentiation. Moreover, the double knockdown of Cysts and RhoGEF2 led to synergistic enhancement of the growth defects. Overall, our data suggests that Cysts is an important regulator of junctional Rho1 activity in the wing disc and its cooperation with RhoGEF2 is essential for controlling Rho1 signaling during wing disc development and tumorigenesis.

1063T **Preliminary characterization of *surfeit-4* gene in *Drosophila melanogaster*** Jada Scott, Nathan Powers, Mayank Kapadia, Ajay Srivastava Biology, Western Kentucky University

Basement membranes (BM) are specialized forms of extracellular matrix that play critical roles during normal development and tumor metastasis. BM properties can be modified by several mechanisms, one of them being by changing the composition of BM itself. We identified Surfeit-4 (Surf-4) as an interacting protein in a biochemical screen for proteins that associate with BM component, Collagen-IV. To further understand the function of this gene we generated a peptide antibody, characterized it, and used it to assess the sub-cellular localization of this protein in *Drosophila* larval tissues. RNAi was used to generate phenotypes associated with this gene. Preliminary results from these endeavors will be presented and point to a localization of Surf-4 in the secretory pathway. Specific wing phenotypes were generated as well and their preliminary characterization will be presented.

1064T **Identifying GPCR genes that affect salivary gland and germ cell migration** Kailey Boyle, Samantha Snyder, Caitlin Hanlon Biology, Quinnipiac University

GPCRs are one of the largest and most widely expressed protein families, found in all manners of life from bacteria to humans. Despite GPCR's prominence throughout biology, they have been surprisingly understudied during Drosophila development. One hundred and sixteen GPCRs are encoded in the Drosophila genome, and although their sequence and many expression patterns are known, what they sense and what they do during development remains unknown. The goal of this project is to systemically investigate the role that GPCRs play in Drosophila embryonic development in the salivary gland and germ cells via an RNAi screen. This project is being completed at a primarily undergraduate institution (Quinnipiac University) by undergraduate independent study students, students participating in a CURE in a upper level Cell Physiology course, and master's level students. Thus far, 40 genes have been knocked-down in the salivary gland, and three potential hits have been identified (*CG11318*, *CG15556*, and *smog*). Twenty-five genes have been knocked-down in the germ cells, and one potential hit has been identified (*FMRFaR).* Here, we present our work knocking down *frizzled* (*fz*), methuselah-like 5 (*mthl5*), and stem cell tumor (*stet*) in the salivary gland and germ cells. We hypothesize that knockdown of *mthl5* will affect the salivary gland and that knockdown of *stet* will affect the germ cells.

1065T **Genetic and Molecular Mapping of two cell growth mutations, d.2.2 and a.2.1 in conjunction with the Fly-CURE** Jennifer Cifranic, Annie Richters, Lauren Heininger, Reese Saho, Delia Adkins, Emma Widmer, Jamie Siders School of Science, Technology, and Mathematics, Ohio Northern University

The Fly-CURE is a **c**ourse-based **u**ndergraduate **r**esearch **e**xperience implemented in undergraduate genetics courses. This CURE utilizes an EMS-based genetic screen in conjunction with the Flp/FRT system to generate hundreds of mutants with irregularities in cell division or cell growth in the eye; mutations analyzed by students are limited to the right hand arm of chromosome 2. Standard complementation analysis is then conducted to map the causative gene. The current work phenotypically characterizes and maps two of the Fly-CURE mutants: d.2.2 and a.2.1. The d.2.2 mutant displayed a standard red>white cell overgrowth phenotype in the eye, while crosses to the BDSC7896 deficiency stock failed to complement. The deletion contained on BDSC7896 maps to between nucleotide positions 20,245,186 and 20,245,490 on chromosome 2R and narrows down the candidate genes to less than 20, including plutonium (*plu*), a negative regulator of DNA replication. The a.2.1 mutant mutant displayed significant red>white cell overgrowth and scarring in the eyes. The a.2.1 mutant was crossed to 98 deficiency stocks on chromosome 2R and none of the stocks resulted in a failure to complement. It is possible the causative gene of the a.2.1 phenotype is contained within a region of 2R that is not covered by an available deficiency stock. Alternatively, it was found that some of the deficiency stocks had lost the curly wing marker on the balancer and some deficiency crosses will need to be performed again. Future work will involve crossing the d.2.2 mutant to single gene alleles of the candidate genes, including *plu*. As genetic mapping failed to identify the causative gene for a.2.1, a whole genome sequencing and Sanger sequencing of candidates in the regions not covered by deficiency stocks will be used to identify the

specific genetic lesion responsible for the cell growth phenotypes observed in the a.2.1 mutant.

1066T **Examining the function of *Dchs1* and *Dchs2* in Mammalian Eye Development** Jennysue Kasiah[1], Helen McNeill[2] [1]Washington University-St. Louis, [2]Washington University in St. Louis

Dchs1 and *Dchs2* are large protocadherins that play crucial roles in mammalian development and disease. *Dchs1* and *Dchs2* are the mammalian orthologs of *Drosophila d*achsous (*ds*). Ds, in conjunction with its binding partner fat (Ft), are regulators of tissue growth via the Hippo pathway, planar cell polarity (PCP). *Dchs1* and *Dchs2* play developmental roles in a variety of mouse tissues including kidneys, lungs, heart, brain, and the skeleton. Human diseases associated with the loss of *DCHS1* and its binding partner *FAT4*, include Hennekam and Van Maldergem syndrome.

Published RNA sequencing show *Dchs1/2* expression in a variety of retinal progenitor cells, and neurons of the retina including bipolar, amacrine, horizontal, and retinal ganglion cells (RGCs). My preliminary RNAscope and western blot data confirm that both *Dchs1* and *Dchs2* are present in the post-natal retina. To determine the role of *Dchs1/2* during retina development, I generated conditional knockouts of *Dchs1* and *Dchs2* using Tg(Rax-cre)1Zkoz (mRx-cre), which targets loss of *Dchs1/2* to the retinal pigment epithelium (RPE), retina and portions of the forebrain. Examination of Tg(Rax-cre)1Zkoz *Dchs1*$^{tm1.1IrvF/F}$ /B6 animals showed that loss of *Dchs1* did not cause any overt retinal histological changes or changes in cell differentiation/ cell number at P0, P15, or P30. Preliminary examination of Tg(Rax-cre)1Zkoz *Dchs2*$^{tm1.2FhelF/F}$/B6 animals at P17 showed an increase in the number of cells in the retina that are positive for the pan retina neuronal cell marker, PROX1, suggesting that *Dchs2*, not *Dchs1*, may play a role in retina development.

It is unknown if *Dchs1/2* serve redundant roles in the retina. Double knockouts globally and specifically in the mouse embryonic kidney demonstrated that loss of both *Dchs1* and *Dchs2* drives synergistic effects leading to greater restriction of the nephron progenitor pool than loss of either gene alone. I am generating double Tg(Rax-cre)1Zkoz *Dchs2* $^{tm1.2FHel}$ *Dchs1*$^{Ftm1.1IrvF/F}$ *tm1.2FhelF/F* /B6 mutants to determine if *Dchs1/2* have redundant roles during retinal development. I am also in the process of fully characterizing the Tg(Rax-cre)1Zkoz *Dchs2* $^{tm1.2FHel}$ /B6phenotype via immunofluorescence on whole eye cryo-sections and retina flat mounts, focusing on specific retina neuronal cell type markers as well as the pan marker PROX1.

1067T **Adams Oliver Syndrome-associated RBPJ variants act as dominant negative proteins that cause developmental defects due to compromised Notch signaling in the vasculature** Alyssa Solano[1], Kristina Preusse[2], Lisa Gutzwiller[2], Rebecca Hotz[2], Shruti Vemaraju[2], Rhett Kovall[3], Rafi Kopan[2], Brian Gebelein[2] [1]Medical Scientist Training Program, University of Cincinnati College of Medicine, [2]Developmental Biology, Cincinnati Children's Hospital Medical Center, [3]Molecular and Cellular Biosciences, University of Cincinnati College of Medicine

The rare genetic condition Adams Oliver Syndrome (AOS) is characterized by the combination of scalp lesions and transverse terminal limb defects present at birth. Previous sequencing of a large AOS patient cohort identified allelic variants in multiple components of the highly conserved Notch signaling pathway, including the ligand *DLL4*, the receptor *NOTCH1*, and the pathway's sole transcription factor *RBPJ*. Notch signaling is activated by ligand-receptor interactions that trigger the proteolytic release of the Notch Intracellular Domain (NICD), which forms a DNA binding complex with RBPJ and activates transcription. In AOS patients, six dominantly inherited autosomal missense mutations have been identified in or near the DNA-binding domain of RBPJ. The mechanism by which these allelic variants bring about AOS phenotypes is not yet known. The goal of this project is to describe the pathogenesis of autosomal dominant AOS variants in RBPJ using a combination of quantitative biochemical assays and animal models. Our current biochemical studies support the idea that AOS-associated RBPJ variants cause dominant phenotypes by weakening DNA binding but not binding to NICD. Using analogous mutations in mouse RBPJ, we investigate whether mice with AOS variants develop autosomal dominant phenotypes consistent with a dominant-negative protein function, and we test the following <u>*hypotheses:*</u> first, that AOS-associated RBPJ variants function as dominant negative proteins that compromise Notch signaling by sequestering NICD from DNA; and second, that the expression of RBPJ variants in the embryonic vasculature drives AOS pathogenesis. The completion of this research will establish the molecular mechanism by which AOS-associated RBPJ variants produce a disease phenotype and ascertain the tissue type(s) driving AOS pathogenesis and the critical temporal window(s) in which the AOS phenotype is established. This improved understanding of Notch biology will facilitate therapeutic manipulation of the Notch pathway for the treatment of AOS and other Notchopathies.

1068T ***In Silico* analysis of two novel variants in voltage gated sodium channel encoding gene SCN1A linked to Epilepsy** Chetan Ghati Kasturi Rangan[1], Yogananda S Markandeya[2], Gautham Arunachal[3], Bhupesh Mehta[4], Madhura Nimonkar[2], Prashanth Vashista[2] [1]Human Genetics, National Institute of Mental Health and Neurosciences, [2]Biophysics, Nimhans, [3]Human Genetics, Nimhans, [4]Nimhans

Dravet syndrome (DS), also known as severe myoclonic epilepsy of infancy (SMEI) is a severe intractable epileptic encephalopathy associated with early onset seizures, developmental arrest in early childhood. Seizures are often temperature sensitive. Despite the availability of several antiseizure medications, it is often a challenge to treat drug-resistant forms. The pathogenic variants in SCN1A gene, located on chromosome 2q24.3 that codes for the voltage-gated sodium channel $Na_V1.1$ leading to channel dysfunction, has been found to be a major genetic cause of this disorder. We performed whole exome sequencing for patients with DS and identified 2 missense variants NP_001159435.1:p.Ile227Thr and NP_001159435.1:p.Glu1032Lys in *SCN1A* gene. The pathogenic variant on exon 8, NM_001165963.4:c.680T>C [clinvar reported: VCV000930374.5] was de novo and leads to substitution of amino acid Isoleucine to Threonine at position 227 in the transmembrane domain of $Na_V1.1$. The variant, NM_001165963.4:c.3094G>A, on exon 19 is novel but was inherited from affected mother. It leads to the substitution of the amino acid Glutamic acid to Lysine at position 1032 in the cytoplasmic domain. To understand the association between the nature of the mutation and the resulting functional alteration, we performed extensive *in silico* analysis to understand and predict the possible pathomechanism. Multiple sequence alignment was carried out using PRALINE and Clustal Omega. In order to quantify the destabilization effects of the mutations, the difference in folding free energy change between native and mutant proteins (DDG or ddG) was calculated. The results from protein stability predictors, namely, iStable, MUpro, and I-Mutant Suite, indicated that the Ile227Thr and Glu1032Lys are leading to decrease in protein stability. The structure based prediction tool, PolyPhen 2 showed that the mutation I227T to be probably damaging with a score of 1.00 and E1032K to be benign with a score 0.21. PANTHER-PSEP, a position specific evolutionary preservation tool classified Ile227Thr to be probably damaging with a score of 0.74 and Glu1032Lys to be possibly damaging with score 0.5. Functional variant prediction was carried out using the funNCion tool which predicted Glu1032Lys to be neutral and Ile227Thr to be pathogenic with a probability of 0.67 and loss-of-function with a probability of 0.56. Results from our *in silico* analysis demonstrates the deleterious effects of the two mutations and serves as reference for planning of further *in vitro* experiments.

1069T **Spatio-Temporal Control of RNAi in Tribolium castaneum** Muhammad Salim Hakeemi University of Maryland

RNA interference (RNAi) is a natural antiviral defense mechanism in plants and animals. As a counter defense strategy, most viruses have evolved viral suppressors of RNAi (VSRs) to antagonize the RNAi pathway. Here, we utilized VSR from Cricket Paralysis virus (CrPV1A) to restrict RNAi spatiotemporally and overcome the limitation of the strong systemic RNAi response in T. castaneum. We found that ubiquitously driven VSR shows a notable rescue of sterility, which so far has hindered the analysis of RNAi mediated phenotypes of Tc-axin and Tc-dpp. Our findings demonstrate the potential use of the newly developed VSR tool on overcoming the limitation of sterility problem in T. castaneum. Moreover, our proof of concept work opens additional avenues for future applications such as separating maternal and zygotic gene function in T. castaneum.

1070T **Solubility phase transition of maternal RNAs during vertebrate oocyte-toembryo transition** Hyojeong Hwang[1], Sijie Chen[2], Meng Ma[2], Divyanshi Divyanshi[3], Hao-Chun Fan[2], Elvan Böke[4], Wenyan Mei[2], Jing Yang[2] [1]Department of Biochemistry and Biophysics, University of Pennsylvania, [2]Comparative Biosciences, University of Illinois, [3]Cell and Developmental Biology, University of Illinois, [4]4Centre for Genomic Regulation (CRG), The Barcelona Institute of Science and Technology

The oocyte-to-embryo transition (OET) is regulated by maternal products stored in the oocyte cytoplasm, independent of transcription. How maternal products are precisely remodeled to dictate the OET remains largely unclear. In this work, we discover the dynamic solubility phase transition of maternal RNAs during *Xenopus* OET. We have identified 863 maternal transcripts that transition from a soluble state to a detergent-insoluble one after oocyte maturation. These RNAs are enriched in the animal hemisphere and many of them encode key cell cycle regulators. In contrast, 165 transcripts, including nearly all *Xenopus* germline RNAs and some vegetally localized somatic RNAs, undergo an insoluble-to-soluble phase transition. This phenomenon is conserved in zebrafish. Our results demonstrate that the phase transition of germline RNAs influences their susceptibility to RNA degradation machinery and is mediated by the remodeling of germ plasm. This work thus identifies important remodeling mechanisms that act on RNAs to control vertebrate OET.

1071T **Regulation of meiotic cytokinesis in *S. cerevisiae*** Matt Durant, Linda Huang University of Massachusetts Boston

In *S. cerevisiae*, cells undergo sporulation in response to starvation. Sporulation is comprised of three main stages: commitment to sporulation, meiosis, and spore wall deposition. During meiosis II, each haploid nucleus is surrounded by a prospore membrane, which is synthesized *de novo*. The closure of this prospore membrane around the newly formed haploid nucleus is the meiotic cytokinesis event. The timing of prospore membrane closure is regulated by the Sps1 STE20-GCKIII kinase acting downstream of the Cdc15 Hippo-like kinase. Closure of the prospore membrane is thought to require the removal of Ssp1, a coiled-coil protein of unknown function that localizes to the leading edge of the growing prospore membrane. A complex of proteins known as the leading edge protein complex (LEP) assembles at the open end of growing prospore membranes and may keep elongating prospore membranes open as meiosis II progresses. Ssp1 is required for the other members of the LEP complex to properly assemble; removal of the LEP occurs before prospore membrane closure.

The mechanism by which the leading edge is removed from the prospore membrane is poorly understood. Interestingly, the sporulation specific MAP kinase encoded by *SMK1* localizes to the PSM in early meiosis II and becomes localized specifically to the leading edge of growing prospore membrane in late meiosis II. Smk1 localization to the LEP requires Ssp1. Our work aims to determine the mechanism by which the LEP is removed from the PSM as part of PSM closure.

1072T **Multiple Prostaglandins Play a Role in the Early Heart Development of Zebrafish (*Danio rerio*)** Jill Parsons Biology, Williams College

The patterning of heart valve precursors occurs during a critical period beginning about 24 hpf. Previous work has implicated prostaglandins in heart valve development and cardiac morphology, but these works focused on time points before and after the critical period for valve patterning. We confirm that inhibition of Cox-2, an enzyme essential for biosynthesis of prostaglandins, inhibits valve leaflet outgrowth and we narrow the period during which this effect occurs. We further investigated the role of specific prostaglandins using live imaging of beating zebrafish hearts at 96 hpf. Prostaglandins previously reported to rescue or phenocopy Cox-2 inhibition at other time points did not provoke the same effects on valve and heart morphology during this critical period. Instead, a different set of prostaglandins appear to be required for heart valve formation and heart morphology beginning at 24 hpf. Our findings highlight the dynamic use and re-use of developmental signals at different stages and in different tissue layers during the course of heart formation.

1073T **Characterizing Hybrid Cell Fate and Formation in Zebrafish Axial Mesoderm Development** Avani Modak[1], Cheng-Yi Chen[2], Jeffrey Farrell[2] [1]Unit on Cell Specification and Differentiation, National Institute of Child Health and Human Development, [2]National Institute of Child Health and Human Development

During development, genes characteristic of specific cell fates are activated in each cell. Typically, only one expression program is activated. However, recent single-cell genomic assays in zebrafish revealed that in normal development, some cells occupy an intermediate, or “hybrid,” state, where they express genes characteristic of more than one cell type. The eventual fates of these hybrid cells and the mechanisms behind their formation remain unknown. We are studying hybrid cells within the axial mesoderm of early zebrafish embryos as a model to understand the behaviors and fates of hybrid cells in development. Early in development, cells in the axial mesoderm share a common progenitor that expresses a single set of genes. As development continues, the anterior portion of the axial mesoderm responds to different signaling factors than the posterior, distinctly specifying cells in both regions. By 7 hours post fertilization (hpf), the anterior is specified into the prechordal plate (PCP) and the posterior is specified into the notochord. However, at this timepoint, a small population of “hybrid” cells at the boundary between the cell types expresses genes specific to both notochord and PCP identities. Here, we characterize the fate of these hybrid cells and using new notochord transgenic lines and hybridization chain reactions (HCR). Fate-mapping using these lines shows that at least some hybrid cells with former notochord expression contribute to the hatching gland, the final-destination of prechordal plate cells. We identified that these hybrid cells eventually differentiate into prechordal plate cells, although they are delayed in this differentiation compared to non-hybrid prechordal plate cells. We aim to characterize the fate and potential functionality of these cells further using single-cell genomics approaches and to investigate the gene network that regulate their development through mutations and signaling molecule manipulation. Additionally, we plan to perform a parallel set of experiments to characterize hybrid cells that end up outside of the PCP. Funding: NIH Intramural ZIAHD008997 to JAF

1074T **Generating transgenic zebrafish for optogenetic control of signaling pathways** William Anderson, Leanne Iannucci, Katherine W Rogers NICHD, National Institutes of Health

A fascinating biological phenomenon is the development of a single cell into a mature organism with a diverse range of tissues and cell types. Signaling pathway activity is crucial to this development. To better understand how signaling generates diverse cell types, we use optogenetic tools to activate the FGF, Nodal, and BMP pathways in zebrafish. Previously, we have used mRNA microinjection to introduce these tools into one-cell embryos, a technique which can be time consuming and result in mosaicism. We now seek to generate transgenic zebrafish lines that express these tools, which should greatly facilitate further experimental pathway manipulation by eliminating the need for microinjections and providing more ubiquitous expression. Some anticipated challenges we are working to overcome include fine-tuning expression levels and housing potentially light-sensitive adult zebrafish. We believe these transgenics will improve the ease and precision of optogenetic signaling manipulation and facilitate longer term experiments than those currently allowed by mRNA microinjection. Funding: NIH Intramural ZIAHD009002-01 to KWR.

1075T **Wnt-signaling dependent mechanisms of zebrafish spinal cord regeneration** Sam Alper[1], Deeptha Vasudevan[2], Maya Wheeler[1], Richard Dorsky[1] [1]Neurobiology, University of Utah, [2]University of Chicago

Spinal cord injury (SCI) leads to severed axons, neuronal death, and a resulting loss of sensorimotor function. In mammals, damaged axons are not efficiently regrown and no new neurons are born after injury. An important barrier to mammalian

spinal cord regeneration is provided by the injury-induced response of non-neural cells. Several cell types including fibroblast, immune, and meningeal cells infiltrate the mammalian injury site and secrete an array of molecules into the extracellular matrix. The resulting fibrotic scar contains inhibitory signals and creates a physical obstacle to regrowing axons. These cellular and molecular responses lead to permanent deficits in sensorimotor function. Zebrafish, however, respond to spinal cord injury with axon regrowth, neurogenesis, and functional recovery. This remarkable ability is underpinned in part by an upregulation of signaling pathways associated with development, including Wnt/β-Catenin. Prior data from the Dorsky lab and others show the Wnt/β-Catenin signaling cascade is required for both axon growth and neurogenesis. However, the cell types that respond to Wnt signaling and the Wnt target genes that promote regeneration remain poorly characterized. Our RNA-seq data show Wnt-dependent regulation of several meningeal marker genes as well as the pro-regenerative fibroblast markers *prrx1a/b*. While Prrx1 has a demonstrated role in regeneration and wound healing across several tissues, a role in nervous system repair has not yet been investigated. Further expression analysis shows that these transcripts are injury-responsive and require Wnt-signaling for their expression. Future work on this project will determine whether meningeal cells, Prrx1+ fibroblasts, and their respective candidate genes, are required for functional recovery after SCI.

1076T **Investigating the Role of Cold-Inducible RNA-Binding Proteins A and B (Cirbpa/b) in Balbiani Body Assembly and Translational Repression of Maternal RNAs** Megan N Guerin, Allison H Jamieson-Lucy, Mary C Mullins Cell and Developmental Biology, University of Pennsylvania

For most vertebrates, axial patterning and germline specification during early embryogenesis depend on establishing polarity within the oocyte. The Balbiani body, an aggregate of maternal RNAs, protein, and membrane-bound organelles, initiates polarity by disassembling at the oocyte cortex. Upon fertilization, disassembled components of the Balbiani body translocate towards the blastomeres and have two notable functions: to induce germ cell fate in the cells that inherit these components and to specify the dorsal organizer, the signaling center that orchestrates dorsal-ventral patterning during gastrulation. It is speculated that an additional role of the Balbiani body is to repress the premature translation of maternal RNAs. Although the Balbiani body is indispensable in acquiring polarity, the molecular mechanisms governing its assembly and role in the translational repression of maternal factors remain elusive. Buc is the only known protein to be required for Balbiani body assembly, which in *bucky ball* mutant females fails to form, resulting in polarity defects that cause embryonic lethality. Biochemical analysis revealed that Balbiani body assembly during oogenesis depends on the self-aggregation properties of the Buc prion-like domain. Our lab has discovered that the zebrafish Balbiani body proteome contains three proteins predicted via bioinformatics analysis to possess prion-like domains: Buc and Cold-Inducible RNA-Binding Proteins A and B (Cirbpa/b). Cirbpa/b are excellent candidates to modulate Balbiani body assembly and function as they possess both a prion-like domain and an RNA-recognition motif within their protein structure, which suggests that they have self-aggregating and RNA-binding abilities. We have generated a mutant Cirbpa CRISPR allele and obtained a mutant Cirbpb allele from the Zebrafish Mutation Project to further investigate the role of Cirbpa/b in Balbiani body assembly and translational repression of maternal RNAs during oogenesis. I will report on my analysis of maternal Cirbpa/b double mutants and observed Balbiani body defects. This research is supported by NIH NIGMS award number R35GM131908.

1077T **A zebrafish gill model of mammalian lung endothelium** Jong Park[1,2], Celia Martinez-Aceves[1], Daniel Castranova[1], Louis Chip Dye[1], Chris Dell[3], Melissa Mikolaj[3], Madeline Kenton[1], Gennady Margolin[1], Van Pham[1], Kedar Narayan[3], Brant Weinstein[1] [1]NICHD/NIH, [2]NIGMS/NIH, [3]NCI/NIH

Endothelial cells (ECs) are a critical component of the lungs and are essential for regulating gas/electrolyte exchange and immune responses. Dysregulation of ECs in the lungs is involved in major cardiopulmonary diseases. Recent studies in mice identified a novel population of lung ECs, “Aerocytes,” that likely play a key role in gas exchange and respiratory pathophysiology. However, the developmental origins and specific functions of these unusual cells are still unknown due to difficulties in observing and manipulating them in vivo in mammalian lungs. Although zebrafish gills function in an aqueous environment, they facilitate gas exchange and share functionally equivalent cell types with lungs. Unlike mammalian lungs, however, externally situated zebrafish gills are readily accessible for high-resolution optical imaging and experimental manipulation, making the fish an excellent comparative model for studying the origins and function of gas exchange endothelium in vivo. We have performed confocal imaging of EC transgenic reporter lines and transmission electron microscopy to characterize gill vascular development and morphology. We have also carried out scRNAseq on dissociated adult zebrafish gills, identifying several distinct novel populations of ECs in the gill, including ECs with a molecular profile that strongly resembles mammalian Aerocytes. In situ hybridization chain reaction (HCR) revealed that zebrafish Aerocytes localize to the highly vascularized lamella of the gill where gas exchange is taking place. We are currently generating transgenic lines marking these cells to better characterize their developmental origins and function. Together, our findings will help establish a new experimentally accessible comparative vertebrate model for studying the development and pathologies of mammalian lung gas-exchange endothelium. This research was funded by the NICHD Intramural research program (to BMW).

1078T **Investigating the role of cytoskeletal dynamics during epiboly morphogenesis in the zebrafish** Bakary Samasa[1], Joe Zinski[2], Mary C. Mullins[2] [1]Cell and Developmental Biology, Perelman School of Medicine at the University of Pennsylvania, [2]Perelman School of Medicine at the University of Pennsylvania

Epiboly is the first coordinated morphogenetic cell movement during zebrafish development, wherein the cells of the embryo spread over and envelop the yolk. These morphogenetic movements are essential to the transition from a group of individual cells to the formation of a body plan during development. Thus, the dynamics and regulation of epiboly remains a fundamental question in biology. Epiboly is initiated by yolk cell doming which is coupled to oriented cell divisions that lead to an expansion of an epithelial enveloping cell layer (EVL). However, the mechanism/s of epiboly progression remain unclear. Here, we investigate the roles of p38 mitogen activated kinase (MAPK) and its substrate Mapkapk2 in epiboly progression. Embryos from homozygous maternal-effect *mapkapk2* null mutant females and dominant-negative p38 expressing embryos exhibit a defect in epiboly wherein the blastoderm margin constricts circumferentially beginning at the 50% epiboly stage, causing the yolk cell to burst. It has been shown that Mapkapk2 functions in the yolk cell to regulate epiboly progression, where it is hypothesized to modulate actomyosin-based contractility. Here I use live and fixed imaging of actin to investigate cytoskeletal dynamics to understand the role of actin dynamics in mediating Mapkapk2 and p38 driven epiboly progression. These initial results set the stage for further investigation of epiboly dynamics in other mutants and fluorescent reporter lines of the cytoskeleton and adhesion factors.

1079T **Investigating Fer Kinase expression during brain development in zebrafish** Madison Korkeakoski, Marissa Bell, Aaron Putzke Whitworth University

Fer kinase is a non-receptor tyrosine kinase that has been highly conserved during evolution across invertebrates and vertebrates alike. This protein is known to play a role in cell-cell adhesion, cell proliferation, and has been linked to the regulation of cancer cell progression and survival. While it is known that Fer is generally required for proper development, in vivo functions of Fer during various developmental stages are not widely described. Previously, we have shown that Fer is required for normal red blood cell development in embryonic zebrafish, in addition to demonstrating important kinase independent functions of Fer that require it for normal vasculature organization. In this study, we demonstrate Fer Kinase expression in the brain during zebrafish embryogenesis with a focus on retinal and neural tube formation, visualized through whole mount in situ hybridization and cryosectioning, as well as knock-down experiments using morpholino analysis.

1080F **Characterizing the role of a novel sperm-supplied protein, SPSP-1, during spermatogenesis and early development in Caenorhabditis elegans** Darline Murat[1], Nancy Duker[2], Ji Kent Kwah[1], Frank Doring[3], Aimee Jaramillo-Lambert[1] [1]University of Delaware, [2]Rutgers University, [3]University of Kiel

SPE-11 is a spermatogenesis specific protein that produces a paternal effect lethal phenotype when mutated (Browning et al.1996). spe-11 mutations have been linked to improper egg activation including defects in eggshell formation, oocyte polar body formation, failure in the first mitotic spindle orientation, and incomplete cytokinesis (Browning et al.1996; L'Hernault et al. 1988; Jaramillo-Lambert & Golden, 2020; McNally & McNally, 2005). In an effort to find interacting partners of SPE-11, a Yeast 2 Hybrid screen was performed and spsp-1 (Sperm Partner of SPE-11) was identified as a potential interactor. spsp-1 is a novel gene, thus the function of SPSP-1 and how it interacts with SPE-11 are still unknown. Two spsp-1 deletion mutant lines were created via CRISPR/Cas9 genome editing (spsp-1Δ1 and spsp-1Δ2). Both spsp-1Δ1 and spsp-1Δ2 have reduced brood sizes at 24℃ compared to wild type. However, wild-type sperm was able to rescue this reduction in brood size indicating a sperm defect. To determine if SPSP-1 plays a role in eggshell formation similar to SPE-11, we performed eggshell permeability assays. The results showed that spsp-1Δ1 and spsp-1Δ2 do not have significant eggshell defects. We also performed localization studies using an N-terminal GFP-tagged SPSP-1 and found that SPSP-1 is expressed in the male germline and colocalizes with SPE-11 during spermatogenesis. Future directions of this study include studying whether SPSP-1 and SPE-11 are reciprocally required for proper localization and epistasis analysis and ultimately determine how SPSP-1 and SPE-11 function in spermatogenesis and egg activation.

1081F **Parallel roles of PAR-1 and UBA-2 in the C. elegans intestine** Melissa Pickett, Zoe Upham Biological Sciences, San Jose State University

Apico-basolateral polarity establishment and maintenance are essential for the function of the epithelial cells that line the organs of animals and act as selective barriers and transporters. Disruption of apico-basolateral polarity is associated with many diseases, including microvillus inclusion disease, polycystic kidney disease, and the progression and metastasis of cancers. The mechanisms underlying apico-basolateral polarity are likely to be highly redundant due to the importance of apico-basolateral polarity for organ function. Indeed, the loss of many polarity proteins individually from epithelial tissues often has only minor effects on the structure and function of the epithelium. Our goal is to elucidate the mechanisms by

which apico-basolateral polarity is established and maintained, using the *C. elegans* intestine as a simple *in vivo* model. We are particularly interested in testing the hypothesis that the conserved polarity kinase, PAR-1/MARK, acts in parallel with UBA-2, a protein involved in SUMOylating pathways, as little work has focused on the role of SUMOylating pathways in apico-basolateral polarity establishment and maintenance. In previous studies, PAR-1 and UBA-2 were redundantly required for the establishment of anterior-posterior polarity in the one-cell *C. elegans* embryo. In a preliminary RNAi screen, we similarly found that intestine specific depletion of PAR-1 (PAR-1$^{gut(-)}$) along with RNAi depletion of *uba-2* arrested worm development while neither PAR-1$^{gut(-)}$ nor *uba-2 RNAi* alone affected worm growth. Therefore, we plan to determine whether UBA-2 is involved in apico-basolateral polarity establishment and maintenance and whether it works redundantly with PAR-1.. We are currently working to endogenously tag UBA-2 with a zinc finger degradation domain and GFP to describe the localization of UBA-2 for the first time. This strategy will also allow us to degrade UBA-2 in a tissue specific manner without affecting its potential roles in other tissues. We will further be able to concurrently deplete both PAR-1 and UBA-2 from the intestine to determine if the two proteins act redundantly in apico-basolateral polarity establishment and/or maintenance Here, we will report on the localization of endogenous UBA-2 in the *C. elegans* embryo and larval stages. We will further report on the growth and localization of polarity proteins in worms depleted of intestinal PAR-1, UBA-2, or simultaneously depleted of both PAR-1 and UBA-2 compared with controls.

1082F **A bacterial genetic screen to identify how diet regulates *C. elegans* germline stem cells** Katherine X Norton[1], Elisa Taine[1,2], Julia Burnett[1], E. Jane Albert Hubbard[3] [1]NYU Grossman School of Medicine, [2]Université Paris Cité, [3]Cell Biology, NYU Grossman School of Medicine

Stem cells are capable of self-renewal and of producing cells that differentiate, and they can respond to changes in an organism's environment such as the quantity and quality of its diet. In many stem cell systems, the stem vs. differentiated cell fate decision is controlled via interaction with a stem cell niche. In the *C. elegans* germ line, ligands for the Notch receptor are expressed in the niche, the distal tip cell (DTC), which activate a Notch receptor (GLP-1) in neighboring germ cells to maintain stem cell fate.

Previously, our lab found that DAF-7 TGFß, the neuronal expression of which is modulated by diet, acts through its receptor DAF-1 on the DTC such that diet alters the expression of *lag-2,* a ligand for Notch, thereby modulating the number of germline stem cells that accrue during larval stages (Dalfó et al., 2012 *Current Biology*; Pekar et al., 2017 *Development*). However, we do not know the specific components of the *C. elegans* diet that act on this TGFß "neuron-to-niche" axis to regulate germline stem cell fate.

To identify key dietary components, we screened through the Keio *E. coli* mutant library for mutants that when fed to worms, affected a read-out of the neuron-to-niche axis. In a prior study (Venzon et al., 2022 *Cell Host and Microbe*), the readout was a fertility assay. Although the screen generated interesting hits, none were related to expression of *lag-2* in the DTC. Therefore, we developed a new screening strategy. In high through-put 96-well liquid format, we tracked a *lag-2* promoter-driven DTC marker that is visible in wild-type worms but is not visible when the DAF-7 TGFß axis is perturbed. Counts of both worms and detectable DTCs were automated, and we developed a pipeline for scoring that considered the density of the bacteria and the number of scorable worms. Secondary screening tested candidate bacterial mutants for robust reproducibility. Primary screening identified 317 candidates from the Keio library (3,985 mutants). From these, one candidate emerged from the secondary screen that reduced detection of the *lag-2*-driven reporter in the DTC. We validated that this Keio library mutant deletes the gene *sodB* (*ΔsodB*). *SodB* encodes a superoxide dismutase enzyme and is one of three superoxide dismutases in *E. coli*. We are testing several hypotheses for how *ΔsodB* might impair expression of the *lag-2* reporter, and whether the effect is dependent on TGFß signaling.

1083F **The Secreted Protein SPE-36 is Dependent on Multiple Other Proteins for Proper Localization in *C. elegans* Sperm** A›Maya Looper, Amber Krauchunas Biological Science, University of Delaware

Fertilization is the process by which sperm and egg fuse to give rise to a zygote. Defects in fertilization can result in sterility. We use the model organism *C. elegans* to study a sperm-specific fertilization defective mutant known as *spe-36. spe-36* belongs to a group of 10 sperm-specific genes required for fertilization. The loss of any single one of these genes renders the worm sterile, but otherwise a healthy adult. Sperm from the mutant are morphologically identical to that of wild-type sperm, however, they fail to fertilize an egg. Together with proteins on the egg›s surface, these sperm proteins help form the fertilization synapse.

In WT, SPE-36 localizes to the membranous organelles (MOs) of spermatids. In spermatozoa, SPE-36 localizes to the pseudopod of the active sperm and the cell body. Because SPE-36 is a secreted protein, we hypothesize that it requires a binding partner to keep it associated with the pseudopod of spermatozoa. We set out to test if SPE-36 localization is dependent on other

sperm-specific fertilization proteins. In order to test this, we are crossing SPE-36::GFP into mutant backgrounds of each of the 9 other proteins. Thus far we have crossed SPE-36::GFP into five different mutant backgrounds: *spe-9, spe-38, spe-13, spe-42* & *spe-49*. Live imaging data shows that SPE-36 localization is dependent on *spe-9, spe-38, spe-13, spe-42* & *spe-49*. In each mutant background, SPE-36 fails to localize to the pseudopod.

These data adds more knowledge to the field and further supports the model that multi-protein complexes help mediate gamete interactions and fusion. In the future, we aim to test if SPE-36 localization is similarly dependent on the other four known sperm-specific fertilization proteins.

1084F **The role of spectrin-mediated mechanotransduction in the morphogenesis of a large extracellular structure in *C. elegans*** Prioty F Sarwar[1], Trevor J Barker[2], Meera V Sundaram[1] [1]Genetics, University of Pennsylvania, [2]University of Pennsylvania

The apical extracellular matrix (aECM) lines, shapes and protects exposed surfaces in animals and often organizes to form elaborate, acellular structures like the scales of a butterfly wing or *Drosophila* denticles. How animals pattern these large structures during development is poorly understood, in part due to the immense diversity of these anatomical features found in the animal kingdom. The *C. elegans* alae, ridges that run along the sides of the worm in three long 'racing' stripes, are an example of one such extracellular structure. Here, we study how a set of cytoskeletal proteins organize at the lateral epidermis at the last larval stage of *C. elegans* development for the *de novo* formation of the adult alae.

Previous research in the lab found that four longitudinal actin filament bundles (AFBs) form at the lateral epidermis, similar to the AFB organization reported in patterning butterfly wing scales or *Drosophila* bristle ridges. We also found that a transient aECM known as the pre-cuticle is required for alae formation. Additionally, ultrastructural data revealed a potential role of pre-cuticle delamination in alae morphogenesis, where four small horizontal areas of delamination demarcate the valleys observed between the developing alae. One hypothesis generated by this observation is that the longitudinal AFBs exert mechanical forces on the overlying matrix to trigger pre-cuticle delamination.

We tested several cytoskeletal proteins that have actin binding and plasma membrane binding domains, making them ideal candidates to aid in the assembly of AFBs at the lateral epidermis and/or facilitate AFB-mediated mechanical forces on the matrix. Super-resolution imaging shows that the spectraplakin VAB-10 and intermediate filament bundles are arranged in a single line at the middle of the lateral epidermis offset from AFBs, while the βH-spectrin SMA-1 is found superimposed on the AFBs. Additionally, *sma-1* null mutant worms show disorganized pre-cuticle and alae structure and reduced mechanosensitive protein localization at the lateral epidermis. Overall, our data support the hypothesis that mechanical forces relayed by cytoskeletal structures play a role in the formation of the *C. elegans* adult alae.

1085F **The role of different PAR-3 domains in establishing and remodeling apico-basolateral polarity across the intestine** Mariam Mortada, Alyza J Escuadro, Adam Brewer San Jose State University

The polarized localization of proteins to specific cellular domains is essential for the function of many cell types, including the epithelial cells that line the organs of all animals. This polarity is critical in creating barriers against pathogens, directing transport of molecules, and providing mechanical resilience to organs, and loss of polarity can lead to diseases including cancerous tumor formation and metastasis. PAR-3 is a conserved scaffolding protein that is required for polarity establishment across epithelial tissues of many species. Previous work using continuous intestine specific depletion of PAR-3 in C. elegans demonstrated that PAR-3 was necessary for the correct timing of polarity establishment and for the formation of a continuous hollow lumen. PAR-3 was found to be dispensable during polarity maintenance in larval worm stages. Surprisingly, when we expressed PAR-3 in the first larval stage (L1) after depleting PAR-3 during polarity establishment in embryonic stages, we found that the cystic intestines were remodeled leading to continuous hollow lumens and correctly oriented apical-basolateral polarity axes in ~30% of the worms. We are currently interested in determining the efficacy of this recovery and in determining which domains of PAR-3 are necessary for the establishment and remodeling of apico-basolateral polarity across epithelial tissues, using the C.elegans intestine as a model. We are testing the hypothesis that the same domains of PAR-3 are necessary in coordinating apico-basolateral polarity establishment and in the observed remodeling. Therefore, we deleted specific domains (PDZ 1-3, PDZ-1, PDZ-2, PDZ-3, the oligomerization domain, or CR3) from PAR-3 and are expressing them either during polarity establishment or in the larval remodeling phases in worms in which endogenous PAR-3 is continuously depleted to determine if the mutated versions are capable of rescuing polarity establishment and intestinal remodeling.

1086F **Establishing an auxin-inducible degron system to dissect spatiotemporal function of GLD-2** Karl-Frederic Vieux[1], Graciela Galvez[2,3], Katherine McJunkin[4] [1]Laboratory of Cellular and Developmental Biology, National Institute of Health, [2]National Institutes of Health, [3]Department of Biology, Colgate University, [4]Laboratory of Cellular and Developmental Biology, National Institutes of Health

RNA translation and stability are critical to reproduction and development. Tailing is the addition of nucleotides to the 3' end of RNA molecules in an untemplated manner. It is mediated by terminal nucleotidyl transferases (TENTs), and it modulates RNA translation and stability. Historically, long poly(A) tails have been associated with stable and highly translated transcripts. However, new high-throughput sequencing methods show the incorporation of non-A-residues in tails and suggest that both nucleotide composition and length determine tail function. RNA tails in the oocyte and early embryo are particularly dynamic, yet our understanding of their function and requirement in oogenesis is limited. GLD-2 is a noncanonical TENT that specialize in cytoplasmic poly(A) tailing. Global loss of *gld-2* prevents the initiation of meiosis and a complete loss of oocytes in the *C. elegans* germline. Here, the auxin-inducible degron (AID) system was used to conditionally deplete *gld-2* expression in the germline of hermaphrodite adults. Unlike a global knockout of *gld-2*, germline-specific depletion of GLD-2 in adults did not prevent the initiation and progression of meiosis: diakinetic oocytes were observed at the distal end of gonads for several days after auxin treatment. This difference may be explained by the broad timing and the ubiquitous nature of a *gld-2* depletion in a null mutant. Yet, triggering the depletion of GLD-2 at larval stages did not recapitulate null phenotypes, nor did a ubiquitous depletion of GLD-2. Within 4hr of auxin induced GLD-2 depletion, these conditional mutants exclusively lay dead embryos that arrest at the early stages of embryogenesis, phenocopying long term *gld-2* RNAi experiments. Fertilization by wild-type sperm does not rescue this embryonic defect. Future experiments will determine the exact developmental and tissue-specific GLD-2 requirements for germline establishment and the initiation of meiosis using the AID system. The acute spatiotemporal control of GLD-2 expression with this system can then be leveraged to broadly identify GLD-2 functional targets in oocytes and early embryos. A novel direct cDNA sequencing method (Nano3P-seq) will be used to accurately resolve mRNA tail length and composition in the absence of GLD-2. These results will shed light on the cellular and physiological implications of RNA tailing and identify molecular pathways that determine terminal oocyte differentiation and embryonic viability.

1087F **Identifying genes involved in the *kin-20* developmental pathway in *C. elegans* through a forward genetic screen** Jadan Hand[1], Vivian Viacobo[2], Michelle Coluzzi[1], Priscilla Van Wynsberghe[1] [1]Biology, Colgate University, [2]Colgate University

C. elegans exhibit rhythmic processes and express an ancestral form of the circadian clock which impacts development and developmental timing. Central to this clock is the transcription factor, Period, whose homolog in *C. elegans* is LIN-42. Like other Period proteins, LIN-42 levels oscillate throughout development. This oscillation pattern is thought to be due in part to the putative kinase KIN-20, whose homolog is Doubletime in Drosophila and CK1ε in humans. Prior work in our lab has shown that *kin-20(ok505) C. elegans* exhibit decreased fertility, a slow growth rate, and an uncoordinated phenotype. Thus, KIN-20 likely impacts other targets beyond LIN-42 to play a significant role in organismal development. To better understand this role, we have begun a forward genetic screen to identify suppressors of these *kin-20(ok505)* phenotypes. To do this, *kin-20(ok505)* worms were exposed to ethyl methanesulfonate (EMS), and F2s were screened for suppressors of the *kin-20(ok505)* delayed growth and movement phenotypes. Populations of suppressors were then more systematically compared to WT N2 worms to identify top candidates for further analysis. Current work aims to further characterize these candidates before identification of mutations by whole-genome sequencing. Altogether this work will increase our understanding of the various functions that this important, conserved gene plays in development.

1088F **Expanded roles for LOTR-1 in the *C. elegans* germline** Noah A Lind[1], Elisabeth Marnik[2], Catherine Sharp[1], Dustin Updike[1] [1]Mount Desert Island Biological Laboratory, [2]College of Science and Humanities, Husson University

LOTUS and Tudor domain-containing proteins play a crucial role in forming biomolecular condensates that support the inheritance of small RNA and germ cell functionality.[1] One such protein, the *C. elegans* TDRD5 homolog LOTR-1, interacts with the helicase ZNFX-1 in cytoplasmic Z-granules to ensure the even distribution of small RNAs across WAGO and Mutator targets.[2] Interestingly, LOTR-1 recruits two essential subunits of the *nuclear* CstF 3'UTR cleavage and polyadenylation complex, CPF-1 and SUF-1, to the *cytoplasmic* LOTR-1/ZNFX-1/WAGO complex.

In Xenopus oocytes, SUF-1/CstF-77 is primarily nuclear but is also found in foci outside the nucleus that contain cytoplasmic polyadenylation proteins (e.g., GLD-2) and the cap-binding initiation factor eIF4E; however, the function of cytoplasmic CstF-77 is unclear and may potentially reduce translation efficiency.[3] Here, we look closely at the nuclear and the cytoplasmic retention of SUF-1-tagged reporters in wild-type and domain-specific *lotr-1* mutants. Localization studies are complemented with total RNAseq and polysome-RNAseq in wild-type and domain-specific *lotr-1* mutants to compare differential expression, differential translation, and identify potential differences in 3'UTR modifications. These investigations aim to clarify LOTR-1's role in the germline and elucidate the function of nuclear CstF factors retained in cytoplasmic condensates.

1089F **Dissecting the gene regulatory networks controlling temporal dynamics of post-embryonic C. elegans somatic gonad development** Brian Kinney[1], Fred Koitz[1], Jason Menjivar[2], Ryan Merritt[1], Christopher Hammell[3], Kacy L Gordon[1] [1]Biology, University of North Carolina, [2]University of North Carolina, [3]Cold Spring Harbor Laboratory

C. elegans larval development consists of four molts in which major genetic and cellular events must be precisely coordinated to shed and regrow the cuticle covering the animal's body. The major genetic regulators of larval developmental timing were identified with the discovery of heterochronic mutants, animals that either continuously repeat or skip developmental events during the larval stages. The genes that make up the core of the developmental timer generate oscillatory expression of *lin-4* miRNA every molting cycle; my recent work revealed that this oscillation is controlled by the *C. elegans* orthologs of highly conserved circadian regulators *nhr-23* (ROR), *nhr-85* (Rev-erb), and *lin-42* (Period). The larval skin operates under this oscillating developmental timer as it undergoes repeated cycles of molting and regrowth, characterized by pulsatile expression of *lin-42*/Period. However, the somatic gonad still develops in a *lin-4* mutant along its linear timeline of migration led by the distal tip cell (DTC), which also acts continuously as the germline stem cell niche. I have discovered that the oscillation of *lin-42* can nevertheless be observed in the DTC with the same period as the pulses in larval skin, suggesting common regulation across tissues. Yet, we found that the developmental regulators of *lin-42* in the larval skin (*nhr-85* and *nhr-23*) are dispensable for proper DTC migration. We set out to discover the regulators and role of the developmental genetic timing system in the DTC, where its known regulators (*nhr-23* and *nhr-85*) and primary target (*lin-4*) are dispensable for proper migration. DTC migration is known to be regulated in part by heterochronic factors such as *lin-42*, *blmp-1*, and *lin-29*, but their transcriptional relationships are not known. Additionally, while *blmp-1* was thought to act only as a repressor in the DTC, recent studies in other cells have shown that it can also act as a pioneer factor. We have found that *blmp-1* acts as a pioneer factor in the DTC and is necessary for localization of integrins necessary for DTC migration. Using yeast 1-hybrid screening we have set out to find the candidates that transcriptionally link *blmp-1* to the effectors of DTC migration. Using genetic techniques and live-imaging confocal microscopy we will uncover the transcriptional gene regulatory networks that regulate DTC migration timing to understand how timing of developmental processes are synchronized across different tissues of the body.

1090F **MLT-11 is necessary for C. elegans embryogenesis and apical extracellular matrix structure** James M Ragle, Ariela Turzo, John C Clancy, Keya Jonnalagadda, Anton Jackson, Max T Levenson, An A Vo, Vivian Pham, Jordan D Ward Molecular, Cell, and Developmental Biology, UC Santa Cruz

Apical extracellular matrices (aECMs) are associated with all epithelia and form a protective layer against biotic and abiotic threats in the environment. Despite their importance, we lack a deep understanding of their structure and dynamics in development and disease. C. elegans molting offers a powerful entry point to understanding developmentally programmed aECM remodeling. A transient matrix is formed in embryos and at the end of each larval stage, presumably to pattern the new cuticle. A number of proteases and protease inhibitor genes are required for this process but their exact functions remain poorly understood. Focusing on targets of NHR-23, a key transcription factor which drives molting, we identified the Kunitz family protease inhibitor mlt-11 as an NHR-23 target. MLT-11 is an unusual predicted protease inhibitor with 10 Kunitz domains. We identified NHR-23-binding sites that are necessary and sufficient for epithelial expression. We generated internal and C-terminal MLT-11::mNeonGreen::3xFLAG (MLT-11::mNG) knock-ins through CRISPR which displayed distinct localization patterns. The C-terminal fusion displayed weak localization in the cuticle and strong lysosomal localization. In contrast, the internal knock-ins displayed more robust cuticular localization with a striking pattern lining the cells of the vulval lumen. Western blot analysis suggested that MLT-11 is processed into two fragments and structure function analysis implicates defects in the N-terminal fragment in a right roller phenotype while the defects in the C-terminal fragment cause embryonic lethality. Deletion of parts of both the N-terminal and C-terminal fragments produced a synthetic phenotype with severe developmental delay, cuticle blistering, and small body size. Tissue-specific RNAi suggests that mlt-11 activity is primarily necessary in seam cells and we observe seam cell fusion defects when we deplete mlt-11. Together, these data show that MLT-11 plays multifunctional roles to coordinate aECM structure and function during development.

1091F ***Sperm-specific sterility conferred by XND-1 paralogs in* Caenorhabditis elegans** Sharon Li[1], Cristina Quesada Candela[2], Judith L Yanowitz[3] [1]Magee-Womens Research Institute, University of Pittsburgh, [2]Chromosome Biology, University of Vienna-Vienna BioCenter, [3]OBGYN, Magee-Womens Research Institute, U. Pittsburgh Sch. of Medicine

The chromatin factor X-nondisjunction factor (XND-1) plays important roles in double strand breaks (DSBs) during meiotic

crossover formation and in regulating germline differentiation. XND-1 has two distant paralogs in *C. elegans*, Y54G2A.26 and Y54G2A.73, that we have nicknamed XLP-1 and XLP-2 (XND-1-like proteins-1, -2) for simplicity. There was no known mutation for *xlp-1*, so we created a complete knock-out of the coding region using CRISPR. We obtained a deletion allele of *xlp-2* from the CGC. Mutations in both *xlp-1* and *xlp-2* were found to be sperm sterile mutants (SPE): hermaphrodites are self-sterile but can be rescued by outcrossing; males are sterile. Through further testing, we found that *xlp-1* sperm fail to undergo spermiogenesis and exhibit defects during the meiotic cell divisions. Our progress in characterizing the defects in both sets of mutants and in determining protein localization will be presented.

1092F **CED-5/CED-12 (DOCK/ELMO) can promote and inhibit F-actin formation via distinct motifs that target different GTPases** Yeshaswi Pulijala, Thejasvi Venkatachalam, Kavya Kadabageri, Maria Dawood, Rose Swan, Martha Soto Pathology and Laboratory Medicine, Rutgers (RWJMS)

Coordinated activation and inhibition of F-actin supports the movements of morphogenesis. Understanding the proteins that regulate F-actin is important, since these proteins are mis-regulated in diseases like cancer. Our studies of *C. elegans* embryonic epidermal morphogenesis identified the GTPase CED-10/Rac1 as an essential activator of F-actin. However, we need to identify the GEF, or Guanine-nucleotide Exchange Factor, that activates CED-10/Rac1 during embryonic cell migrations. The two-component GEF, CED-5/CED-12, is known to activate CED-10/Rac1 to promote cell movements that result in the engulfment of dying cells during embryogenesis, and a later cell migration of the larval Distal Tip Cell. It is believed that CED-5/CED-12 powers cellular movements of corpse engulfment and DTC migration by promoting F-actin formation. Therefore, we tested if CED-5/CED-12 was involved in embryonic migrations, and got a contradictory result. CED-5/CED-12 definitely support embryonic migrations, since their loss led to embryos that died due to failed epidermal cell migrations. However, CED-5/CED-12 inhibited F-actin in the migrating epidermis, the opposite of what was expected for a CED-10 GEF. To address how CED-12/CED-5 could have two opposing effects on F-actin, during corpse engulfment and cell migration, we investigated if CED-12 harbors GAP (GTPase Activating Protein) functions. A candidate GAP region in CED-12 faces away from the CED-5 GEF catalytic region. Mutating a candidate catalytic Arginine in the CED-12 GAP region (R537A) altered the epidermal cell migration function, and not the corpse engulfment function. A candidate GEF region on CED-5 faces towards Rac1/CED-10. Mutating Serine-Arginine in CED-5/DOCK predicted to bind and stabilize Rac1 for catalysis, resulted in loss of both ventral enclosure and corpse engulfment. Genetic and expression studies showed the GEF and GAP functions act on different GTPases. Thus, we propose CED-5/CED-12 support the cycling of multiple GTPases, by using distinct domains, to both promote and inhibit F-actin nucleation. We are investigating how CED-5/CED-12 are recruited to distinct membranes. In addition, we are characterizing additional Guanine-nucleotide Exchange Factors that regulate morphogenesis through the Rac1 GTPase.

1093F **From Migration to Mature Elaboration: Exploring *C. elegans* Stem Cell Niche Transformation via Morphology and Transcriptomics** Xin Li[1], Kin Gomez[2], Adriana San Miguel[2], Kacy Gordon[1] [1]Biology, University of North Carolina, Chapel Hill, [2]North Carolina State University

The *Caenorhabditis elegans* hermaphrodite distal tip cell (DTC) acts as the germline stem cell niche and has served as a model for cell migration and stem cell niche biology. DTCs migrate along a stereotyped path, lead gonad elongation, and determine gonadal morphology during post-embryonic development. At the larval-to-adult transition, the DTC undergoes dramatic morphological changes and grows long processes that wrap adjacent germline stem cells in the distal gonad. Many genes and signaling pathways have been identified that regulate migration and niche behavior. However, how DTC transitions from its gumdrop-shaped migratory state to the elaborated mature niche is still not well understood. We are undertaking an in-depth investigation of this transformation using several approaches. At the morphological level, we are using microfluidics to record the transformation of DTCs from compact cells to large, branched cells. Microfluidics approaches mitigate the risk of germ cell quiescence due to starvation during long-term time lapsing. At the transcriptome level, we are sequencing DTC nuclei across this developmental transition to identify gene expression differences that correlate with DTC elaboration, which will furnish candidates for subsequent studies of niche migration and structure. Furthermore, we are also tagging endogenous loci and analyzing expression patterns of genes that are selectively expressed in the DTC identified in previous transcriptomic studies. By elucidating how a stem cell niche transitions from migratory to stationary and compact to elaborated, our results will provide a more comprehensive vision of genes that regulate cell migration and cell-cell interactions. Because many pathways regulating DTC niche behavior have turned out to be highly conserved in other stem cell niches, our findings will give new insights into the molecular control of niche-stem cell associations that are likely to be acting in other stem cell systems.

1094F **Identification of the spatial requirement for the DAF-2 insulin receptor in food type-dependent oogenesis onset and fertilization in *C. elegans*** Asra Akhlaq, Joy Alcedo Department of Biological Sciences, Wayne State University

The nematode worm *Caenorhabditis elegans* is highly genetically tractable and has hundreds of oocytes that can be easily

imaged *in vivo*. This makes the worm an excellent model in which to dissect the mechanisms that regulate oocyte biology in response to different diets. Recently, our lab showed that the onset of oogenesis and oocyte fertilization rates in *C. elegans* are modulated by the type of bacteria it eats (1). Our lab also found that this bacterial-dependent regulation of oogenesis and oocyte fertilization require the insulin receptor DAF-2 (1). However, the insulin-like peptide (ILP) ligand that regulates onset of oogenesis differs from the ILP(s) that regulate fertilization (1). Because the 40 ILPs in *C. elegans* are expressed in different subsets of cells (2), this raises the hypothesis that the insulin receptor, DAF-2, acts from different cells to regulate diet-dependent oogenesis versus oocyte fertilization rates. To test this hypothesis, we employ the auxin-inducible degron system (AID) to determine in which cells DAF-2 is required to modulate oogenesis or fertilization in response to the worm's bacterial diet. Identification of the cells or tissues in which DAF-2 acts to regulate these two aspects of oocyte biology will potentially delineate two different circuits through which diet regulates oogenesis onset versus fertilization.

1095F ***C. elegans* ALFA-1^{C9orf72}/SMCR-8 functions via ARF-6 to Negatively Regulate LET-23 EGFR via its C-terminal PDZ interaction motif.** Ahmed Sabbir[1], Aida Sobhani[1,1], Stephanie Deng[2], Kimberley Gauthier[2], Christian Rocheleau[1] [1]Anatomy and Cell Biology, McGill University, [2]McGill University

C9orf72 is the most common mutated gene associated with Amyloid Lateral Sclerosis (ALS) and Frontal Temporal Dementia (FTD). C9orf72 forms an obligate complex with SMCR8 to regulate membrane trafficking. Biochemical and structural data indicate that C9orf72/SMCR8 is a GTPase Activating Protein (GAP) for Arf and Rab GTPases *in vitro*, but the *in vivo* targets have not been identified. We have recently found that both homologues of human C9orf72 and SMCR8 in *C. elegans*, ALFA-1 and SMCR-8, negatively regulate LET-23 Epidermal Growth Factor Receptor (EGFR) signaling in an ARF-6 GTPase dependent manner. LET-23 EGFR signals via a Ras GTPase and MAPK cascade to specify vulval cell fates. LET-23 most closely resembles human EGFR family member, ErbB4/HER4, in that they share a C-terminal PDZ interaction motif (PIM). The LET-23 PIM binds the PDZ domain of LIN- 7 (mLin7) which in turn interacts with LIN-2 (CASK) which binds LIN-10 (APBA1) protein to target LET-23 to the basolateral membrane of the *C. elegans* vulva precursor cells. Mutation of the LET-23 PIM or any component of the LIN-7/2/10 complex leads to apical only localization of LET-23 and a strong vulvaless phenotype. We found that *alfa-1* and *smcr-8* deletion mutants strongly suppress the *lin-2(-)* vulvaless phenotype. Surprisingly, we found that *smcr-8* does not suppress the vulvaless phenotype of *let-23(sy1)* which specifically deletes the PIM of LET-23 or a *lin-7* mutant. To our knowledge, this is the first negative regulator of LET-23 EGFR signaling that suppresses *lin-2(-)*, but not *lin-7(-)* or *let-23(sy1).* Our data suggests that ALFA-1/SMCR-8 functions as an ARF-6 GAP to negatively regulate LET-23 EGFR signaling in a manner that is uniquely dependent on LIN-7 and the PIM of LET-23 EGFR. Considering this specific interaction, it is interesting to note that like C9orf72, ErbB4 is also mutated in familial cases of ALS and FTD.

1096F **Exploration of the roles for essential genes in C.elegans male tail tip morphogenesis using the Auxin inducible degron system** Zarifa Z Akbary, Karin Kiontke, David H.A. Fitch New York University

Morphogenesis is the universal process in the normal growth and development of animals as it involves changes in cell shape and position that must be coordinated at precise times and in specific tissues. Disruption in this process can have consequences ranging from embryonic lethality to disease. The C. elegans male tail tip provides an opportunity to address questions of morphogenesis. In males, the tail tip undergoes morphogenesis post-embryonically through the process of tail tip morphogenesis (TTM). In the larvae of both sexes, these cells form a pointed tail, but for males only, during the L4 stage, they fuse, change shape, and retract– resulting in rounded tail by adulthood. Prior findings have shown that the transcription factor, DMD-3 is required and sufficient for TTM to occur. NHR-25, a nuclear hormone receptor, is essential for the initiation of dmd-3 expression. We are addressing when exactly NHR-25 is required for TTM by using AID (auxin inducible degron system). We use a somatic promoter to drive expression of the TIR1 F-box protein in this system, allowing us to degrade NHR-25 during the L3 stage in males and measure the consequences on TTM. Preliminary data showed that there were strong male defects in the tail tip: phasmids were bludging, rays were variably fused or missing, all adult males lacked a hook, had misshapen spicules. We also found hermaphrodites were Pvul and Egl, also indicating that the degron system was effective. Similarly, we are using this system to explore the regulatory roles of other essential proteins involved in TTM, including par-3 and fos-1.

1097F **The evolution of sexually dimorphic morphogenesis.** Raya Jallad[1], Alyssa Woronik[2], Yash Patel[3], Karin Kiontke[3], David H.A. Fitch[3] [1]Biology, New York University, [2]Biology, Sacred Heart University, [3]NYU

Differences between sexes (i.e sexual dimorphism) are common in nature. Although the processes that regulate these

differences vary between taxa, a group of genes known as DM domain transcription factors (DMRTs) play a conserved role in the development of male-specific traits. However, how the development of sexual dimorphism is regulated is insufficiently known. As a model system to better understand the gene regulatory network (GRN) responsible for sexually dimorphic morphogenesis and its evolution, we study the 4 tail tip cells of *Caenorhabditis elegans.* During the last larval stage, in males only, these cells undergo a process known as Tail Tip Morphogenesis **(TTM)**, resulting in short round tail tips in males (hermaphrodites retain the pointed tips of the larvae). The DMRT transcription factor DMD-3 is required and sufficient for TTM in *C. elegans* and is hypothesized to be at the center of a bow-tie GRN (Mason et al. 2008, Nelson et al. 2011). TTM evolved multiple times independently in related nematode species, but how TTM is regulated in these species is unknown. One hypothesis for convergent evolution («hotspot» hypothesis) predicts that the architecture of GRNs biases evolution, such that the same genes/modules are co-opted when similar traits evolve repeatedly. To test this hypothesis for the convergent evolution of TTM, we are comparing TTM transcriptome profiles among several rhabditid species. As a first step in this comparison, we are characterizing transcriptome dynamics in tails of *C. elegans* males, hermaphrodites, and mutants of DMD genes using tail-tip-specific RNA-seq at several time points during the last larval stage, when TTM occurs in males. Because GRNs control cell behaviors at the transcriptional level, the key points involved in GRN evolution are proposed to be transcription factors like DMD-3, their regulation, and their interaction with target genes. Because such transcription factors generally control groups of genes, We are sorting genes into different categories of gene expression dynamic (e.g. static, upregulated, downregulated, etc.) to identify co-regulons. By comparing co-regulon profiles between species where TTM is conserved, independently gained, lost, or is ancestrally absent, we intend to identify which genes/modules are conserved and test the «hotspot» hypothesis for sexually dimorphic morphogenesis.

1098F **TORC2 in *C. elegans* Germline Development** Anke Kloock, E. Jane Albert Hubbard Department of Cell Biology, NYU Grossman School of Medicine

Certain populations of proliferating cells – from stem cells to tumors – are nutrient-responsive. Signaling pathways relay information about the surrounding environmental or organismal nutrient conditions to these pools of cells. One such pathway is the Target of Rapamycin (TOR) pathway. The TOR kinase exists in two complexes, TOR complex 1 (TORC1) and TOR complex 2 (TORC2). TORC1 has been researched extensively and its regulation, particularly by amino acids, is well characterized. In *Caenorhabditis elegans*, previous work from our lab showed that low nutrient conditions impede the establishment of the germline stem cell pool in larval stages. In one case, we determined that germline-autonomous TORC1 is required to establish the stem/progenitor pool and that nutrient conditions are relayed by germline autonomous activity of S6 kinase, a target of TORC1. By contrast, while TORC2 has been characterized for its roles in dauer entry, fat storage and body size, mitochondrial homeostasis and brood size, its role in germline stem cell development has not been previously investigated.

To begin to investigate whether and how TORC2 affects the germline stem/progenitor cell pool, and if it relays a response to nutrients, we are characterizing the role of the key TORC2 component, *rict-1*/Rictor. We generated four CRISPR/Cas9 *rict-1* null alleles and found that worms carrying these mutations fail to properly expand the germline stem/progenitor pool during development. We also noticed that the extent to which the germline stem/progenitor pool expands in *rict-1* mutants is somewhat dependent on their particular bacterial diet. Further, unlike the germline-autonomous roles of TORC1 components, the stem/progenitor pool defect of *rict-1* mutants can be rescued non-autonomously by expression of *rict-1* in the intestine alone. I am currently testing several hypotheses for how intestinal TORC2 activity regulates the size of the germline stem/progenitor cell pool, and its possible connections to nutrient availability. Due to the high conservation of TORC2 these results can have implications for how Rictor/TORC2 are non-autonomously regulating other pools of proliferating cells.

1099F **Characterization of the *C. elegans* intestinal transcriptome with spatiotemporal resolution** Justin Ellis, Robert Williams, Erin Nishimura, Jessica Hill BMB, Colorado State University

At a mere 20 cells, the *Caenorhabditis elegans* intestine functions to regulates digestion, energy homeostasis, and host defense, all while dynamically responding to its environment. It also serves to direct yolk production for the next generation and signals genetic aging. However, how these functions are regulated throughout the intestine remains unclear. The current model assumes monolithic function, uniformly performing organ-specific processes throughout the intestine and overlooks its multifaceted roles. Although sparse, research supports the spatial patterning of select transcripts among intestinal cells, lending itself to the cellular and morphological differences observed throughout the *C. elegans* intestine. Given this, we think a more accurate hypothesis is that the intestine carries out its intestinal functions heterogeneously throughout, resulting in sub-functionalized intestinal cells. Here, we seek to spatiotemporally resolve the intestinal cell transcriptome and determine if intestinal cells indeed take on specific sub-functions. To assess intestinal cell gene expression profiles, we used Fluorescence Activated Cell sorting (FACs) combined with single cell RNA sequencing (scRNA-seq). This allowed us to generate a complete transcriptional profile of the *C. elegans* intestine in a mixed stage embryo population. After identifying unique intestinal cell clusters, we then have to link them with their specific cell identity post hoc. To do this, we use small molecule inexpensive

Fluorescent In Situ Hybridization (smiFISH). This allows us to visualize individual mRNA molecules and assess their spatial expression throughout the intestine. By clustering on cellular gene expression profiles, we found that several unique intestinal cell states could be identified through scRNA-seq, supporting a heterogenous model of intestinal gene expression. From these intestinal clusters, we then selected marker genes to probe using smiFISH. One notable marker gene probed is *clec-56*, a C-type lectin. Turning on at the 1.5-fold stage, *clec-56* displays spatial localization within the mid intestine and is sequestered to four intestinal cells. This preliminary data advances our current understanding of intestinal physiology within *C. elegans* and begins bridging a critical knowledge gap in the field. Moreover, it sheds light on if and how critical functions are sub-functionalized throughout the intestine and spatiotemporally regulated over developmental time.

1100F **Assessment of heterogeneity within the *Drosophila* germline stem cell niche** Jennifer Viveiros, Ambarisha Samantaray, Erika Matunis Cell Biology, Johns Hopkins School of Medicine

Adult stem cells reside in dynamic, supportive microenvironments termed niches, which are generated by specialized niche cells. Niches are often complex and composed of functionally cooperative subpopulations of cells rather than uniform populations. Gaining insight into niche composition is fundamental to our understanding of tissue homeostasis. Using the *Drosophila melanogaster* testis stem cell niche as a model, we can further our understanding of stem cell niches by investigating their cellular composition and gene expression programs. This niche contains three cell populations: post-mitotic somatic hub cells (or niche cells), which are surrounded by two types of stem cells, germline stem cells (GSCs) that differentiate into sperm, and cyst stem cells (CySCs) that give rise to somatic support cells. Previous *in situ* hybridization (ISH) and immunostaining experiments have suggested that hub cells may not uniformly express the same transcriptional program, raising the possibility that they are a heterogeneous population of cells. Intriguingly, hub cells descend from somatic gonadal precursors (SGPs), which arise from three distinct parasegments (PS) in embryogenesis, suggesting that developmental origin could underly previously observed heterogeneity. Here, we examine hub cell heterogeneity with respect to function, origin, and position. We observe that not all hub cells require expression of proteins integral to anchoring the hub to the basement membrane but loss of these proteins in the entire hub alone displaces the cluster of cells. Using lineage tracing tools, we find that adult hub cells arising from PS 11 do not differ in position or signaling compared to their counterparts in unperturbed testes. These findings will begin to determine if hub cells are functionally distinct and whether developmental origin correlates with function, localization within the niche, and transcriptional program.

1101F **The *Drosophila* ovary as a model to identify transcriptional targets of the Frazzled receptor** Rhegan M. Murray[1], Kierra P. Parsons[1], Camila M. Barrios-Camacho[2], Greg J. Bashaw[2], Kaitlin M. Laws[1] [1]Biology, Randolph-Macon College, [2]Neuroscience, University of Pennsylvania

In the fruit fly *Drosophila melanogaster,* quality checkpoints during oogenesis prevent female energy investment in low-quality oocytes. For example, either aberrant development or suboptimal nutritional status can activate the mid-oogenesis checkpoint, leading to germ cell degeneration through apoptosis. We previously reported that the axon guidance receptor Frazzled [Fra; Deleted in colorectal cancer (Dcc) in vertebrates] regulates the mid-oogenesis checkpoint. Specifically, germline loss of Fra leads to germline apoptosis at mid-oogenesis; however, how Fra controls oocyte development remains unclear.

Previous investigations of Fra/Dcc signaling focused on the nervous system, where Fra responds to its Netrin ligands to regulate axon guidance and circuit formation. In *Drosophila* commissural neurons, Fra also acts independently of Netrins to regulate gene expression through the transcriptional activity of its intracellular domain. While several players in this Netrin-independent pathway have been identified, only one transcriptional target of Fra is known. Although Netrins are expressed in the adult ovary, *netrin* mutants do not activate the mid-oogenesis checkpoint, and oocytes mature normally. Instead, germ cells require the transcriptional activity of Fra to develop into mature oocytes.

Our central hypothesis is that the transcriptional activity of Fra controls expression of genes that regulate oocyte quality. We expected that transcriptional targets of *frazzled* would also be expressed in the germline and required for progression through mid-oogenesis. To identify these transcripts, we sequenced the transcriptomes of ovaries with and without germline Fra. We identified 177 differentially expressed genes, 155 of which are reported to be expressed in the wild-type ovarian germline. To validate candidate gene expression, we are using publicly available genetic reagents, including gene and enhancer traps. We are concurrently investigating the role of these candidates in the ovary using genetic analyses with both behavioral and morphological readouts. For example, we are using transgenic RNAi lines to reduce candidate gene expression specifically in the fly germline. If the candidate, like Fra, promotes germline survival, we expect these flies to lay fewer eggs than age-matched controls and, upon dissection, to observe cell death at mid-oogenesis. Follow-up experiments will determine whether observed phenotypes are Fra-dependent. Together, these studies will serve as a model for future investigations of guidance receptor signaling in the *Drosophila* ovary and invite comparisons to mechanisms used in the nervous system.

1102F **Bruno1 Isoforms have distinct functions during IFM Myogenesis in *D. melanogaster*** Jenna DeCata[1], Elena

Nikonova[2], Thomas Harr[2], Danei Smith[1], Maria L. Spletter[1] [1]School of Science and Engineering, University of Missouri- Kansas City, [2]Physiological Chemistry, Ludwig-Maximilians-Universitat Munchen

Different muscle fiber types have distinct morphologies and contractile abilities that are established during development by the expression of fiber-type specific isoforms of structural proteins. Developmental and fiber-type specific patterns of isoform expression are regulated through alternative splicing. RNA-binding proteins (RBPs) including members of the conserved CELF (Bruno) family regulate alternative splicing in muscle. Our previous work demonstrated that Bruno1 (Bru1) is required for indirect flight muscle (IFMs) development in *D. melanogaster*, and we recently uncovered a requirement for Bru1 both in early muscle development and later during maturation of the sarcomeres. Bru1 regulates a developmental switch in IFM-specific sarcomere gene isoform expression. Curiously, Bru1 is itself alternatively spliced, but specific functions of the long (RB), middle (RA), and short (RD) isoforms are currently unknown. To test if different Bru1 isoforms have distinct roles in myogenesis, Gal4-UAS was used to control when and where Bru1 isoforms are expressed. Him-Gal4 and Fln-Gal4 were used to drive early and late overexpression of the different Bru1 isoforms. Functional tests and confocal microscopy of adult IFMs revealed distinct roles for Bru1 isoforms in myogenesis. Bru1-RB overexpression resulted in muscle detachment and tubular-like fiber morphology. Bru1-RA overexpression was dosage sensitive and disrupted the actin cytoskeleton causing zebra-bodies in sarcomeres. Bru1-RD overexpression resulted in only minor phenotypes in muscle tissue. There is also a difference in the localization of these isoforms in the IFMs, with some isoforms localized to the nucleus and others cytosolic. These findings demonstrate that the correct isoform as well as the correct expression level of Bru1 isoforms are required for proper IFM formation and function. Our results provide novel insight into mechanisms of RNA regulation during development, potentially identifying a conserved mechanism to fine-tune CELF activity in response to cell identity and developmental status.

1103F **A Conserved Cardiomyocyte-Specific Endocycle Program Underlies Heart Development** Archan Chakraborty[1], Meera Gangasani[1], Alexandra Purdy[2], Dawn Bowles[1], Matthew Wolf[3], Michaela Patterson[2,2], Don Fox[1] [1]Pharmacology and Cancer Biology, Duke University, [2]Medical College of Wisconsin, [3]University of Virginia

During adolescence, mammalian cardiomyocytes lose their ability to proliferate and instead transition to growth through whole genome duplication. A common mechanism of whole genome duplication is the endocycle, which repeatedly replicates the genome to produce a polyploid cell. Unlike many polyploid tissues, the heart has limited flexibility with regards to the upper and lower limit of ploidy needed for optimal function and development. As evidence of this limited flexibility of polyploidy, we discovered that both *Drosophila* and human cardiac organs undergo chamber-specific polyploidization. Manipulating this chamber-specific ploidy asymmetry in *Drosophila* impacts the proper functioning of the fly's cardiac organ, mimicking cardiomyopathies. Therefore, identifying the regulators of cardiac-specific polyploidization is important. To further understand the regulation of cardiac polyploidy we performed a genetic screen using RNA interference (RNAi) in the *Drosophila* larval heart. Leveraging publicly available human cardiomyocyte RNA-Seq data and GWAS data for cardiac ploidy in rats, we targeted 128 ortholog genes in *Drosophila* larval hearts. We identified several classes of genes that regulate cardiac ploidy including chamber-specific polyploidy. Additionally, we identified evidence of a cardiac specific endocycle program. Notably, COX7A, a component of mitochondrial respiratory complex IV showed opposing effects in heart vs salivary gland, another polyploid tissue. In summary, through a genetic screen we have identified conserved cardiac-expressed genes with specific roles in regulating ploidy of heart tissue. This work reveals heart-specific mitochondrial regulation of polyploidy that is distinct from general endocycle regulation.

1104F **Exploring the impact of germ granule diversity on germline development in *Drosophila*** Gisselle A Hidalgo[1], Ahad L Shabazz-Henry[1], Bianca M Ortega[1], Suneth Tissera[1], David A Joiner[1], Matthew G Niepielko[1,2] [1]School of Integrative Science and Technology, Kean University, [2]Department of Biological Sciences, Kean University

The development and maintenance of the germline, the set of highly specialized cells responsible for passing on genetic material to the following generation, is essential for animal reproduction. Germline function and maintenance require the formation of highly conserved ribonucleoprotein (RNP) granules called germ granules. Germ granules are biomolecular condensates that contain many types of mRNAs and proteins that have important roles in germline differentiation, proliferation, and maintaining transcriptional quiescence through post-transcriptional gene regulation. In animals including *Drosophila*, *Xenopus*, and zebrafish, primordial germ cell specification relies on the inheritance of germ granules that reside at a specific location within the egg. Despite the conserved function of germ granules and their components, how quantitative changes in germ granule mRNA content influences germline development remains unclear. We hypothesize that changes in germ granule mRNA content leads to differences in germline development and reproductive health. To test our hypothesis, we analyzed the natural diversity of germ granule mRNA content and its relationship to differences in germline development that occurs in several *Drosophila* species. Using a combination of single molecule fluorescence *in situ* hybridization (smFISH), computational modeling, and immunofluorescence, our preliminary results suggest that changes in germ granule mRNA content leads to an increased presence of defective primordial germ cells in the *Drosophila* embryo.

Together, our findings demonstrate how germline development relies on genetic mechanisms that have the capacity to fine-tune germ granule mRNA content.

1105F **Regulation of Stem Cell Lineage Behavior in *Drosophila* Testes by the Novel Gene, *CG11180/Chigno*** Claire Aminuddin, Rina Shou, Natalie Luffman, Morgan Claybrook, Oliver Kerscher, Matthew Wawersik Biology Department, College of William and Mary

Stem cells are critical for organ function and tissue homeostasis. Through asymmetric division, they produce two daughter cells – one that retains stem cell fate, and one that differentiates according to organ function. Stem cells can also divide symmetrically to restore or amplify the stem cell population. *Drosophila* testes are a key model system for understanding molecular mechanisms regulating stem cell maintenance and differentiation. This system consists of two stem cell types: sperm-producing germline stem cells (GSCs) and somatic cyst stem cells (CySCs), which maintain the GSC population and produce cyst cells that nurture spermatogenesis. These two stem cell types are docked at a cluster of somatic hub cells that reside at the testis apex. Work from the Wawersik lab has identified the novel gene, *CG11180/Chigno*, as a potential regulator of CySC maintenance and differentiation (Rinhart et al, 2021). Somatic knockdown of Chigno in the CySC lineage causes an expansion of under-differentiated germ cells and defects in spermatogenesis that lead to infertility. Here we further explore the function of Chigno in *Drosophila* testes. Specifically, we examined Chigno expression, sub-cellular localization, and the impact of Chigno RNAi knockdown on CySC maintenance and differentiation. Data indicate that Chigno is localized to the nucleolus of GSCs, CySCs, and their early progeny in adult testes, with low expression in hub cells. We also find that knockdown of Chigno in the CySC lineage causes CySC expansion and defects in cyst differentiation. Interestingly, an expansion of hub cells is also observed. Ongoing experiments examine mechanisms by which these defects occur, and potential roles of Chigno in the germline. As Chigno shares homology with PINX1, an RNA binding protein and telomerase inhibitor expressed in mammalian reproductive tissues, these data have important implications for human infertility and reproductive cancer.

1106F **Controlling BMP Pathway with Optogenetic Receptors in Drosophila Embryos and Germline Stem Cells Niche** Hung-Yuan (Zeke) Chen, Gregory Reeves Chemical Engineering, Texas A&M University

The Bone morphogenetic protein (BMP) signaling pathway is highly conserved and regulates several cellular processes across the animal kingdom, such as tissue patterning and stem cell maintenance. In Drosophila, the BMP homolog Dpp activates the Type I receptor, Thickveins (Tkv), and the Type II receptor, Punt (Put), and the activated receptor complex then phosphorylates the Smad1 homolog Mothers against Dpp (Mad). Phosphorylated Mad (pMad) then binds to the cofactor Medea (Smad4 homolog) and the complex translocates to the nucleus to regulate BMP target genes. Here we performed live imaging with fluorescently-tagged Mad and Medea in the early Drosophila embryo (2-3 h old) and in female germline stem cells (GSCs). We quantified the dynamics of the BMP gradient and used raster image correlation spectroscopy (RICS), a derivative of fluorescence correlation spectroscopy, allowing us to visualize their absolute concentration and the extent to which they are in a complex with each other. We also used the optogenetic LOV2 system to photoactivate the Type I and Type II BMP receptors. This opto-receptor system forms dimers when exposed to blue light, leading to phosphorylation of Mad and initiation of the pathway without Dpp. We tested these constructs in Schneider 2 cells and quantified BMP dynamics in cell culture. These methods have allowed us to probe the longstanding question of how signaling dynamics regulates gene expression on a fundamental level.

1107F **Myosin II is required for seamless tubulogenesis and unicellular branching morphogenesis in *Drosophila* tracheal terminal cells** Jodi Schottenfeld-Roames[1], Tanner Simpson[1], Ivan Ruiz Leon[2], Kaelix Johnson[2] [1]Molecular Biology, Princeton University, [2]Princeton University

Transformation of epithelial cells into complex functional organs is a critical step in development. Organs such as the lungs and kidney are composed of multicellular tubes (two or more cells attached to one other by junctions), whereas a large percentage of capillaries in the vertebrate vascular system are composed of seamless tubes (single cells that lack junctions). Although the morphogenetic events that help generate a multicellular tube can vary, it is clear how cells joined together by epithelial junctions create a membrane-bounded lumen; what is not obvious is how a single cell hollows out to create an internal lumenal membrane *de novo*. Specialized tips cells in the *Drosophila* tracheal system called “terminal cells” go on to form branched seamless tubes. Using terminal cells as a model, we have uncovered a number of cytoskeletal and membrane trafficking regulators that help orchestrate this seamless cell-to-tube transformation in previous work. Candidate RNAi screens to identify additional factors required for terminal cells morphogenesis have served as the foundation for an upper-level undergraduate research course. One such protein identified by students in the course is the actin contractibility regulator, Myosin II. Here, we show a novel role for Myosin II during the process of seamless tubulogenesis and unicellular branching morphogenesis the fly tracheal system. RNAi against the fly *myosin II regulatory light chain* (*spaghetti-squash)* and *myosin II heavy chain* (*zipper)* results in changes to terminal cell architecture and discoordination between branch and lumen formation.

A student-developed method for analyzing branch density within defined quadrants of space around a designated plane of a terminal cell reveals that Myosin II depleted cells have reduced spreading compared to wild type control cells. Efforts to determine the mechanism by which Myosin II regulates branching and tube formation in terminal cells are currently underway.

1108F **Fox transcription factor-mediated morphogenesis of the alary muscles associated with the *Drosophila* heart** Kuncha Shashidhar, Rajnandani Katariya, Md. Rezaul Hasan, Mofazzal K Sabbir, Abbigayle J Gamble, Shaad M Ahmad Biology, Indiana State University

Eight Forkhead box (Fox) transcription factors (TFs) are required for proper cardiogenesis in mammals while mutations in four Forkhead box (Fox) genes have been linked to human congenital heart disease. Our prior work had identified the conserved roles of two *Drosophila* Fox genes, *jumeau* (*jumu*) and *Checkpoint suppressor 1-like* (*CHES-1-like*) in mediating cardiac progenitor cell specification, division, differentiation, and positioning. Here we describe an additional role of the *Drosophila* Fox gene *CHES-1-like* in mediating the development of alary muscles (AMs), structures which connect the heart to the embryonic/larval exoskeleton and are essential for supporting the heart, stabilizing its location, maintaining its lumen, and controlling ostia opening and heart beating. In *CHES-1-like* loss-of-function mutants, one or more of the fourteen AMs per embryo exhibit significant morphological defects, being deformed, truncated, or missing. One or more of the following hypotheses could explain these defects in AM morophogenesis: (1) incorrect specification of AM founder cells, (2) defective myoblast fusion, (3) flawed myotube elongation, (4) incorrectly positioned AM attachment sites on the heart due to cardiac progenitor cell division errors, and (5) improper muscle attachment site selection. We are in the process of conducting experiments to determine which of these hypotheses are correct and thereby to begin exploring the mechanism by which this Fox gene mediates development of associated tissues supporting the heart.

1109F ***Drosophila pseudoobscura* sperm heteromorphism: Genetic and cellular processes regulating sperm length** Fiona Messer[1], Helen White-Cooper[2] [1]Biosciences, Cardiff University, [2]Cardiff University

Drosophila pseudoobscura produce three distinct sperm morphs: a long fertilising morph, the eusperm, and short and medium non-fertilising morphs, parasperm 1 and 2. Parasperm protect the eusperm from female-derived spermicides in the female reproductive tract. The three morphs are produced simultaneously and consistently throughout the lifetime of the fly. *D. pseudoobscura* is therefore an ideal system to investigate the genetic and cellular processes regulating sperm length.

Drosophila spermatogenesis follows a well-characterised pattern of differentiation, mitosis, meiosis, elongation, and individualisation. Transcription of genes whose products are required during meiosis and post-meiosis predominantly occurs during the pre-meiotic primary spermatocyte stage. Our previous work has identified transcriptional differences between sub-sets of cysts, prior to the onset of meiosis, including components of the testis meiotic arrest complex (tMAC) and the tMAC regulator *kumgang (kmg)*. We propose that these transcriptional differences underpin sperm morph differentiation. GFP-tagged Kmg protein is also differentially expressed in *D. pseudoobscura* spermatocytes, and cell culture establishes morph identity of high, medium, and low Kmg-expressing cysts.

HCR-FISH screening of the cup- and comet-class genes has also revealed post-meiotic differential gene expression and localisation between elongating spermatid morphs. Some of these post-meiotically expressed genes are transcribed and localise to the growing tail ends of all sperm morph cysts (*f-cup, sunz2B, stress response protein NST1*), however others localise to a sub-set of cysts, either by developmental stage (*schuy*) or by morph (*wa-cup, sunz2A, sunz3*).

Whole testis single-cell RNA sequencing is used to identify the transcriptional profiles of each sperm morph throughout spermatogenesis, in addition to the somatic cyst cell profiles. Trajectory analysis can also reveal the timing of morph differentiation, early differentially expressed genes and potential downstream targets of previously identified differentially expressed TMAC components and Kmg.

1110F **Distinct roles for COMPASS core subunits Set1, Trx, and Trr in the epigenetic regulation of *Drosophila* heart development** Junyi Zhu, Joyce van de Leemput, Zhe Han University of Maryland Baltimore

Histone methylation regulates transcriptome dynamics during development and aging, as well as in disease. Various methyltransferases have been linked to heart disease, through disrupted expression and activity, and genetic variants associated with congenital heart disease. However, in vivo functional data for many of the methyltransferases in the context of the heart are limited. Here, we used the *Drosophila* model system to investigate different histone 3 lysine 4 (H3K4) methyltransferases for their role in heart development. A series of multiprotein complexes termed Complex of Proteins Associated with Set1 (COMPASS) are involved in H3K4 methylation. *Drosophila* Set1, trx and trr formed the core subunits of these complexes. Development in flies deficient for these three core subunits was notable for the high lethality at eclosion and significantly shortened lifespans for adults that did emerge. Silencing of *Set1*, *trx,* and *trr* in the heart led to a reduction

of H3K4 monomethylation (H3K4me1) and dimethylation (H3K4me2) differently indicating their different roles in H3K4 methylation. Furthermore, we identified the gene expression patterns regulated by *Set1*, *trx,* and *trr*. These data suggest each of the COMPASS core subunits controls methylation of different sets of genes, with many metabolic pathways on early in development and throughout, while muscle and heart differentiation processes are methylated during later stages of development. Taken together, our findings demonstrated the roles of COMPASS series complex core subunit Set1, trx, and trr in regulating histone methylation during heart development, with implications for CHD.

1111F **Dissecting the temporal dynamics of histone inheritance through *Drosophila* neural development** Jason T Palladino[1], Xin Chen[1,2] [1]Biology, Johns Hopkins University, [2]Howard Hughes Medical Institute

Proper development depends on asymmetric cell division (ACD), a process by which dividing stem cells produce a renewed stem cell and a differentiating cell. Many intrinsic and extrinsic factors guiding ACD have been found, however, the role of chromatin to ACD is poorly understood. Previously, our lab discovered asymmetries in histone and histone post-translational modification (hPTM) inheritance in *Drosophila* male germline stem cells (mGSCs). Disruption of these asymmetries results in both stem cell loss and overpopulation of progenitor cells phenotypes, suggesting that asymmetric histone inheritance is an essential process in tissue health. Further, deterioration of this process may be common among diseases including tissue degeneration and cancer. Investigation into other adult stem cell lineages showed asymmetric histone inheritance, suggesting it is a general mechanism. However, whether histone inheritance patterns influence cell-fate decisions for more potent developmental stem cells remains to be determined.

To interrogate the role of histone inheritance in development, I use *Drosophila* neural stem cells, neuroblasts (NBs), a well-studied model for ACD. Similar to mGSCs, inheritance of total H3 and H4 in NBs is also asymmetric, suggesting histone density asymmetry is conserved between mGSCs and NBs. Despite commonalities, histone inheritance in NBs is distinct from mGSCs in several ways. First, the polarity of histone asymmetry in NB ACD is extremely dynamic with all possible patterns being observed. Second, the strength of asymmetric histone inheritance increases with developmental age with older NBs displaying a higher degree of histone asymmetry. As NB progeny identity is also dynamic and dictated by molecular clocks, I hypothesize inheritance of histones and associated epigenetic information contributes to cell-fate determination in NB lineages. Indeed, tracking of the Polycomb-associated hPTM H3K27me3 using an eGFP-tagged mintbody shows a high positive correlation between H3K27me3 and total H3 inheritance during NB ACD. Given that H3K27me3 is enriched with old histones, this positive correlation indicates that old H3-enriched sister chromatids have higher histone density, consistent with the results we have obtained in mGSCs. Further manipulation of NB identity and epigenetic regulators will elucidate the contribution of epigenetic inheritance to complex cell-fate decisions during development, which I will discuss further.

1112F **Deciphering the function of CNK during thorax closure in Drosophila** Eloïse Duramé[1,2], Caroline Baril[1,2], Malha Sahmi[1,2], Marc Therrien[1,2] [1]Université de Montréal, [2]IRIC

Scaffold proteins enable selectivity and precise spatiotemporal regulation of signal transduction. They achieve this by assembling molecular complexes and directing them to particular subcellular sites. Connector eNhancer of Kinase suppressor of RAS (CNK) family members serve as scaffolds that have been conserved throughout evolution. CNK was initially identified in Drosophila, where it acts as a positive regulator of the receptor tyrosine kinase-induced RAS/MAPK pathway. Although the exact role of CNK family proteins is not fully understood, our recent findings highlight CNK2A's importance in promoting human cancer cell migration by activating RAC1 and inhibiting RHOA through ARF6 activation. This led us to explore the role of CNK during cell migration in Drosophila.

In this study, we used thorax closure as a model to study migration. During pupal thorax morphogenesis, the dorsal epithelium of the two imaginal wing discs migrate over an underlying larval epidermis and fuses at the midline to form a continuous thorax. Interestingly, knockdown of *cnk* during thorax morphogenesis using the pannier-Gal4 driver led to thorax closure defects. Time-lapse imaging of thorax closure showed that *cnk* depletion disrupts larval epidermis integrity, reduces thoracic cell velocity and prevents the fusion of the migrating discs. Overexpressing the C-terminal part of CNK, but not the N-terminal part, produced the same defect as *cnk* depletion. Notably, CNK›s role during thorax closure appears to be independent of its function in the RAS-MAPK pathway but relies on its localization to the plasma membrane through its PH domain. To gain mechanistic insights into the function of CNK in this biological event, we used the miniTurboID technique to identify proximal CNK interactors during thorax closure. This approach uncovered interesting candidate interactors, including Par-1 and subunits of the PP2A complex. We are currently assessing these candidates in the context of thorax closure and their functional connections with CNK through genetic interaction experiments.

Together, our results strongly suggest a role for CNK during thorax morphogenesis in Drosophila, and further work should refine our understanding of the molecular mechanisms underlying epithelial migration. Additionally, it will shed light on the

role of CNK in signaling contexts beyond the RAS-MAPK pathway.

1113F **Investigation of gene functions in secretory granule formation in *Drosophila* salivary glands** Navid Tahan Zadeh, Yevin Chung, Liping Zhang, Kelly Ten Hagen, Olivia Fish, Robin Black, Amy-Claire Dauphin National Institute of Health

Regulated secretion is an essential process by which proteins, stored in secretory granules, are released into the extracellular environment in response to some stimulus. Defects in this process, can contribute to numerous diseases, including cystic fibrosis and inflammatory bowel disease. In *Drosophila* larval salivary glands, large and highly glycosylated proteins, such as mucins, are produced, packaged, and released in response to developmentally regulated pulses of the hormone, 20-hydroxyecdysone. To understand this highly orchestrated process and identify the factors responsible for mucin biosynthesis and secretory granule maturation, we performed single-cell RNA sequencing on *Drosophila* salivary glands and revealed the presence of five secretory cell-like clusters. To further identify genes involved in mucin synthesis, packaging, and secretion, we performed RNAi on the genes identified from secretory cell clusters. Here we show that two genes, *CG3168* and *Gale* are involved in secretory granule formation. In the future, deeper analysis of the scRNA-seq data and further investigation of genes identified in each secretory cell clusters will allow for a better understanding of the secretory granule biogenesis and regulated secretion.

1114F **Invagination in the *Drosophila* Salivary Gland is Mediated by Huckebein Through Regulated Secretion of the GPCR-Pathway Ligand Folded gastrulation (Fog)** Ashleigh M Shoemaker[1], Ji Hoon Kim[1], Anuradha Ratnaparkhi[2], Deborah J Andrew[1] [1]Cell Biology, Johns Hopkins School of Medicine, [2]Developmental Biology, Agharkar Research Institute

Drosophila melanogaster is a valuable model organism for revealing the cellular and molecular basis of congenital diseases. Our laboratory utilizes the embryonic *Drosophila* salivary gland (SG) as a simple model of epithelial tube formation analogous to the mammalian lungs and glandular tissues. While the cellular mechanisms contributing to SG invagination have been described, the signaling pathways coordinating this process remain unclear. We hypothesize that the SP1-like transcription factor Huckebein (Hkb) mediates the localized secretion of the signaling molecule encoded by Folded gastrulation (Fog), thus activating the downstream G-protein-coupled-receptors (GPCRs) critical for cellular invagination. Fog and/or its GPCR may then be recycled to the apical membrane by vesicles expressing the kinesin-binding protein Klarsicht, whose transcription is *hkb*-dependent. Utilizing targeted gene disruption of *hkb* by CRISPR/Cas9 genetic engineering, in combination with tissue-specific misexpression of *hkb*, I test the model that Hkb regulates secretion of Fog. Our work reveals that high levels of Fog secretion is limited to the SG cells about to invaginate, and that misexpression of Hkb in all SG cells affects the levels and distribution of secreted Fog. Preliminary data suggests that changes in Hkb expression result in aberrant invagination. Next, we will determine the localization of Fog and its corresponding GPCR in the absence of *hkb* and Hkb downstream transcriptional targets linked to vesicle trafficking. Our findings suggest that Hkb facilitates the localized secretion of Fog from SG cells, which then activates the downstream GPCR-mediated pathway required for the cell shape changes that underlie invagination.

1115F **Dissecting Fox transcription factor-mediated regulation of Polo kinase activity essential for cardiac progenitor cell divisions** Rajnandani Katariya[1,2,3], Abbigayle J. Gamble[1,2], M. Rezaul Hasan[1,2,3], Kuncha Shashidhar[1,2], Mofazzal K. Sabbir[1,2], Shaad M. Ahmad[1,2,3] [1]Biology, Indiana State University, [2]The Center for Genomic Advocacy, Indiana State University, [3]Rich and Robin Porter Cancer Research Center (PCRC), Indiana State University

Forkhead box (Fox) transcription factors are critical for cardiogenesis in both mammals and *Drosophila*. Previous work from our laboratory has shown that the *Drosophila* Fox gene *jumeau* (*jumu*) mediates three distinct categories of cardiac progenitor cell division—asymmetric, symmetric, and cell division at an earlier stage—by upregulating Polo kinase activity. However, a comparison of transcription expression profiles of flow cytometry-sorted mesodermal cells from wild-type embryos and *jumu* null mutants showed that *jumu* does not transcriptionally regulate *polo*, thereby suggesting that the Fox-mediated activation of *polo* for cardiac progenitor cell division may be posttranscriptional. A known crucial step in the post-transcriptional activation of *polo* is the post-translational phosphorylation of Polo protein. Two serine-threonine kinases that activate Polo protein via phosphorylation are Aurora B (AurB) and Back seat driver (BSD). Intriguingly, *aurB* and *bsd*, the genes encoding these kinases, are both transcriptionally activated by *jumu*, making these kinases promising candidates through which the Fox gene may activate *polo. aurB* is already known to play multiple roles in mitosis. And while *bsd* has previously been characterized only as mediating the post-mitotic activation of Polo necessary for somatic muscle morphogenesis, it does not preclude *bsd* from also being utilized for mitosis in cardiac progenitor cells. If *jumu* does indeed utilize *aurB* and *bsd* to activate *polo* for cardiac progenitor cell division, then we would expect *aurB* and *bsd* mutants to exhibit cardiac defects similar to those in *jumu* and *polo*mutants. Here we show that loss-of-function mutations of *aurB* and *bsd* do indeed phenocopy all three categories of cardiac progenitor cell division defects observed in *jumu* and *polo* mutants, consistent with such a role. We are presently utilizing genetic interaction and rescue assays to conclusively determine whether *aurB* and *bsd* mediate Polo activation by *jumu*. If *jumu* does indeed activate Polo using one of these two candidate genes, then that candidate gene should

exhibit pairwise synergistic genetic interactions with both *jumu* and *polo*. Furthermore, independent cardiac-specific ectopic expression of the candidate gene should partially rescue the cardiac progenitor cell division defects of *jumu* mutants, but not of *polo* mutants.

1116F **Shocking development: Heat shock factor functions through Hsp83 to regulate *Drosophila* development** Noah Reger[1], Jinghong Tang[2], Somes Schwinghammer[2], Michael Welte[2] [1]Biology, University of Rochester, [2]University of Rochester

Heat shock factors (HSFs) are a family of conserved transcription factors well-known for their roles in regulating stress responses. Here, HSFs largely act through upregulation of Heat Shock Proteins (HSPs) which function as molecular chaperones to facilitate proper protein folding post-stress. Compared to this canonical role of HSFs, their non-canonical roles have garnered relatively little attention. HSF functions in the regulation of early development in *C. elegans* and is required for proper post-natal growth in mice. Mammalian HSF1 is also necessary for robust growth of almost all tumors. The targets of HSF in these developmental contexts are either known or suspected to be proteins not typically upregulated upon stress. Here we interrogate the developmental role of the single HSF family member in *Drosophila*. Because larvae lacking HSF die early during development, we selectively knocked down HSF in several larval tissues that undergo massive growth. Knockdown in the prothoracic gland (PG) resulted in a reduction of both cell size and DNA content. Similar results were observed in the salivary glands—another endoreplicative tissue. Knockdown in wing discs lead to malformed adult wings. These results strongly indicate that HSF functions broadly in *Drosophila* development. Additionally, we observed that PG knockdown of HSF caused larvae to arrest during the third instar stage. The PG secretes the hormone ecdysone necessary for the juvenile-to-adult transition in flies. Ecdysone feeding was sufficient to rescue larval arrest indicating that these animals fail to generate sufficient ecdysone. Previous work had shown that under non-stress conditions HSF enhances Hsp83 expression in cultured cells and salivary glands; Hsp83 is the fly version of Hsp90. We find that the PG highly expresses Hsp83 during normal development and expression is lost in an HSF deficient background. Overexpressing Hsp83 in such a background was sufficient to fully rescue the PG phenotypes as well as larval arrest, indicating HSF functions through Hsp83 to promote PG development. Hsp83 overexpression also partially rescues the defects observed in salivary glands and wing discs lacking HSF. Future experiments will focus on determining whether Hsp83 regulation explains all of HSF's developmental roles or whether HSF works in addition with the ecdysone signaling pathway.

1117F **Rho kinase regulates spermatogenesis in Drosophila germline** Carihann M Dominicci-Cotto[1], Josefa Steinhauer[2], Andreas Jenny[3,4] [1]Developmental and Molecular Biology, Albert Einstein College of Medicine, [2]Biology, Yeshiva University, [3]Develomental and Molecular Biology, Albert Einstein College of Medicine, [4]Genetics, Albert Einstein College of Medicine

A higher species' survival requires proper gamete production and formation. Sperm count in men has decreased significantly over the last 50 years. Therefore, understanding the signaling pathways that regulate sperm production and fertility is crucial for humanity's survival. During spermatogenesis in *Drosophila melanogaster*, syncytial spermatids differentiate and individualize into mature sperm tightly enclosed by a plasma membrane. Specialized actin cones move along the sperm tails to separate spermatids during individualization. In this process, inter-spermatid bridges and the excess of the cytoplasm are removed, a prerequisite for sister spermatids to become individual, functional spermatids.

Our laboratory previously showed that Combover (Cmb), a member of the family of intrinsically disordered proteins and an effector of planar cell polarity under the control of Rho kinase (Rok), is essential for sperm individualization and fertility in Drosophila. We demonstrated that the individualization defects present in the *cmb* mutant can be rescued by the expression of wild-type Cmb. Intriguingly, the rescue depends on the presence of WT Rok phosphorylation sites in Cmb, suggesting that Cmb function on sperm individualization requires Rok. Here, we show that loss of Rok in the germline, using a CRISPR-generated *rok* mutant (Crispant), causes infertility in adult male flies. To determine the cause, we measured the length of the testis and quantified the individualization defects. We found that Rok decrease causes a reduction in testis length and an increase in defects of individualization complexes. Furthermore, we find that endogenously tagged GFP-Cmb is enriched in the axoneme elongation complexes (ECs), which show a reduced αSpectrin staining in *rok* Crispants. We, therefore, show for the first time that Rok and Cmb are required in the male germline and hypothesize that they regulate a transition between elongation and individualization of spermatids.

1118F **Fox transcription factors mediate proper positioning of cardiac cells by restricting the expression of ECM genes** Rajnandani Katariya[1,2,3], Manoj Panta[1,2], Andrew J. Kump[1,4], Neal Jeffries[5], Shaad M. Ahmad[1,2,3] [1]Biology, Indiana State University, [2]The Center for Genomic Advocacy, Indiana State University, [3]Rich and Robin Porter Cancer Research Center (PCRC), Indiana State University, [4]The Center for Genetic Advocacy, Indiana State University, [5]Office of Biostatistics Research, National Heart, Lung and Blood Institute, NIH

The development of a complex organ requires the specification of appropriate numbers of each of its constituent cell types as well as their correct positioning of these cell types within the organ. We previously showed that the Fox transcription factors (TFs) Checkpoint suppressor homologue (CHES-1-like) and Jumeau (Jumu) determine the correct number of different cardiac cell types by regulating cardiac progenitor cell divisions. Here we show that *CHES-1-like* and *jumu* are also required for the correct positioning of these cardiac cell types: null mutations in either gene result in the misalignment and incorrect location of cardial and pericardial cells within individual hemisegments. Since defective cardiac progenitor cell divisions in *CHES-1-like* and *jumu* loss-of-function mutants frequently result in individual hemisegments having different numbers of cardiac cells than their partners across the dorsal midline, we first examined this asymmetry as a possible steric cause of incorrect positioning. Our analysis revealed that steric constraints imposed by the differing number of heart cells in contralateral hemisgments cannot explain all of the observed defects in cardiac cell positioning: statistically significant increases in the number of positioning defects are also observed in Fox mutants compared with wild-type embryos when only members of contralateral hemisegment pairs having the same number of each cardiac cell type are compared. In order to discover the other cause underlying positioning defects, we compared genome-wide transcription expression profiles of purified mesodermal cells from wild-type embryos and embryos lacking functional copies of *CHES-1-like*, *jumu*, or both Fox genes to identify Fox-regulated targets. Among the 2,131 target genes we identified, genes encoding extracellular matrix (ECM) proteins were overrepresented among genes repressed by the Fox TFs. In particular, the ECM proteins Viking, Collagen type IV alpha 1, and Terribly reduced optic lobes were all overexpressed in Fox mutants. Our preliminary phenotypic analysis of these specific targets suggests that the Fox TFs bring about the correct positioning of cardiac cell types by restricting their expression: independent ectopic overexpression of each of these ECM genes in the mesoderm phenocopies the cardiac cell positioning defects observed in *CHES-1-like* and *jumu* loss-of-function mutants.

1119F **The Role of Drop on Salivary Gland Morphogenesis** Matthew Elliott[1], Deborah Andrew[2] [1]Cell Biology, Johns Hopkins University, [2]Cell Biology, Johns Hopkins School of Medicine

Recently, single cell RNA sequencing (scRNA-seq) data from our lab revealed transient expression of *Drop* (*Dr*) mRNA in the salivary gland (SG) during early organ development. *Dr* is commonly known for its dominant gain-of-function mutation, which results in the small eye phenotype that is used as genetic marker for easy identification in crosses with the 3rd chromosome. *Dr* encodes for a homeodomain transcription factor most closely to the human Msx1 and Msx2 proteins. Previous data implicates *Dr* in the specification of myoblasts and neuroblasts, development of muscle and neuronal cells, and regulation of glucose metabolism. Since *Dr* expression in the SG was unknown, its role in the SG has not yet been elucidated. Our preliminary findings from immunostained embryos from a *Dr* insertion line showed a phenotypical change in SG morphology consistent with abnormal cell invagination. Furthermore, our scRNA-seq data showed *Dr* mRNA expression only in cells that are first to invaginate during SG morphogenesis. Thus, we hypothesize *Dr* may play a role in SG invagination, tube elongation, and/or cell viability. To test this idea, we have developed tagged and untagged Gal4/UAS-expression constructs to drive persistent expression of *Dr* in the entire embryonic SG. We are also developing CRISPR-Cas9 knock-outs of Dr to determine the effects of null mutations in *Dr* on formation of the SG. These tools will allow us to gain a full understanding of the involvement of *Dr* in the SG during morphogenesis. Furthermore, our findings may shed light on the role of its human orthologs in early developmental processes.

1120F ***trithorax (trx)* and *trx* group (*trxG*) regulation of cardiac *Hox* gene expression and patterning of the *Drosophila* dorsal vessel** Sumaiya Islam, Md Sayeed Abu Rayhan, Adam J Farmer, Shaad M Ahmad, Kristopher R Schwab Biological Sciences, Indiana State University

The *trx* and *trxG* genes encode conserved chromatin regulatory proteins that positively control developmental genes, such as the *Homeotic (Hox*) genes, during embryogenesis. In addition to patterning the anterior-posterior embryonic axis, *Hox* genes control the regional patterning of the developing heart in both insects and mammals. However, the precise regulation of cardiac *Hox* expression by these genes has yet to be explored in experimental models of heart development.

In *Drosophila, abdominal-A (abd-A)* expression patterns the posterior embryonic dorsal vessel into the heart proper. This cardiac region is characterized by an enlarged lumen containing valvular ostial cells, which regulate hemolymph flow through the dorsal vessel. We have previously identified that the *trx* is necessary for *abd-A* expression within the posterior dorsal vessel, while *Polycomb (Pc)* represses *abd-A* expansion into the anterior aorta. For example, the loss of *abd-A* expression within the *trx* mutant causes a dramatic homeotic transformation of the posterior heart tube into an anterior aortic-like fate.

The TrxG family of proteins controls the activation and maintenance of gene transcription via the recruitment of multi-protein complexes that perform diverse regulatory functions, including chromatin remodeling, histone methylation, and transcriptional co-activation. Furthermore, Trx regulatory activity is separable into catalytic H3K4 methyltransferase activity and non-catalytic transcriptional coactivation. Therefore, the loss of *abd-A* expression and heart-proper patterning offers a robust assay to further characterize the TrxG control of cardiac *Hox* regulation within cardiogenesis. An allelic series

of *trx* mutant strains that rescue null *trx* embryonic lethality were investigated for *abd-A* expression and heart-proper defects. Interestingly, the trx^{B20} and trx^{B26} homozygous embryos maintained posterior *abd-A* expression and heart-proper patterning. Key components of the Trx Complex Proteins Associated with Set1-like (COMPASS-like) were also investigated for heart defects. Surprisingly, homozygous will die *slowly (wds)* and *absent, small, or homeotic discs 2 (ash2)* mutants possess no significant changes to *abd-A* expression or heart-proper development. Overall, these results suggest diverse *trxG* regulatory activities controlling *Hox* expression and patterning in embryonic heart development.

1121F **Investigating the role of C(2)M dynamics in Cohesin Protein Loading and Formation of the Synaptonemal Complex During meiosis in Female *Drosophila melanogaster*** Margaret Howland[1], Helen Nguyen[2], Kim R McKim[1] [1]Genetics, Rutgers University - New Brunswick, [2]Rutgers University - New Brunswick

Meiosis allows sexually reproducing organisms to reduce their chromosome content in half, which is required for the production of sperm and oocytes. Errors in meiosis can lead to nondisjunction events, aneuploidy, and infertility in humans. Fidelity of homologous chromosome pairing is critical during the first meiotic division to ensure the accuracy of the reductional division. The Synaptonemal Complex (SC) is necessary for chromosome pairing during the formation of bivalents and to initiate DNA double-strand breaks (DSBs), crossover events, and eventual chromosome segregation. There are two meiotic cohesin complexes that facilitate chromosome cohesion and assembly of the SC in Drosophila oocytes. The first complex containing SMC1/SMC3/C(2)M/SA is involved in homologous chromosome pairing while the other complex containing SMC1/SMC3/SOLO/SUNN is required for sister chromatid cohesion. Previous immunofluorescence studies have led to the hypothesis that C(2)M is a kleisin protein that makes a ring structure by binding to both SMC1 and SMC3. How this promotes SC assembly is not known. In support of this hypothesis, we have found that point mutations that would disrupt the proposed C(2)M-SMC interaction domains leads to defects in SC assembly. We have also used heat shock induced expression of SA and SMC, and C(2)M co-expression experiments, to show that the nuclear import and dynamic protein loading of SA and SMC during meiotic prophase depends on C(2)M co-expression. This result indicates that C(2)M may be the limiting factor in dynamic SC formation. It is possible that there are two populations of C(2)M that allow both dynamic and more stable loading throughout prophase I, or that the C(2)M loads flexibly in and out of the complex while the rest of the ring stays on the chromosomes. While C(2)M heat shock induced expression in prophase can rescue a defective SC, future experiments will use RNAi to knockdown C(2)M late in meiotic prophase to determine if prophase loading is required to maintain the SC. Additional future directions include analyzing the role of cohesins in the formation and location of chromatin loops in topologically associating domains and their role in organizing the genome during meiosis. These results will help us understand the role of C(2)M in cohesin protein loading and the formation of the synaptonemal complex.

1122F **A cell death sensitivity and injury resistance switch in long-lived intestinal enterocytes** Jessica Sawyer, Ruth A Montague, Paulo Belato, Olivia Goddard, Don T Fox Department of Pharmacology & Cancer Biology, Duke University

Many metazoan tissues harbor long-lived cells that are not replenished by stem cells. In the absence of stem cells, long-lived cells depend on cellular survival mechanisms. Here, we show that adult *Drosophila* hindgut ileum is a model to uncover mechanisms of tissue longevity and injury resistance. The *Drosophila* hindgut epithelium contains the pylorus, an anterior contractile segment, that moves food along the alimentary canal. The posterior ileum contains large, polyploid enterocytes that are important for salt and water balance. We have previously shown that ectopic expression of pro-apoptotic genes *hid* and/or *rpr* causes tissues injury and cell death, followed by regenerative hypertrophy in the pyloric epithelium. In contrast, we show that expression of *hid* does not injure the adult ileal epithelium, nor does it activate a caspase sensor or cause cell death. This apoptotic insensitivity is specific to *hid*, as ectopic expression of a downstream *hid* target, caspase *dronc* (Caspase-9), injures the adult ileum. Unlike the compensatory hypertrophic regenerative response to cell death in the pylorus after *hid* expression, *dronc*-mediated cell death in the ileum does not activate a robust regenerative response. The *hid*-sensitive pylorus and *hid*-insensitive ileum are derived from the same progenitor population during metamorphosis. *hid*-sensitivity arises during development, as *hid* expression causes injury and cell death in the ileum in young adult animals (less than one day post eclosion). We find that in young animals, both the pylorus and ileum are *hid*-sensitive. Our results suggest that long-lived, non-regenerative intestinal enterocytes of the ileum activate resistance to cellular insults as the adult hindgut matures. To understand the mechanisms of resistance to injury and cell death that arises as the hindgut matures, we isolated ileums from young and mature adults and performed RNAseq. Using these data, we are conducting two candidate screens. First, an RNAi screen of genes elevated in mature ileums. Second, an overexpression screen of genes elevated in young ileums. In both of these screens, we will determine if any of our candidate genes can sensitize the mature ileum to *hid*-mediated injury and cell death. Our results demonstrate that the *Drosophila* hindgut is an excellent model to reveal unique molecular regulation underlying a tradeoff between regeneration and longevity.

1123F **Understanding *Drosophila* neurogenesis at the niche level** Sagar N Kasar, Sarah Siegrist Biology, University of Virginia

Neural stem cells (NSCs) are required to produce the immense diversity of neuron types in the correct time and space for functional neural circuitry. In the developing brain of *Drosophila*, the NSCs, called neuroblasts reside within contained microenvironments called niches, which regulate their behavior by orchestrating intrinsic and extrinsic cues. Neuroblasts are closely associated with glia and thought to form a major structural component of the neurogenic niche. Glia establish an extensive network in the developing brain but little is known about how individual glial subtypes contribute to neuroblast behavior during neurogenesis. We aim to understand how cortex glia contribute to the neurogenic niche. During larval neurogenesis, cortex glia ensheath individual neuroblasts and their newborn progeny to form checkerboard-like cell compartments. We found that the temporal loss of cortex glia causes neuroblast death that leads to the significant reduction in the neuroblast number and smaller sized brains with defects in neuropil structures in surviving adults. We also observed significant structural changes in cortex glial morphology where previously established cortex glial membrane processes retract to form globular glia. We further aim to study the characteristics of such globular cortex glia as well as the signaling crosstalk between neuroblast and cortex glia. This project will help us understand the regulatory role of glial niche during neurogenesis which can provide a novel approach to designing therapeutics for microcephaly and brain tumors.

1124F **Tube dimensional control by apical extracellular matrix modification** James L Woodward[1], Se-Yeon Chung[2] [1]Louisiana State University, [2]Biological Sciences, Louisiana State University

The generation of appropriate tube dimensions during organ formation is critical for organ function and animal homeostasis. Increasing evidence suggests that the apical extracellular matrix (aECM), the extracellular layer on the apical (luminal) side of epithelia, actively contributes to epithelial morphogenesis. In particular, post-translational modifications of aECM components, such as modification of chitin by chitin deacetylases and hydroxylation of collagen by prolyl 4-hydroxylase, are essential for proper tube dimensions. However, very little is known about the structural components and biological functions of aECM, and the mechanisms of tube size control by aECM remain elusive. From our pilot screen in the *Drosophila* embryonic salivary gland (SG) to identify key enzymes that affect tube morphology, we identified Papss, an enzyme that synthesizes the universal sulfate donor PAPS, as a critical regulator of SG lumen expansion. Our confocal and transmission electron microscopy (TEM) analyses of *papss* mutants reveal several defects in the apical membrane and the aECM in the SG, including defects in apical membrane expansion and microvilli formation, sparse aECM structures, and detachment of the aECM from the apical membrane. We also detect mislocalization of the key apical protein Crumbs and the recycling endosome marker Rab11 in *papss* mutants, suggesting defects in apical membrane organization and intracellular trafficking. The zona pellucida (ZP) proteins Dumpy (Dpy) and Piopio, as well as signals for wheat germ agglutinin (WGA; a lectin that recognizes mucin-type O-linked glycans), are disorganized in the SG lumen in *papss* mutants, suggesting a potential role for these proteins as key aECM components. Analysis of mutants for each of these components is ongoing, and the initial analysis for *dpy* mutants shows that disruption of *dpy* function results in irregular lumen diameter. In addition, we show that loss of *papss* also disrupts the basal ECM, allowing hemocytes to invade the SG epithelia. These findings shed light on the organization of the aECM and the mechanism of lumen expansion during tubular organ formation and add a new dimension to our understanding of aECM-mediated tube size control.

1125F **Homothorax is enriched in the adult Drosophila testis stem cell niche and is essential for its maintenance** Margaret de Cuevas, Erika Matunis Dept Cell Biology, Johns Hopkins Sch Med

In the adult Drosophila testis, germline stem cells (GSCs) and somatic cyst stem cells (CySCs) adhere to a small cluster of somatic niche cells called hub cells, which produce the signals that maintain and regulate adjacent stem cells. Hub cells normally divide only during embryogenesis and were thought to be quiescent and terminally differentiated in adult flies, but upon genetic ablation of all CySCs, they can be induced to divide, leave the hub, and convert into new, functional CySCs (Hétié et al., 2014). The adult Drosophila testis hub is thus a great genetic model for understanding niche plasticity and stem cell regeneration. Although some of the signals that regulate hub cells have been identified, much remains unknown about this small but essential cluster of cells. Using a single nucleus RNA-seq resource covering all of the adult Drosophila testis (Raz et al., 2023), we identified genes upregulated in hub cells and performed a small-scale RNAi-mediated knockdown screen, which revealed that *homothorax (hth)* is required to maintain the adult hub. *hth* encodes a homeodomain transcription factor that binds to another homeodomain transcription factor, encoded by *extradenticle (exd)*, and allows its nuclear import. Both are Hox cofactors that are essential for patterning of the Drosophila embryo but also have additional Hox-independent functions throughout development. We found that when *hth* is knocked down in adult hub cells, they convert to CySCs and are rapidly lost, followed as expected by loss of all GSCs and CySCs, which are not maintained in the absence of signals from hub cells. By contrast, when *exd* is knocked down in adult hub cells, some convert to CySCs but the hub remains intact, suggesting that *hth* has additional functions in the hub that are independent of *exd*. We are currently investigating potential downstream targets of *hth* and *exd* in the hub and asking whether or not they are required in other cell types within the testis niche.

1126F **Characterization of test-specific sugar transport and glycolysis genes in *Drosophila melanogaster*** Mark Hiller,

Bryanne Manley Goucher College

The genome of *Drosophila melanogaster* contains twenty-five genes that are annotated as SLC2 type sugar transporters, and five of the sugar transporters appear to be expressed only in the testis. During spermatogenesis, germline cells develop into sperm while completely surrounded by two somatic cyst cells. How sugars molecules transit the cyst cells and enter germline cells is not understood. Mutations in each of three predicted transporters, *sut3*, *sut4*, or *CG14605*, are fertile. One alternative model is that pyruvate generated in the cyst cells is converted to lactate which is then transported from cyst cells to the germline cells. The enzyme lactate dehydrogenase could convert lactate back to pyruvate which could be used to generate ATP. The *Drosophila* germline encodes one testis specific homolog of lactate dehydrogenase. Likewise, there are several genes that function in glycolysis that have testis specific homologs or testis specific spice forms. To assess the role of glycolysis and lactate transport during spermatogenesis, we are using RNAi in the germline and cyst cells of the testis to knockdown function of genes that potentially play a role in the lactate shuttle between cyst and germline cells.

1127F **The Regulation of Cell Fate Determinants by miR-190 During Asymmetric Cell Division in *Drosophila* Neuroblasts** Laura Galvan[1], Gerson Ascencio[2], Blake Riggs[3] [1]Biology Department, San Francisco State University, [2]Stanford University, [3]Department of Biology, San Francisco State University

Stem cells in the *Drosophila* brain, known as neuroblasts, generate most of the neurons in the brain by undergoing asymmetric cell division (ACD). ACD gives a product of two daughter cells with two separate identities facilitated by cell fate determinants such as Scribble, a scaffolding protein that regulates apical-basal polarity, Prospero, a transcription factor, and L(2)gl, a tumor suppressor protein. These determinants are partitioned asymmetrically to drive cell fate selection, with Prospero moving towards the basal end to promote cell differentiation in what will become the ganglion mother cell (GMC). The mechanism of ACD is highly conserved across all multicellular organisms. However, the organization and regulation of partitioning cell fate determinants is poorly understood. Recently, microRNAs (miRNAs) have been suggested to play a role in cellular functions such as cell fate specification and differentiation. Specifically, they modulate gene expression post-transcriptionally by inhibiting mRNA translation or inducing mRNA degradation, which comes from the complete or incomplete binding to the 3' untranslated region (3'-UTR) of specific mRNAs. Using the computational tool TargetScanFly we predicted a perfect conserved binding site in the 3'-UTR of Prospero to miR-190. Here we hypothesize that miR-190 regulates Prospero during ACD. Our qPCR data highlighted Prospero, a transcription factor, as a potential target transcript for miR-190. Our data shows an increased Prospero mRNA expression in miR-190 deficient embryos. This suggests that Prospero mRNA is regulated by miR-190 and induces more differentiated progenitor cells. Using immunohistochemistry and high-resolution confocal microscopy, we found that Pros is not localized correctly at the GMC in miR-190 mutant embryos. Instead, we discovered that Pros is localized around the two daughter cells during ACD. These findings suggest that miR-190 is a crucial regulator of Prospero by targeting Prospero mRNA and preventing Prospero from translating into a protein. Our results will help us understand how cell fate determination is established by a novel pathway and help close the knowledge gap regarding how cellular fate determination is organized correctly and how miRNAs can assist undifferentiated cells in obtaining their cellular determination.

1128F **The Mechanism of Histone Exchange between Lipid Droplets** Alicia Shipley[1], Asmita Dutta[2], Pakinee Phromsiri[2], Michael Welte[2] [1]Biology, University of Rochester, [2]University of Rochester

Lipid droplets (LDs) are highly conserved fat storage organelles with fundamental roles in lipid metabolism. They also sequester specific proteins, yet the underlying mechanisms are poorly understood. The best characterized example of such sequestration occurs in Drosophila embryos, where LDs handle certain histone proteins (H2A, H2B, and H2Av) in the cytoplasm. H2Av exchanges (transfers back and forth) between LDs via transient sequestration to the LD protein Jabba. This exchange mechanism paces the nuclear import of H2Av, which is critical for downstream regulation of chromatin assembly and gene expression. Exchange of H2Av is dynamic for the first 2+ hours of embryogenesis and then suddenly (in less than 15 min) stops and the transient Jabba-H2Av interactions become static. This switch in H2Av behavior occurs during the midblastula transition (MBT), a critical developmental time for the embryo. However, the mechanism driving the switch in H2Av dynamics and its biological function are unknown. Therefore, we aim to answer the central question: How is the exchange of H2Av between LDs temporally regulated? We are testing the roles of two candidate regulators of H2Av dynamics: Importin alpha 2 (Impα2) and Cyclin-dependent kinase 1 (Cdk1). Impα2 is necessary for H2Av exchange between LDs and is developmentally dephosphorylated just as H2Av exchange halts. Cdk1 activity has been proposed to mediate the effects of a molecular timer which modulates certain MBT events, including H2Av exchange. Because in mammals Cdk1 phosphorylates the ortholog of Impα2 at a site conserved in *Drosophila*, we hypothesize that Cdk1 controls Impα2's phosphorylation status which in turn affects H2Av dynamics. To test these ideas, we are generating phosphomimetic and phospho-null mutants of Impα2 and disrupt Cdk1 activity with inhibitors and cyclin knockdown. To follow Impα2's localization live, we have tagged it endogenously with GFP. As expected, we find that Impα2 is present on the nuclear envelope during interphase and enters the nucleoplasm during mitosis. In addition, during syncytial stages, Impα2 localizes to as-yet unidentified cytoplasmic puncta in a cell-cycle

dependent manner, dispersing during mitosis. Finally, when H2Av exchange stops in nuclear cycle 14, Impα2 becomes highly enriched on LDs as well as at the cellularization front. These dynamic spatial patterns suggest that Impα2 plays multiple roles in the early embryo.A long-term goal of this project is to determine which of these roles are relevant to H2Av exchange.

1129F **Hinge-Specific Cell Fate Plasticity and Ribosome Biogenesis in *Drosophila* After Radiation Damage** Caitlin Clark, Nathan Gomes, Tin Tin Su MCDB, CU Boulder

Ionizing radiation (IR) is used to treat approximately half of all cancer patients due to its ability to induce cell death. However, IR can also induce cancer stem cell-like properties in non-stem cancer cells, potentially prompting tumor regeneration and diminishing therapeutic success. Our published studies show we can model IR-induced stem cell-like properties in *Drosophila melanogaster* larval imaginal wing discs: IR-resistant cells from the hinge of the wing disc translocate and change their fate to replace the ablated pouch cells (Verghese and Su, 2016, PloS Biology, PMID: 27584613; Verghese and Su, 2018, PloS Genetics, PMID: 30462636). Genome-wide RNAseq analysis of disassociated wing discs cells identified several IR-induced gene expression changes specific to the hinge, such as up-regulation of genes that encode ribosome biogenesis factors. Functional testing showed that ribosome biogenesis is required specifically in the hinge for IR-induced cell fate change (Ledru et al, 2022, PloS Genetics, PMID: 34990447). We are currently expressing tagged ribosomes in the hinge so that we can use the tag to isolate ribosomes specifically from the hinge and perform Ribo-seq to identify mRNAs that become differentially ribosome-associated during a time course of regeneration. This identification may help us understand why increased ribosome biogenesis is required for IR-induced fate change.

1130F **METTL3 is required for Germline Function During *Drosophila* Spermatogenesis** Alannah Morse[1,1], Corinne Leighty[2], Emily MacLean[1], Hailey Kaba[2], Antonio L Rockwell[2] [1]Biology, Susquehanna University, [2]Susquehanna University

Work focused on RNA methylation which is a novel layer of gene expression regulation has contributed to the emerging field of epitranscriptomics. Epitranscriptomics is the study of how RNA modifications impact RNA metabolism, and ultimately cellular function. Our lab is focused on the methylation of N^6 residues on adenosine (m^6A), which is required for processes such as cell proliferation, differentiation and cell maintenance. Depletion of m^6A results in problems with numerous biological processes, for example neurogenesis, embryogenesis, and gametogenesis. Investigations focused on m^6A in gametogenesis have become prominent given the link between the modification and reproductive rates. Studies have shown errors in m^6A machinery result in gamete production issues in eukaryotes. Our lab is investigating the role of the enzyme that contains the catalytic domain of the m^6A complex, Drosophila Inducer of Meiosis 4 (*Dm* Ime4) also known as METTL3. Specifically, we are studying the role of METTL3 in spermatogenesis. Our work is currently focused on the later stages of spermatogenesis known as spermiogenesis, the development of spermatids into fully mature sperm. We find that germline knockdown of METTL3 results in spermatid bundle disassociation evident by phalloidin actin staining. This disassociation phenotype is coupled with a complete ablation of actin waste bags, a phenotype associated with late-stage progression through spermiogenesis. Additionally, we find germline knockdowns lack mature sperm in seminal vesicles. Data we collected from qPCR analysis suggests several genes required for normal spermiogenesis are downregulated in knockdowns. The spermatid and sperm phenotypes coupled with the downregulation of key spermiogenesis genes results in decreased fertility in our knockdowns relative to controls. Overall, our data suggests a critical role for METTL3 during germline development in *Drosophila*. Our findings may provide additional insight into the overall role of METTL3 and subsequently the m^6A modification in metazoan reproduction.

1131F **The stress response transcription factor Atf4 regulates wing development** Kenza Lahbabi, Deepika Vasudevan Cell Biology, University Of Pittsburgh

Emerging evidence shows that ‘stress response’ pathways are required for development and homeostatic function of various cell types. We recently discovered that hypomorphic mutants for Activating Transcription Factor 4 (Atf4), a stress response transcription factor, show reduced wing size and venation defects (PMID:34919148), leading us to determine Atf4 mechanisms in wing development. RNAi depletion of *Atf4* using Hh-GAL4 resulted in convex misshapen adult wings, indicating distorted growth in the wing disc’s posterior half in absence of *Atf4*. Depletion of *Atf4* in the dorsal compartment using Ap-GAL4 also resulted in misshapen adult wings. Contrastingly, depleting *Atf4* at the dorsal-ventral boundary using Wg-GAL4 showed no adult wing phenotypes, leading us to hypothesize that Atf4 is required for regulating the growth rate in the wing disc during development. Thus, a mismatch in growth of anterior/posterior or dorsal/ventral compartments due to *Atf4* loss leads to misshapen adult wings. Canonically, Atf4 expression is regulated by *Atf4* mRNA translation. We previously demonstrated the extra-ribosomal proteins, DENR and eIF2D, to be required for Atf4 translation (PMID:32938929). Thus, we also sought to determine if these factors were required for Atf4-mediated wing phenotypes. Our preliminary results indicate that depleting these translational factors in the posterior or dorsal compartments of the wing discs show misshapen wing phenotypes similar to Atf4. Together, our data suggest that Atf4 is required for ensuring proper rate of growth across wing disc compartments during development. We are currently investigating molecular mechanisms underlying such regulation, including whether loss

of *Atf4* impacts cell size, number, or differentiation.

1132F **The anilin Scraps, the kinesins Nebbish and Pavarotti, the citron kinase Sticky, and the Rho GTPase Tumbleweed are downstream effectors of Fox transcription factor-mediated cardiac progenitor cell divisions** Md Rezaul Hasan[1,2,3], Rajnandani Katariya[1,2,3], Kuncha Shashidhar[1,2], Mofazzal K. Sabbir[1,2], Andrew J. Kump[1,2,3], Manoj Panta[1,2], Kristopher R. Schwab[1,2,3], Mark H. Inlow[2,4], Shaad M. Ahmad[1,2,3] [1]Department of Biology, Indiana State University, [2]The Center for Genomic Advocacy, Indiana State University, [3]Rich and Robin Porter Cancer Research Center, Indiana State University, [4]Department of Mathematics and Computer Science, Indiana State University

Forkhead/Fox transcription factors (TFs) mediate multiple conserved cardiogenic processes in both mammals and *Drosophila*. We showed previously that the *Drosophila* Fox genes *jumeau* (*jumu*) and *Checkpoint suppressor homologue* (*CHES-1-like*) control three categories of cardiac progenitor cell divisions—asymmetric cell division, symmetric cell division, and cell division at an earlier stage—by regulating Polo kinase activity. Those observations raised two questions: whether other Fox TF-controlled genes mediating cardiac progenitor cell divisions are also regulated by both *CHES-1-like* and *jumu* in a *polo*-like manner and whether such Fox-regulated genes mediate all three categories of cardiac progenitor cell division or a subset thereof. By comparing transcriptional expression profiles of wild-type, *jumu* loss-of-function, and *CHES-1-like* loss-of-function mesodermal cells, we identified multiple genes transcriptionally activated by *jumu*, but not regulated by *CHES-1-like*. Phenotypic analysis of mutations of these exclusively *jumu*-regulated genes showed that two, the kinesin-encoding gene *nebbish* (*neb*) and the anilin-encoding gene *scraps* (*scra*), mediate only symmetric cardiac progenitor cell divisions and cell divisions at the earlier stage; while three other exclusively *jumu*-regulated targets, the citron kinase-encoding gene *sticky* (*sti*), the kinesin-encoding gene *pavarotti* (*pav*), and the Rho GTPase-encoding gene *tumbleweed* (*tum*), are required for all three categories of cardiac progenitor cell divisions. Synergistic genetic interactions between *scra*, *neb*, *jumu*, and *polo*; the absence of such synergistic interactions between either *scra* and *CHES-1-like* or *neb* and *CHES-1-like*; and the rescue of solely symmetric and earlier cardiac progenitor cell division defects in *jumu* mutants by ectopic cardiac mesoderm-specific expression of *neb* demonstrate that *scra* and *neb* comprise an exclusively *jumu*- and *polo*-regulated subnetwork mediating a specific subset of cardiac progenitor cell divisions. Using further pairwise genetic interaction assays, we are attempting to assess whether *sti*, *pav*, and *tum* are additional components of this subnetwork. Subsequently, by utilizing qPCR and rescue assays, we intend to determine where each of these subnetwork components is positioned topologically relative to one another. Collectively, our results illustrate how an individual regulator can utilize different combinations of downstream effectors to control distinct developmental processes.

1133F **Spargel/dPGC-1 is involved in chorion gene amplification and endoreplication** Mohammed Shah Jalal, Atanu Duttaroy Biology, Howard University

The vertebrate *PGC-1* (Peroxisome proliferator-activated receptor-gamma coactivator-1) family of transcriptional co-activators serve as the master regulators of energy metabolism and robust activators of mitochondrial biogenesis. Like in vertebrates, the *PGC-1* ortholog appears in Drosophila called Spargel/*dPGC-1* (*srl*), which is now known to be crucial for cellular growth, insulin signaling, and mitochondrial oxidative phosphorylation. Drosophila Spargel/dPGC-1 is abundantly expressed in adult ovaries because it is required in ovarian growth and female fertility. Here, we report that reduced maternal Spargel leads to defective dorsal appendages in the eggs and nuclear fallout in the syncytial embryonic stage, which suggests that maternally contributed Spargel plays a significant role in eggshell patterning and proper embryonic development. During oogenesis, Spargel is required for proper chorion gene amplification, where Cyclin E activity plays an essential role. Although there is a nuclear predominance of Spargel in the ovary, recent observations reveal that Spargel is dynamic as expressed in the cytoplasm of larval tissues. This cytoplasmic Spargel is active since ubiquitous and tissue-specific knockdown of *srl* causes growth arrest. Could this alternative subcellular localization of Spargel in somatic tissues be subject to the Post Translational Modification event? Such a possibility could be real since the global phosphoproteome profile of Drosophila embryos identified Spargel as a candidate for phosphorylation. Somatic clonal analysis shows complete loss of Spargel expression in growing somatic cells retards cellular growth, hence srl^{null} cell clones in salivary glands and fat body cells fail to attain the normal nuclear size. The absence of EdU incorporation in srl^{null} cell clones in the salivary gland indicates reduced endoreplication. Thus, our findings support that Spargel plays an essential role in eggshell biogenesis during oogenesis and endoreplication during larval development.

1134F **The deletion of *midline/H15* ventral leg enhancer causes pleiotropic abnormalities across tissues** Helen L Stott[1], Cody A Stevens[2], Julia Dodd[3], Alan Rozenblit[4], Nir Yakoby[2] [1]Center for Computational and Integrative Biology, Rutgers University - Camden, [2]Center for Computational and Integrative Biology, Rutgers University - Camden, [3]Forensic Science, Rutgers University - Camden, [4]Biology, Rutgers University - Camden

Animal development is controlled by a tightly regulated network of gene expression where genes are often reused across

multiple life stages and tissues. Our understanding of the mechanisms underlying the regulation of the same gene in multiple tissues is limited to only a few genes. Although we know that *cis*-regulatory modules (CRMs) provide spatiotemporal information for genes, we do not know how many are necessary for robust gene expression during development. Using the the *Drosophila* tandem paralogs *midline (mid)* and *H15, homologs of the* mammalian Tbx-20 gene, we examined the roles of three CRMs on *mid/H15* patterning and tissue development. Generally, *mid* and *H15* are expressed in overlapping domains. They sit within an isolated topologically associating domain (TAD) that contains no other genes. Using CRISPR-Cas9 gene editing, we deleted combinations of the three CRMs. Two (G04 and F11) were associated with *mid/H15* expression in the ovarian follicle cells, and one, the ventral leg enhancer (VLE) had been predicted to regulate their expression in the ventral domain of the leg disc. Interestingly, while the impact of G04 and F11 was only evident in the ovaries, the deletion of the VLE caused pleotropic effects on egg hatching, embryogenesis, leg and wing morphogenesis, larval survival, and eclosion. Specifically, wing abnormalities included spotting, issues with unfolding following ecolsion, and in rare cases extra appendage material projecting from the wing blade or margin. Abnormal legs phenotypes included the duplication of dorsal bristles and twisted or truncated tarsal segments. While the VLE deletion did not entirely eliminate *mid/H15* expression in the leg disc, reduction of their expression in the disc center can account for some of the leg phenotypes. We note, additional CRMs, yet to be found, should regulate *mid/H15* expression in this tissue. We will also discuss the effect of VLE deletion on gene patterning during other developmental stages.

1135F **Somatic gonadal precursors are transcriptionally related to the dorsal vessel** Megan B Butler[1], Ji Hoon Kim[1], Daniel Peng[2], Deborah J Andrew[1] [1]Cell Biology, Johns Hopkins University School of Medicine, [2]Biomedical Engineering, Johns Hopkins University

Primordial germ cells (PGCs) are specified during embryonic development and later differentiate into the mature cells of the adult testis or ovary. The cells that help the PGCs mature, and are essential for their survival, are the somatic gonadal precursors (SGPs). In *Drosophila melanogaster*, SGPs are thought to derive from the dorsolateral mesoderm of parasegments 10-12 during stage 11 of embryogenesis. Previous work suggests that SGPs come from a population of cells that also become the fat body (FB) – loss of *serpent*, a key FB transcription factor, leads to the production of more SGPs instead of FB. Multiple transcription factors contribute to the specification of SGPs within the mesoderm: *abd-A* expression is necessary to define a cellular environment permissive for SGPs, whereas *eya* and its activator *abd-B* are necessary to specify and maintain SGP fate. Loss of *tinman (tin),* an essential regulator for dorsal vessel (DV) development, decreases SGP number even though previous work reported that expression of *tin* in the SGPs was not detected. Thus, there is a potentially understudied relationship between cells that become the DV and those that become SGPs. Our lab generated single-cell RNA-sequencing data from early (stages 10-12) and late (stages 13-16) stages of embryonic organ formation. In the late-stage data, the SGPs clustered within the DV cells on the UMAP – not within the FB. We also saw mRNA expression of *tin* and other DV transcription factors in the SGP cluster. We confirmed expression and nuclear localization of Tin in the SGPs by immunostaining. Apontic, another DV marker, is also expressed in the SGPs as shown by scRNA-seq and immunostaining. While the presence of these DV fate-specifying transcription factors in SGPs does not give direct evidence that SGPs come from the DV, these results do suggest that there is a greater connection between the DV primordium and SGPs than previously appreciated. Using genetic manipulation on cell type-specifying transcription factors and quantitative cell tracking, we will investigate lineage relationships between the SGPs, DV, and FB. This study will advance our understanding of developmental mechanisms and how functionally differentiated organs - reproductive (SGP), circulatory (DV), and metabolic (FB) - are generated from common or adjacent primordia.

1136F **Phosducin-like Protein 3 is a critical regulator of spermatogenesis** Jennifer Mierisch[1], Christopher Petit[2], Claire C Chaikin[2], Grace C Flemming[2], Gabi C Rant[2], Anthony C Roukoz[2], Michaela C Marra[2], Elizabeth C Kojak[2], Stefan C Kanzok[2] [1]Biology, Loyola University Chicago, [2]Loyola University Chicago

Phosducin-like protein 3 (PhLP3) homologues have been shown to possess redox-activity and are hypothesized to function as a co-chaperone in the folding of cytoskeletal proteins. However, the relationship between these two functions is unclear. The *Drosophila melanogaster* homolog of PhLP3 is encoded by the previously uncharacterized *CG4511* gene and will be referred to as Phlp3 here. We find that Phlp3 plays a role in the regulation of spermiogenesis in *Drosophila melanogaster.* Males homozygous for a P-element insertion in the 5' UTR of *Phlp3* exhibit decreased *Phlp3* expression, infertility, and a failure to produce mature sperm. Further examination of these *Phlp3*$^{-/-}$ testes reveals that actin-based individualization cones are absent, as are the needle-like nuclei indicative of mature sperm. Spermatid nuclei fail to align, appearing scattered throughout the syncytium. Microtubule-rich dense complexes (DCs), which serve as a scaffold for nuclear shaping, appear reduced in size, suggesting a reduction in the number of microtubules in the DC. Thus, nuclei may fail to fully elongate due to a defective DC. As a result, mature sperm are not produced in *Phlp3* mutants and seminal vesicle size is severely reduced. Excision of the P-element restores male fertility, spermiogenesis, and seminal vesicle size. Given our observations and the hypothesized role of PhLP3 proteins as co-chaperones for cytoskeletal proteins, we hypothesize

that Phlp3 functions to regulate the microtubule dynamics that are vital for DC formation and the nuclear-shaping process during spermiogenesis, as well as the function of the actin-based individualization complexes. We are currently examining the importance of thioredoxin activity for Phlp3 function in spermatogenesis, as well as the effects Phlp3 mutation on the cytoskeleton using Transmission Electron Microscopy. PhLP3 proteins are well-conserved in humans, suggesting that our results on Phlp3 function in flies. Therefore, we are testing the ability of the human homologue of Phlp3, Txndc9, to functionally substitute for Drosophila Phlp3 during spermatogenesis. This

1137F **Determining how Doublesex and sex-specific steroid hormone signaling control gonad development** Samantha C Goetting[1], José Pac Cordero[2], Mark Van Doren[2] [1]Biology, Johns Hopkins University, [2]Johns Hopkins University

In the animal kingdom, most species exhibit sexual dimorphism, or phenotypic differences between the sexes. In *Drosophila*, the key factor controlling sexual dimorphism is Doublesex (Dsx). Dsx is the founding member of the Doublesex/Mab-3 Related Transcription Factor (DMRT) family and is conserved in many animals, including humans. Our lab has shown that Dsx regulates sex-specific steroid hormone Ecdysone (E) signaling through female-specific Ecdysone Receptor (EcR) expression, and that this functions to promote ovary development and repress testis development. Bioinformatic analyses have been used to predict Dsx targets, and many are transcription factors that contain a BTB (Broad-complex, Tramtrack, and Bric-a-brac) domain that promotes homo- and heteromeric BTB protein interactions. An RNAi screen of BTB domain transcription factors revealed that several are important for normal gonad development. Here we focus on three of these factors: *broad (br), chinmo (chronically inappropriate morphogenesis)* and *mamo (maternal gene required for meiosis)*.

Knockdown of *br* in the somatic gonad causes severe somatic cell defects in the ovary from third larval instar (L3) onwards. Loss of *br* or *mamo* leads to severely disorganized adult ovaries and loss of egg production, with a female-specific phenotype. Conversely, loss of *chinmo* leads to formation of follicle-like cells in the developing testis. Upon examining Mamo and Chinmo expression during development, I found that Mamo is female-specific while Chinmo is male specific. Previous studies revealed a relationship between *br, chinmo,* and *mamo*. In the wing disc, a mid-L3 Ecdysone pulse mediates a Chinmo-to-Br switch; in neurons, temporal expression of Chinmo or Mamo can specify neuronal fates. These observations provide useful groundwork for their potential roles in the gonad. Given these data, I hypothesize that *br* and *mamo* are important for proper ovary development and function, and that they lie downstream of Dsx and/or E signaling to help maintain a female sexual fate. I plan to characterize what cell types are affected in the absence of *br, chinmo,* and *mamo* using cell-specific markers and examine how altering *dsx* and E signaling affects expression of these genes. This work will expand current knowledge on how DMRTs control sexual dimorphism and could uncover genes critical for sexual identity in both flies and mammals. Due to the universal nature of DMRTs in controlling sex-specific development, understanding their targets and how they function is of great importance for reproductive health and has the potential to broaden our knowledge of human infertility.

1138F **Peroxisome Proliferator Activated Receptor Gamma Co-activator-1 (PGC-1): Functional convergence and divergence between vertebrates and invertebrates** Swagota D Roy[1], Mohammed Shah Jalal[2], Sabarish Nagarajan[3], Atanu Duttaroy[2] [1]Biology, The Howard University, [2]Biology, Howard University, [3]Genetics/ Biotechnology, University of Wisconsin, Madison

Peroxisome Proliferator Activated Receptor Gamma Co-activator-1 (PGC-1) is a canonical transcription co-activator in all Chordates and misregulation of these coactivators leads to a wide range of diseases, including cancer and lethality. In vertebrates, the *PGC-1* (Peroxisome proliferator-activated receptor-gamma coactivator-1) family of transcriptional co-activators consists of *PGC-1α*, *PGC-1β*, and *PRC* (PGC-1-related Coactivator) are well known since they serve as master regulators of energy metabolism and a robust activator of mitochondrial biogenesis. In addition to bioenergetics, the PGC-1 group of proteins is also involved in myriads of activities in specific tissues like gluconeogenesis and anti-apoptosis in the liver, thermogenesis in adipose tissues, fiber-type switch in skeletal muscles, etc. Many invertebrates including *Drosophila* carry a single homolog of PGC-1 named Spargel/dPGC-1 that shows many functional convergence and divergences with vertebrate PGC-1. Since Drosophila homolog is prevalent as a single copy gene could it circumvent the redundancy issue in vertebrates? Indeed, significant functional similarities are shared between vertebrate and invertebrate PGC-1's based on their role in mitochondrial functions and biogenesis, gluconeogenesis, growth, and cancer. Development is delayed in both Spargel and PGC-1 related coactivator (PRC), a member of PGC-1 gene family and complete knockouts of *srl* and *PRC-1* are embryonic lethal. In terms of divergence, we not only established that Spargel plays an essential in *Drosophila* oogenesis but the critical role of Spargel RRM and RS domains are established in oogenesis. Spargel is a maternal effect gene, which is potentially involved in Endoreplication in polytene cells. These specific aspects of PGC-1 biology are to be explored in vertebrates. Therefore, a complete functional comparison between Spargel/dPGC-1 and PGC-1 will pave the way to uncover unexplored functional equivalence in mammals.

1139F **Regulation of growth and patterning in the developing eye of *Drosophila melanogaster* by the Hippo pathway**

coactivator *yorkie* and dorsal selector *defective proventriculus* Rohith BN[1], Amit Singh[2,3,4], Madhuri Kango-Singh[1,3,4] [1]Growth Regulation and Signalling Laboratory, Department of Biology, University of Dayton, [2]Drosophila Development and Disease Laboratory, Department of Biology, University of Dayton, [3]Premedical Program, University of Dayton, [4]Integrative Science and Engineering Center, University of Dayton

The developing eye of *Drosophila* is a well-established model for studying developmental genetic processes and growth regulation. The developmental genetic networks discovered in *Drosophila* are highly conserved in all animals including higher mammals. Our long-term goal is to understand the molecular basis of Dorsal-Ventral patterning and growth in the eye by interactions of the dorsal selector genes and growth regulatory genes. We recently identified *defective proventriculus* (*dve*) as a candidate for dorsal-ventral eye patterning that acts as a transcriptional regulator. Gain of function of Dve, results in eye suppression, while loss of function of *dve*, exhibits dramatic eye enlargement phenotypes which raised an interesting question, whether the dorsal patterning gene *dve*, apart from its main function of specifying cells fate, plays a dual role in regulating growth during eye development in *Drosophila*? We hypothesized that Dve may interact with the Hippo growth regulatory pathway to control patterning and growth of the eye. We tested the interactions between Hippo pathway and dorsal-ventral patterning using the GAL4-UAS system and MARCM. To investigate whether *yki* is involved in *dve* domain growth, we used GAL4 drivers in the eye like Dve Gal4 to drive the spatiotemporal expression of transgenes in the dorsal eye, and Ey-Gal4 and GMR-Gal4 to test the effects of Dve and Yki modulations before and after MF formation in the larval eye antennal disc. Initial data suggests genetic interactions between Hippo and DV patterning genes are important in early eye development. We have tested *wingless* (*wg*) a known and conserved Hippo downstream target for Dve and Yki mediated effects using reporter assays, clonal analysis and qRT-PCR- based approaches; and our results will be discussed.

1140F **Transcriptional co-repressor Atrophin regulates Hippo pathway target genes in *Drosophila*** Deimante Mikalauskaite[1], Cordelia Rauskolb[2], Tom Lehan[2], Srividya Venkatramanan[2], Kenneth D Irvine[2] [1]Waksman Institute, Rutgers University, [2]Department of Molecular Biology and Biochemistry, Waksman Institute, Rutgers University

The Hippo signaling pathway controls expression of target genes through its downstream effector, the transcriptional co-activator Yorkie (Yki). With our expanding knowledge of Hippo pathway activity, other components regulating expression of Yki target genes still need to be identified. Previous studies suggest that the transcriptional co-repressor Atrophin could regulate expression of the Yki target gene *four-jointed*.

Using gene knock down and overexpression approaches we investigated whether Atrophin contributes to Hippo signaling in the wing imaginal disc, and what molecular mechanisms underlie this regulation. We found that Atrophin regulates multiple Hippo pathway target genes. Interestingly, our results show that Atrophin represses the expression of Yki target genes in the distal wing and activates them in the proximal wing. When we investigated Atrophin's effect on Yki, we found that Atrophin knock down resulted in decreased Yki nuclear levels throughout the wing, while overexpression had an opposite effect, suggesting that Atrophin controls Yki nuclear localization. This result implies that Atrophin regulates Hippo pathway activity. We further identified that depletion of Atrophin leads to changes in component levels of Fat-Dachsous (Ft-Ds) signaling, which controls Hippo pathway activity.

We are now investigating how Atrophin regulates the levels of the Ft-Ds factors. In addition, we plan to identify direct transcriptional targets of Atrophin. These studies will help us understand how Atrophin exerts its regulatory function on the components of the Ft-Ds network and explain its downstream effects on Yki target gene expression.

1141F **Functional analysis of a Drosophila Hox gene enhancer essential for segment-specific sense organ development** Xinyuan Liu, Teresa V Orenic Biological Sciences, University of Illinois at Chicago

Hox genes encode conserved transcription factors (TFs) that specify segmental or regional identity along the anterior-posterior (A/P) axis of developing animal embryos and also function during later developmental stages in patterning of limbs and other organs. During embryonic development, the Hox TFs function at the top of the hierarchy that controls intra-segmental patterning to generate differences in segmental/regional patterning. On the other hand, recent studies in Drosophila and other insects suggest that the Hox genes are targets of intra- segmental patterning genes and function downstream of these genes to generate morphological differences among limbs. We are investigating the regulation of the Hox gene *Sex combs reduced (Scr)*, in response to the intra-segmental patterning networks that control development of the Drosophila adult legs. *Scr* is expressed throughout legs of the first thoracic segment (T1) legs, but its expression is elevated in defined domains of developing legs within the primordia of a group sense organs, the transverse bristle rows (TBRs). We have identified an *Scr* enhancer (*ScrE*) that drives expression in the TBR primordia and is required for TBR development in T1 legs. Furthermore, the proximal/distal (P/D) patterning genes *Distalless* (*Dll*), *dachshund* (*dac*) and *bric-a-brac1/2* (*bab1/2*) regulate *Scr* expression through the enhancer. Dll, a homeodomain (HD) TF, activates *Scr* expression through multiple sites dispersed throughout the *ScrE* enhancer. Dac

is a conserved TF that is required for upregulated expression of both *Scr* and *ScrE-GFP.* The *bab* locus contains 2 paralogous genes, *bab1* and *bab2.* Previous studies suggested Bab1 function is not essential for leg development. However, we recently found that both Bab1 and Bab2 are essential for TBR patterning and *Scr* distal repression in T1 legs. In addition, *ScrE* is responsive to repression by Bab1/2, and potential Bab-response sequences have been mapped to a 78bp conserved block within *ScrE*. An in vivo functional analysis of these sequences is in progress to determine the necessity of these sites for *Scr*expression and patterning of T1 leg sensory organs. This investigation will provide insight into Hox gene regulation of segment-specific sense organ patterning in response to leg P/D patterning TFs.

1142F **Characterization of novel *Drosophila* Egf receptor signaling targets with roles in eggshell morphogenesis** Kayla Eckrote, Autumn Bullek, Sara Delgado, Lisa Kadlec Biology and Earth Systems Science, Wilkes University

Drosophila epidermal growth factor receptor (Egfr) signaling plays a critical role in many aspects of development including oogenesis, embryogenesis, and proper development of wing and eye tissues. For example, during wing development Egfr signaling helps specify vein tissues, and in the ovary Egfr signaling is known to establish the body axes during oogenesis. Microarray screens by our lab and others have identified potential downstream transcriptional targets of the Egf receptor using the *Drosophila* ovary as a model system. Our initial work compared gene expression in fly ovaries where the activity of the Egfr pathway was reduced (gurken mutant), wild-type (OreR), or constitutively active (CY2/λTop). We have employed a number of approaches to further investigate the expression, biological function, and mechanism of action of a subset of putative genes of interest, focusing primarily on genes of previously unknown function. A small-scale functional screen using available collections of UAS-RNAi transgenic flies and P-element insertion lines was used to investigate the possible functions of a group of these novel EGFR-responsive genes. This screen has identified multiple genes activated by EGFR signaling that appear to have roles in the morphogenesis, rather than the patterning, of eggshell features. Gene mutant/knockdown phenotypes include severely decreased chorionic integrity, shortened eggs, and various dorsal appendage malformations, as well as decreased fertility. We have also used the CRISPR-Cas9 system to create mutations in some of these genes, with a goal of generating null mutant lines. Characterization of these mutants has so far revealed expected (previously observed) phenotypes, and in some cases additional eggshell phenotypes not seen with the original knockdown or P-element flies. We are continuing to characterize our most recently generated CRISPR lines, as well as using existing CRISPR mutants for further study and characterization of our genes of interest.

1143F **Transcriptional pausing mechanism: A common link for two independent homeostatic pathways of apoptosis and autophagy** Anuradha V Chimata[1], Hannah Darnell[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration & Engineering (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

During development, cell death mechanisms like apoptosis and autophagy work independently in regulating cellular homeostasis. Cellular homeostasis, crucial for organ growth and development, is regulated by signals generated by activation of specific gene cascades. These signals are governed at a transcriptional level by several mechanisms including transcriptional pausing. Motif 1 binding protein (M1BP), a functional homolog of human ZKSCAN3, is a transcription pausing factor that binds to several developmentally regulated genes. Recently, we have shown that loss-of-function of M1BP results in a “reduced-eye” or “no-eye” phenotype due to cell death. We employed a genome-wide forward genetic screen strategy to identify downstream targets of M1BP, which resulted in identification of members of evolutionarily conserved Jun-amino-terminal-(NH2)-Kinase (JNK) signaling pathway as modifiers of the “reduced-eye” or “no-eye” phenotype of $MIBP^{RNAi}$. JNK pathway is a pro-death pathway that is a master regulator of different types of cell death. We found that downregulation of M1BP resulted in activation of JNK signaling pathway, which resulted in induction of caspase-dependent cell death. However, blocking caspase-dependent cell death did not provide a complete rescue of “reduced-eye” phenotype of M1BP downregulation. Previous studies in mouse models have shown that double knock-out mice for apoptosis genes still showed delayed but increased cell death via compensatory autophagy mechanism. Therefore, we looked for other cell death mechanisms and found that autophagy is also upregulated when M1BP is downregulated. Interestingly, JNK is also known to induce autophagy, a caspase-independent cell death mechanism. Blocking both apoptosis and autophagy along with M1BP downregulation resulted in a significant rescue of M1BP “reduced-eye” phenotype. Our study revealed for the first time that M1BP activates both apoptosis as well as autophagy in JNK dependent manner. Here, we demonstrate a novel cellular homeostasis mechanism where transcriptional pausing is regulating these two genetically distinct modes of cell death during eye development to promote cell survival and regulate cellular homeostasis.

1144F **Unraveling adherens junction signaling complexity in the oral epithelia during palatogenesis** Juliet S King[1], Kendall Lough[2], Akankshya Jena[2], Scott Williams[3] [1]Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, [2]University of North Carolina at Chapel Hill, [3]Pathology and Laboratory Medicine Department, University of North Carolina

at Chapel Hill

Cleft palate (CP) is among the leading congenital diseases in the US and across the globe. CP results from a failure to separate the oral and nasal cavities during embryogenesis, a process known as palatogenesis. One contributing factor to the widespread nature of CP is the over 200 genes in humans and mice that when mutated disrupt palatogenesis. Among the CP-linked genes, components of the adherens junction (AJ) complex expressed in the oral epithelia, have garnered recent attention. Mutations in genes that encode AJ receptors, like cadherins (*CDH1*) and nectins (*NECTIN1*), are associated with CP in humans. However, we still do not understand the mechanism by which AJ receptors facilitate palate closure. To address this, our lab has disrupted nectins and cadherins, as well as their downstream signaling effectors, to determine their effect on palate closure. Currently, we are focused on segregating the relative contribution of AJ signaling across the two oral epithelial layers, the progenitor basal keratinocytes and the protective periderm layer. To do so, we are knocking down and knocking out AJ proteins in both a periderm-specific manner as well as a whole oral epithelial loss. Our lab utilizes two genetic manipulation techniques: 1) traditional Cre/LoxP mediated gene knockout as well as 2) *in-utero* guided lentiviral injections that transduce the outer ectoderm with short-hairpin RNAs (shRNAs) and gene expression constructs. Preliminary evidence has suggested that periderm-specific loss of cadherin 1, aka E-cadherin (*Cdh1*) demonstrates a similar palatal fusion defect as *Cdh1* knockdown in both oral epithelial layers. This suggests that E-cadherin signaling is at least in part required in the periderm. Future directions are focused on determining if periderm-specific loss of afadin (*Afdn*), the downstream nectin binding partner, can drive CP at the same penetrance as whole epithelial *Afdn* loss does. These experiments aim to discern between two possible functions of the periderm: A passive function, where the periderm simply protects underlying basal keratinocytes from unwanted intraoral adhesions. Or an active role, where the periderm participates in palatal fusion through AJ-based cell adhesion programs. Moreover, this work continues to elucidate important signaling mechanisms that regulate palatogenesis with the potential to generate novel models of CP in mice.

1145F **Understanding the aberrations in male reproduction caused by the mouse t-haplotype.** Ana M Velasquez[1,2], Camilo Hernandez-Aviles[3], Luisa Ramirez-Agamez[3], David W Threadgill[1,2] [1]Interdisciplinary Graduate Program in Genetics and Genomics, Texas A&M University, [2]School of Medicine, Department of Cell Biology and Genetics, Texas A&M University, [3]School of Veterinary Medicine and Biomedical Sciences, Texas A&M University

The mouse t-complex is one of the most well-known examples of naturally existing super-Mendelian inheritance. Despite decades of intense research, the mechanism underlying such special inheritance pattern is yet to be fully understood. The t-haplotype comprises a series of four non-overlapping inversions on mouse Chromosome 17. It has been established that the t-haplotype accomplishes biased transmission by disrupting motility of wild type sperm in heterozygous males.

Many genes that play important roles in such dysregulation have been mapped and identified. Nonetheless, it is yet to be established exactly how these gene products interact together to produce the phenotypes observed. Several studies have detected a series of morphological and physiological abnormalities present in the sperm of t-carrying males. However, some of these studies contradict each other.

A likely explanation for the differing results is the use of different t-carrying mouse strains. There are numerous versions of either partial or complete t-haplotypes that vary in inheritance rates ranging from 20% to 99% between t-haplotypes. Additionally, some of these strains carry a homozygous lethal gene that makes sperm analyses challenging, while for the remaining strains homozygous males are sterile.

This study aims to better understand the reproductive aberrations on males carrying the tw2 haplotype. The tw2 strain was originally captured in 1946 and has been maintained in laboratory since. This specific haplotype is advantageous as these mice carry a complete t-haplotype with 95-99% inheritance rates but lack lethal mutations allowing for the study of sperm from homozygous males. In addition, this specific haplotype has recently attained attention from scientists as a potential tool for genetic biocontrol of invasive rodents. In collaboration with the Texas A&M University Theriogenology Laboratory, we are studying a series of morphological, physiological, and molecular parameters in reproductive tissues of tw2 mice to identify the underlying issues resulting in homozygous male sterility, as well as aberrations in heterozygous males.

Results from this study will guide scientists on their use of the t-haplotype, and specifically the tw2 haplotype, for mouse eradication purposes, as well as inform future experiments to better understand of the mouse t-haplotype.

1146F **Temporality and Mechanisms of Retinogenesis in Human Retinal Organoids** Benvindo Chicha, Robert Johnston Biology, Johns Hopkins University

Human vision is dependent on the retina, a multilayered tissue that detects, processes, and relays light information. Vision

begins with the detection of light by photoreceptors. This light-induced signal is transmitted via interneurons including bipolar cells, amacrine cells, and horizontal cells, to retinal ganglion cells. All light information converges at retinal ganglion cells before being transmitted to the brain. In addition to these neurons, Müller glia span the retina and are responsible for architectural and metabolic functions. The numerous neuronal types of the retina are generated at different overlapping timepoints, yet a high resolution timeline of cell birth, maturation, and death in the developing human retina has not been achieved, due to the experimental inaccessibility of human fetal retinal tissue. Moreover, the spatiotemporal mechanisms controlling neuronal development in the human retina are poorly understood. It is unclear if the temporality of cell fate specification reflects the birth timing or maturation rates of these cells. The main goal of this study is to identify temporal mechanisms governing the generation and maturation of neurons in the human retina using human retinal organoids.

To assess the timing of neuronal type birth, maturation, and death, I am using nucleotide analogs (i.e. EdU) to label newly replicated DNA for 48 hours every 7-days across organoid development. Whereas dividing progenitor cells will dilute the label over time, post-mitotic cells will retain this label, enabling me to track cells born at distinct times. While larger windows are preferred, my preliminary experiments showed that EdU is toxic when administered in >48-hour pulses, limiting the length of the temporal windows. In a parallel approach, I am developing a transgene-based strategy to birth date cells with H2B-GFP in wider windows. Mitotic cells will divide and dilute the label while neurons born in the window will retain the H2B-GFP. this system, allows more fine-tuned control and adaptability for later experiments.

The Johnston lab found that retinoic acid (RA) acts early and thyroid hormone (TH) acts late during retinogenesis to specify photoreceptor fates. To test how these signals affect the timing of cell generation, I am examining changes in cell birth dates upon changes in signaling environments. These studies will determine how signaling pathways govern the timing of cell type generation and cell fate specification decisions.

1147F **Evidence for essentiality of 1-aminocyclopropane-1-carboxylic acid (ACC), a precursor of phytohormone ethylene in Arabidopsis thaliana** Husan Turdiev[1], Bret Cooper[2], Caren Chang[1] [1]Cell Biology and Molecular Genetics, University of Maryland, [2]Soybean Genomics and Improvement Laboratory, USDA ARS

Ethylene is a gaseous phytohormone that has major effects on plant growth and development, including seed germination, root growth, fruit ripening, and senescence, as well as tolerance to biotic and abiotic stresses. In angiosperms, ethylene is produced in a two-step reaction: S-adenosylmethionine (SAM) is converted to 1-aminocyclopropane-1-carboxylic acid (ACC) by the enzyme ACC synthase (ACS), and ACC is then converted to ethylene by the enzyme ACC oxidase (ACO). Recent evidence suggests that ACC itself can induce responses independent of its role as the ethylene precursor. However, the roles of ACC as a potential signal are unclear, in part because there is no *acs* null mutant. In *Arabidopsis thaliana*, the only available *acs* octuple mutant shows incomplete knock-down of two of the eight Arabidopsis *ACS* genes by artificial micro-RNA silencing (Tsuchisaka et al., *Genetics* 2009), and we have found that this “octuple” mutant still produces ACC. We therefore aimed to create a true *acs* null mutant in Arabidopsis by utilizing a multiplex CRISPR-Cas9 system (Stuttmann et al., *Plant J.* 2021) to target all eight *ACS* genes. Surprisingly, we have only been able to generate an *acs* septuple mutant lacking all but a single *ACS* gene. We found that seeds of the *acs* septuple mutant consistently fail to germinate when they carry the CRISPR-Cas9 transgene, suggesting that editing of all eight *ACS* genes is responsible for the failure to germinate. This contrasts with the apparent dispensable role of ethylene production (Li et al., *Mol. Plant* 2022) and raises the possibility that ACS function is essential for plant growth. Currently, we are testing whether ACC can rescue the seed germination defect and are designing a conditionally viable *acs* octuple mutant to investigate the requirement for *ACS* activity. Our work will potentially reveal a novel ACC function in plants.

1148F **Wnt4 and ephrinB2 instruct apical constriction via Dishevelled and non-canonical Wnt signaling** Jaeho Yoon, Ira Daar NCI

Apical constriction is a cell shape change critical to vertebrate neural tube closure, and the contractile force required for this process is generated by actin-myosin networks. The signaling cue that instructs this process has remained elusive. Here, we identify Wnt4 and the ephrinB2 transmembrane ligand as playing instructive roles in neural tube closure as members of a signaling complex we termed WERDS (Wnt4, EphrinB2, Ror2, Dishevelled (Dsh2), and Shroom3). Disruption of function or interaction among members of the WERDS complex results in defects of apical constriction and neural tube closure. The mechanism of action involves Wnt4 binding the non-canonical Wnt receptor, Ror2, and enhancing an interaction with the transmembrane protein, ephrinB2, through the main Wnt scaffold protein, Dsh2. This complex in turn recruits the adaptor protein Shroom3, which activates Rho-associated kinase (Rock) to induce apical constriction. Remarkably, we also discovered that a key part of this mechanism is that ephrinB2 antagonizes Wnt/β-catenin signaling through the interaction with Dsh2, which switches Dsh2 function from canonical to non-canonical Wnt signaling that is required for proper neural tube closure.

1149F **Meiosis II Spindle disassembly requires two distinct pathways** Xheni Mucelli, Brian C. Seitz, Maira Majano, Zoey

Wallis, Ashley C. Dodge, Catherine Carmona, Matthew Durant, Sharra Maynard, Linda S. Huang Biology, University of Massachusetts Boston

Budding yeast undergo sporulation when starved of adequate nutrients. Sporulation involves meiosis and the packaging of the haploid nuclei into spores. At the end of meiosis II, *Saccharomyces cerevisiae* cells must disassemble the meiosis II spindle and undergo cytokinesis; these two events must be coordinated. Meiosis II cytokinesis occurs by prospore membrane closure: the prospore membrane is a newly synthesized membrane that grows around each of the haploid nuclei for cellularization of the developing spore within the mother cell. *SPS1*, which encodes a STE20-family GCKIII kinase that acts downstream of the Hippo-like kinase encoded by *CDC15*, and *AMA1*, which encodes a meiosis specific activator of the Anaphase Promoting Complex, are required for both spindle disassembly and cytokinesis in meiosis II. To better understand the regulation of spindle disassembly and cytokinesis in meiosis II, we examined roles of *SPS1* and *AMA1* in exit from meiosis II. We find that the prospore membrane closure defects of both *sps1Δ* and *ama1Δ* cells do not result from the failure of spindle disassembly. Instead, these two processes are regulated independently of one another by *SPS1* and *AMA1*. We also find that *sps1Δ* and *ama1Δ* cells exhibit distinct defects in spindle disassembly. By examining known microtubule-associated proteins important for spindle disassembly in mitosis, we find *AMA1*is required for the removal of Ase1 and Cin8 from the meiosis II spindle, while *SPS1* is required for proper removal of Bim1. Our data indicate that the two pathways represented by *SPS1* and *AMA1* are required for different aspects of meiosis II spindle disassembly. Furthermore, these microtubule associated proteins are regulated by meiosis-specific regulatory proteins that act in similar pathways as the pathways used to regulate mitotic spindle disassembly.

1150F **Control of Yeast Cell Fusion by Regulated Secretion** Ursula Machi[1], Emily Mazur[1], Annika Sundlof[2], Jean Smith[3], Mark Rose[2] [1]Georgetown University, [2]Georgetown University - Washington, DC, [3]Stetson University

Cell-cell fusion is a critical event in many systems, including muscle development, fertilization, and immune response. In yeast mating, partner cells must first degrade the intervening cell wall material before plasma membrane fusion can be achieved. Cell wall removal is carried out by secreted remodeling enzymes including Scw4, Gas1 and Scw10, which have been implicated in mating previously or in this study. The action of these enzymes must be tightly controlled, as premature or ectopic cell wall degradation would cause cell lysis. Yeast cell fusion requires continuous secretion, as revealed by mutations in the standard secretory pathway. Electron microscopy demonstrated the appearance of mating-specific vesicles in pheromone-responding cells and at the Zone of Cell Fusion (ZCF) in prezygotes. The vesicles dissipate after fusion is complete. The behavior of the vesicles appeared to be regulated by proteins required for fusion including Fus2, Rvs161, and Cdc42. Deletion of *FUS2* and function specific mutations in *RVS161* and *CDC42* appear to block vesicle fusion with the plasma membrane (as judged by their retention at the ZCF) and cause defects in subsequent cell wall degradation, but do not show evidence of defects in general secretion. Interaction between these proteins is required for cell fusion, likely through facilitation of secretion of these vesicles. To study the possibility of a mating-specific regulated secretion pathway in yeast, we developed a single-cell microscopic secretion assay using a Fluorogen-Activated Protein (FAP) tag fused to Scw4, Scw10 and Gas1. Secretion is assayed using a membrane-impermeant fluorogenic dye; binding to secreted FAP generates a fluorescent signal. Secretion of FAP-Scw4 and FAP-Gas1 at the ZCF is dependent on Fus2, whereas FAP-Scw10 secretion is not, revealing both general secretion and Fus2-regulated secretion at the ZCF. Blocking the interaction between Fus2 and Cdc42 with function specific alleles altered the secretion pattern of FAP-Scw4 and FAP-Gas1. Whereas WT cells largely had a singular focused burst of secretion at the ZCF, loss of the interaction caused multiple transient secretion foci. As Scw4 and Gas1 expression is high in mitotic cell and shut off during mating, we conclude that Scw4 and Gas1 are likely preloaded into the mating-specific vesicles, which are specifically secreted during conjugation to help effect cell wall removal. Rather than being required for secretion per se, Cdc42 facilitates Fus2 localization to ensure wall degradation cargo is secreted in a concentrated fashion, capable of overcoming cell wall repair regulated by the Cell Wall Integrity Pathway.

1151F **Zebrafish as a new model to analyze tooth development and homeostasis** Kanako Inoue[1], Kiyohito Taimatsu[2], Brant Weinstein[2] [1]NIH, [2]NICHD, NIH

Although the process of tooth development is highly conserved from fish to mammals, the process of tooth development has not yet been fully elucidated because it begins during embryonic stages and teeth are opaque hard tissues that are relatively inaccessible to observation and experimental. Until now, tooth analysis methods have been conducted only on isolated teeth, such as histological sectioning and *ex vivo* culture of tooth germs, and the behavior of cells involved in the development and the three-dimensional (3D) localization of surrounding tissues such as blood vessels have not been elucidated to any significant degree. We are developing the zebrafish as a powerful new model organism for *in vivo* study of tooth development.

Zebrafish have pharyngeal teeth attached to the fifth branchial arch in the pharynx. Zebrafish dentition consists of three rows of teeth on each side for a total of 11 teeth - five in the ventral row, four in the mediodorsal row, and two in the dorsal row. Zebrafish pharyngeal teeth are constantly replaced every about two weeks throughout life, allowing observation of multiple

stages of tooth development at all times in the same animal. Our group has pioneered a new imaging technique using a novel clearing reagent to render the teeth and bones of the zebrafish optically clear. This allows analysis of tooth 3D structure and the dynamics of cell populations involved in tooth development. We have performed high-resolution imaging of fluorescent reporter lines labeling a variety of tooth cell types including odontoblasts, dental epithelial cells, and surrounding mucous cells, revealing their detailed 3D distribution in the dental pulp and surrounding structures. We have succeeded in 3D imaging the differentiation of dental epithelial cells into enamel-secreting ameloblasts and have even visualized minute microstructures such as dentin tubules in odontoblasts. Together, our work reveals the comprehensive three-dimensional structure of the developing and adult tooth, from the pulp to the surrounding tissues, underscoring the utility of the zebrafish as a powerful model for analyzing tooth development and homeostasis.

1152F **Vgll3 as a Transcriptional Regulator in Embryonic Hindbrain Cell Fate Pathways** Cameron E Bennett, Yong-Il Kim, Rebecca O›Rourke, Charles Sagerström Pediatrics-Developmental Biology, University of Colorado Anschutz Medical Campus

Understanding what drives neural progenitor cell fate decisions is a key question in developmental biology as incorrectly timed and placed neural circuitry is associated with neurodevelopmental disorders. One proposed mechanism for controlling spatiotemporal neural development are neuromeres, called rhombomeres in the hindbrain. These seven or eight segmented regions are highly conserved across vertebrates and have restricted cell lineages, but how they form remains unknown. Previous investigation identified pre-rhombomeres, however, it was uncertain if they were an artifact of mechanical cell migration forces or represented progenitors with distinct fates. Previous work in the field showed that mutations in transcription factor Mafba (Mafb in Humans) inhibit the formation of distinct r5 and r6 rhombomeres, resulting in the retention of rX, a distinct progenitor domain, in their place. This finding is some of the only molecular evidence in the existing body of literature for the existence of pre-rhombomeres. Our single-cell RNA-seq analysis shows molecular evidence for pre-rhombomeres at 10 hours post fertilization (hpf) as well as identified distinct cell identities for each rhombomere at 13hpf in zebrafish. In our data, we find three clusters at 10hpf that we postulate correspond to r2/r3, r5/r6, and r4, respectively. These data show the first molecular definition for pre-rhombomeres, and we have verified these expression patterns *in vivo* using HCR RNA-FISH. Notably, we find that transcription factor Vestigial-Like 3 (Vgll3) has restricted expression at r2 at 13hpf but is coexpressed with egr2b, an r3 marker, in progenitor cells at 10hpf. We hypothesize that transcription factor Vgll3 is necessary for promoting rhombomere 2 cell fates and suppresses rhombomere 3 cell fates by disrupting egr2b's autoregulatory loop. To do so, embryos from the in-cross of our heterozygous Vgll3 mutants as well as our Vgll3 transgenic line will be screened for phenotypes in rhombomeres 2 and 3. Rhombomere phenotypes will be screened for using confocal imagery HCR RNA-FISH in fixed embryos at 10, 13, and 16 hpf, with probes labeling markers for rhombomeres 1 (irx1b), 2 (Vgll3), and 3 (egr2b). The width of the labeled rhombomeres will be measured using FIJI image processing software. Embryos will then be genotyped blind after imaging using the allele-specific genotyping method KASP. Funded by NIH #NS038183 and NIGMS #5T32GM136444-04.

1153F ***Dpp9* regulates lower jaw bone development and inflammasome activation in zebrafish** Sarah LaPotin, Madeleine Servais, Kristen M. Kwan Human Genetics, University of Utah

DPP9 deficiency is an autoinflammatory disease caused by loss of function mutations in DPP9. In this disease, there is typically persistent inflammasome activation and associated skin, craniofacial, and/or skeletal defects. The presence of developmental defects in patients with DPP9 deficiency suggests DPP9, in addition to functioning as a regulator of the immune system, could have an uncharacterized role in embryonic development.

In order to investigate the function of DPP9 in development, we generated stable *dpp9* mutant zebrafish. *Dpp9* mutants have craniofacial abnormalities and display a defect of a specific lower jaw bone. The affected bone, the anguloarticular, is highly reduced and misshapen in all homozygous mutants. Similar to wild type and heterozygous siblings, anguloarticular calcification begins in mutants at 7-8 dpf and starts to occur in the correct location. However, by 10 dpf and forward in developmental time, the anguloarticular is significantly shorter and smaller in mutants suggesting a defect impacting the subsequent bone growth and shaping rather than initiation. Interestingly, although cartilage defects frequently accompany lower jaw bone defects, the jaw cartilage elements appear normal in morphology in *dpp9* mutants, suggesting a defect specific to this bone formation.

Moving forward, a major goal is to uncover the cellular mechanisms underlying the anguloarticular defect in *dpp9* mutant zebrafish. Potential cellular mechanisms we are currently investigating include localized ectopic cell death and dysregulated osteoclast activity. We are also investigating the possibility of hyperproliferative cartilage or premature ossification of skeletal elements outside the jaw impacting the anguloarticular.

We also aim to determine the molecular mechanisms underlying this phenotype. Similar to humans with DPP9 deficiency, *dpp9* mutant zebrafish display inflammasome activation. We are investigating the spatial and temporal dynamics of

inflammasome activation in these fish, and if inflammasome is ultimately driving the anguloarticular phenotype. Additionally, as *dpp9* appears ubiquitously expressed, another goal is to determine how global loss of a ubiquitously expressed gene can cause what appears to be this specific defect of a lower jaw bone.

1154F **Cornea morphogenesis in normal development and in a model of Axenfeld-Rieger Syndrome** Emily D Woodruff, Ella S Habbeshaw, Kristen M Kwan Department of Human Genetics, University of Utah

The cornea is the transparent anterior-most tissue that protects the eye and refracts light entering the eye. Three main tissues comprise the cornea: the corneal epithelium (outer layer), corneal stroma (middle layer), and corneal endothelium (innermost layer). Proper formation of these three tissue layers during development is crucial for function; improper formation can lead to visual impairment, as seen in manifestations of a congenital genetic disorder, Axenfeld-Rieger Syndrome (ARS). ARS is characterized by structural defects in the anterior eye including the cornea, iris, and anterior chamber. Despite the importance of the cornea for vision, the cellular and molecular mechanisms underlying cornea formation in normal conditions and in ARS remain poorly understood.

We are investigating the cellular basis for cornea formation under normal conditions and in an ARS model, the *pitx2* mutant zebrafish. Our initial observations of the *pitx2* mutant zebrafish eye, which are consistent with previous reports of *pitx2* mutant and *pitx2* deficient zebrafish, revealed that *pitx2* mutant corneas lack the multiple cell layers seen in wild type, and the anterior chamber is reduced. The corneal endothelium could not be distinguished from the overlying epithelium, suggesting it may be reduced or possibly absent.

We asked whether cell proliferation or death might contribute to normal corneal development, and whether these processes might be disrupted in the *pitx2* mutant. In wild type embryos, we detected relatively few mitoses in the developing cornea from 30-120 hours post fertilization and very few apoptotic cells were observed. We next assayed cell proliferation and death in *pitx2* mutant embryos and found similar results compared to the wild type. This suggests that aberrant cell proliferation and apoptosis are unlikely to contribute to the mutant phenotype, and that other processes, such as cell migration, may be affected in the *pitx2* mutant, consistent with previous predictions.

Cranial neural crest cells, which express *pitx2*, migrate into the anterior eye and form the corneal endothelium, therefore, this cell population may be affected in the *pitx2* mutant, leading to defects in the anterior segment. We are currently testing this using multidimensional confocal imaging and 4D cell tracking using our custom software to track individual cells as they assemble to form the corneal endothelium in live zebrafish embryos.

1155F **Thyroid hormone regulates cell migration via PDGF signaling during post-embryonic zebrafish dermal development** August Carr, David Parichy, Andrew Aman Biology, University of Virginia

The dermis is an important component of vertebrate skin that provides mechanical strength and underlies patterning and morphogenesis of skin appendages. Zebrafish are a useful model system for discovering mechanisms that govern dermal development because we can easily visualize the entirety of this process in live animals while conditionally manipulating gene expression. We have shown that zebrafish dermal development requires migration of dermal progenitor cells from the larval hypodermis which subsequently differentiate as fibroblasts and papillary dermal cells. Our previous live imaging experiments showed that dermal progenitor migration spreads across the larval skin in a ventral to dorsal wave and is regulated by thyroid hormone. To further probe mechanisms that regulate thyroid hormone dependent migration, we used single cell RNA sequencing on skins from control and hypothyroid fish to analyze differential gene expression. Multiple transcripts were downregulated in hypothyroid skin and therefore represent potential thyroid hormone target genes. Among these candidates were genes encoding ligands in the PDGF (platelet derived growth factor) pathway. To test the role of PDGF signaling in dermal development, we performed conditional gain and loss of function analyses of PDGF pathway ligands and receptors. These experiments revealed that PDGF signaling is necessary and sufficient for dermal progenitor cell migration and differentiation, but not for skin appendage formation. Thyroid hormone has complicated effects on vertebrate skin development and homeostasis, and this work provides a novel mechanism connecting the hormone to cellular and molecular mechanisms of development.

1156F **Elucidating the Role of *Iroquois Transcription Factor 4a* in Kidney Development** Aisling L Kruger, Hannah Wesselman, Rebecca A Wingert Department of Biological Sciences, University of Notre Dame

Chronic kidney disease is a prominent problem in the US, impacting millions of Americans a year. In order to better address this issue, more advanced knowledge of kidney function and development is critical. The kidney is a vital organ responsible for both filtering waste from the blood, and balancing ion concentrations in the blood. These roles are carried out by the nephron, the functional unit of the kidney. Although nephron development is vital to renal function, there has been limited

research into the genetic mechanisms that regulate their formation. There are many genetic pathways that play crucial roles in the various components of kidney formation, one of which is the Iroquois (Irx) gene family of transcription factors. Of these, *Iroquois transcription factor 4a* (*irx4a*), is previously unstudied in regards to its role in nephrogenesis. The zebrafish is a useful model to study nephron development due to the high conservation in nephron composition with humans. Here, using whole mount in situ hybridization to assess spatiotemporal expression, we found that *irx4a* was expressed in the proximal straight tubule (PST) and distal early (DE) regions of the embryonic nephron. Interestingly, *irx4a* transcripts were first expressed at around the 12 somite stage (ss) in the renal progenitors which found these segment regions. Further *irx4a*+ cells exhibited a speckled expression pattern within the nephron, which suggests that it is likely a marker of either multiciliated cells (MCCs) or transporter cells. In the zebrafish kidney, MCCs are responsible for driving fluid flow through the kidney. We hypothesize that *irx4a* acts redundantly with *irx2a*, another member of the Iroquois gene family, because the two genes have very similar expression patterns. *irx2a* is expressed in MCCs, so it is believed that *irx4a* is as well. To examine whether *irx4a* is required for nephrogenesis, *irx4a* deficient embryos were created through the microinjection of a splice blocking morpholino. *irx4a* knockdown caused a significant decrease in the number of MCCs present in the nephron. This implies that *irx4a* plays a vital role in proper MCC formation. Future studies will examine the consequence of dual *irx4a*/*2a* deficiency on MCC ontogeny. Gaining insight into the function of genes such as *irx4a* will allow for greater understanding of how kidneys develop. This knowledge could provide critical insight into better understanding and eventually treating congenital and chronic kidney diseases.

1157F **Mural cells in an injured zebrafish heart change their identity to fibroblast-like cells and promote regeneration.** Subir Kapuria, Ching-Ling Lien Cardiothoracic Surgery, Children›s Hospital Los Angeles

Mural cells associate with the blood vessels on their abluminal surfaces and regulate vessel growth, stability, and contractility. Besides being a mere structural support and modulator of the vessels, mural cells also affect other surrounding cells during zebrafish heart regeneration. Previously we showed that, the mural cells express injury-responsive genes in the amputated hearts. Here we are showing not only do the mural cells change the gene expression but they also change their identity by expressing fibroblast marker genes and migrating away from the vessels toward the injury area. By Notch activity reporter, I observed that the mural cells on the injury surrounding blood vessels activate notch signaling and show this activity throughout the heart regeneration. Some of these notch-activated mural cells migrate toward the injury site away from the blood-vessels. By single-cell RNA sequencing analysis and confocal imaging of the mural cells in the injured hearts, I found that these mural cells express different fibroblast markers and genes that encode growth factors, angiogenic factors, extracellular matrix components, and cytoskeletal structure regulators what indicate their growth-promoting and migratory nature. Alltogether by changing their gene expression, identity, and cellular communications, the mural cells generate a conducive environment for heart regeneration. In this process, the mural cells interact with the immune cells including macrophages, endothelial cells, cortical cardiomyocytes, and epicardial cells. From this finding, the mural cells appear as the responsive, plastic cells which change their identity according to the surrounding need and a potential target for treating cardiovascular diseases.

1158S **Tissue-specific RNA-seq identifies genes governing male tail tip morphogenesis in *C. elegans*** Karin C Kiontke[1], Alyssa Woronik[2], Adam Mason[3], Antonio Herrera[4], David H. A. Fitch[5] [1]New York University, [2]Biology, Sacred Heart University, [3]Biology, Siena College, [4]Science, Baylor School, [5]Biology, New York University

The 4 tail tip cells (hyp 8-11) of *C. elegans* undergo male-specific changes in L4, making a round instead of pointed tail tip. A main regulator for this Tail Tip Morphogenesis (TTM) is the transcription factor DMD-3 (Mason et al. 2008). RNA-seq of laser-dissected early L4 tail tips identified 564 genes differentially expressed (DE) in wild-type (WT) males vs. *dmd-3(-)* males and hermaphrodites. To validate our data, we made transcriptional reporters for 40 DE genes. We found male tail tip-specific expression for 20 of these genes. Analysis of the RNA-seq data showed that: (1) The transcription profile of *dmd-3(-)* tail tips is similar to that in hermaphrodites. (2) Only 11 DE genes were also found in a whole-genome RNAi screen for defective TTM (Nelson et. al. 2011). (3) GO analysis of genes that are more highly expressed in WT male tail tips finds enrichment of terms that indicate high translational activity. (4) GO terms enriched for genes with reduced expression in WT males are consistent with these genes being involved in cuticle maintenance. (5) Only 4 collagens are upregulated in WT male tail tips; two of these, BLI-1 and COL-20, are found in the cytoplasm of the tail tip cells. (6) Several genes in the chondroitin synthesis pathway are DE. Their reporters are expressed in male tail tips, and knockdown results in a TTM phenotype. We hypothesize that a chondroitin proteoglycan is secreted into the space between male tail tip and L4 cuticle. FBN-1 is a candidate for the core protein. 39 transcription factors are DE, indicating that the gene-regulatory network downstream of DMD-3 is complex and potentially modular.

Using reporters for tail-tip-specific proteins identified in this study along with markers for cellular components (adherens junctions, extracellular matrix, cytoskeleton, etc.), we provide a detailed description of TTM and the fate of the tail tip cells.

We are developing a protein reporter toolkit to further study the subcellular events during TTM.

1159S **Integrating temporal, positional, and sex-specifying cues in *C. elegans* neurogenesis** Jennifer R Wolff[1], Emma Carlson[1], Jisoo Yeom[1], Andrea K Kalis[2] [1]Biology, Carleton College, [2]Biology, St. Catherine University

Development of neural circuits that control reproductive behaviors requires that neuronal precursors adopt programs of survival, division, and differentiation that are unique to each sex. We seek to understand how sex-determining signals are integrated with sex-shared programs of neural development, using the well-understood neuronal development of *C. elegans* as a model. In *C. elegans*, several neuroblasts of the P lineage divide in males, but not in hermaphrodites, initiating divergent programs of differentiation in the ventral cord and tail. These sex-specific programs depend on the sex determination factor TRA-1 and the Hox proteins MAB-5 and LIN-39. With our students at Carleton College and St. Catherine University, we have developed reagents to address how these regulators interact with each other and with unidentified factors to promote sex-specific nervous system organization. Notably, using a cell-cycle sensor, *mcm-4p::cdksensor::gfp*, we can directly observe neuroblast divisions that occur during sexual maturation to produce male-specific ventral cord and tail neurons relatively late in development, after the majority of sex-shared neurons have started differentiating.

One class of these "late-blooming" neuroblasts, the ventral cord Pn.aap neuroblasts, generates CA and CP neurons that influence mating movements and sperm transfer. Pn.aap neuroblasts divide in males to generate nine CA/CP neuron pairs, and either die or differentiate in hermaphrodites to produce six VC neurons, which modulate egg-laying. We have previously shown that differentiation, division, and survival of sex-specific ventral cord neurons depends on the coordinated activities of LIN-39 and MAB-5. We find that *mcm-4p::cdksensor::gfp* is expressed male-specifically in the ventral nerve cord beginning in late L2, with GFP expression becoming cytoplasmic in early-mid L3, indicating cell cycle commitment. The Pn.aap cells divide in mid-late L3 and continue to express GFP in both daughters through L4. Analysis of sex-specific cell cycle dynamics will allow us to investigate how LIN-39 and MAB-5 interact with cell cycle regulators and developmental timers to influence sex-specific fates of CA and CP neurons.

To further investigate sex-specific Pn.aap division, we have created a strain, P-masc, in which the P lineage has been selectively masculinized with an *hlh-3p::fem-3::mCherry* transgene. In XX P-masc worms, mCherry is expressed in all ventral cord neurons from L1 through adulthood. Strikingly, Pn.aap neuroblasts divide during L3, with posterior daughters differentiating as serotonergic neurons, a fate normally reserved for males. Further study of masculinized neurogenesis in the context of an otherwise female soma will shed light on the role of Hox proteins and other key regulators in both cell-autonomous and non-autonomous aspects of sex-specific neuronal development.

1160S **EGL-38/Pax controls cell type-specific matrix identity in the *C. elegans* vulva** Helen F Schmidt, Chelsea B Darwin, Meera V Sundaram Genetics, University of Pennsylvania

The development and function of tubular organs, including the lungs, intestines, and inner ear, depends in part on an apical extracellular matrix (aECM) that lines the organ interior. aECMs contain many components that are shared across organisms such as mucins, collagens, and zona pellucida domain (ZP) proteins. We are interested in how these components become organized into distinct spatial domains. Our lab found that in the *C. elegans* vulva, several matrix factors are associated with the surface of specific cell types despite being ubiquitously transcribed. Therefore, we hypothesize that each cell type expresses different matrix organizing factors that recruit its unique set of aECM proteins.

In the vulva, the two major cell types are determined by signaling - EGF-Ras-ERK specifies primary (1˚) cells (vulE/F) while Notch specifies secondary (2˚) cells (vulA/B1/B2/C/D). How downstream targets of signaling control the unique features of each cell type is less clear, as no "master regulator" transcription factors have been found. Since aECM is one marker of cell type identity, we focused on understanding what controls this feature.

We tested whether mutants in vulva-expressed transcription factors affected the localization of fluorescently tagged ZP proteins LET-653 and NOAH-1. Both proteins are broadly expressed in the vulva, but LET-653 assembles via its ZP domain (LET-653(ZP)) near the surface of 1˚ cells, while NOAH-1 is enriched in a matrix "spike" near the membrane of the 2˚ cell vulC. We found that the paired-box transcription factor EGL-38 is required to recruit LET-653(ZP) to the 1˚ cell matrix and exclude NOAH-1 from it. Consistent with the lab's previous result that LET-653(ZP) matrix assembly requires EGF-Ras-ERK specification of 1˚ cells, we found EGL-38 expression depends on the same signaling pathway. We propose that vulva cell identity is controlled by multiple transcription factors each driving gene regulatory sub-programs for distinct features of the cell type, and that EGL-38 controls the aECM sub-program of 1˚ cells. Our ongoing work is using single-nucleus RNA-Seq of sorted vulva nuclei to better understand the biology of the 7 different cell types and identify EGL-38 targets and candidate matrix organizers with cell type-specific expression.

1161S **SPN-4 promotes 3'UTR-dependent *lin-41* mRNA clearance during the oocyte-to-embryo transition in *Caenorhabditis elegans*** Karissa Coleman[1], Naly Torres[1], Caroline Spike[2], Tatsuya Tsukamoto[2], Micah Gearhart[2], Erika Tsukamoto[2], David Greenstein[2], Erin Nishimura[1] [1]Colorado State University, [2]University of Minnesota

Regulation of maternally inherited mRNA transcripts during the early stages of zygotic development drives the cellular divisions at the oocyte-to-embryo transition (OET). Many maternally inherited transcripts enriched in the oocyte are rapidly degraded after fertilization (Stoeckius et al., 2014) by associating with SPN-4, a cytoplasmic RNA-binding protein that likely recruits the Ccr4-Not deadenylase complex. Using immunopurification, we purified SPN-4 from late-stage oocytes and performed RNA-seq to identify 728 mRNAs that associate with this RNA-binding protein with 4-fold enrichment, $P<0.05$. Of these, *lin-41* mRNA was confirmed as a SPN-4 associated target. Indeed, single-molecule fluorescence *in situ* hybridization (smFISH) studies confirm that *lin-41* mRNA requires SPN-4 and its own 3'UTR for proper clearance in early embryos. To determine the sequence within the *lin-41* 3'UTR required for *lin-41* mRNA degradation in early embryos, we systematically deleted regions within the *lin-41* 3'UTR and performed smFISH to assess *lin-41* mRNA abundance. Using a FISHquant analysis pipeline, we observe deletions that remove a sequence within the FOX region of the *lin-41* 3'UTR significantly increase *lin-41* mRNA abundance. This result suggests this region recruits SPN-4 to promote mRNA clearance. We hypothesize other maternally inherited transcripts that contain potential SPN-4-binding sites also associate with SPN-4 to regulate their abundance and ultimately control cell fate during the OET.

1162S **Understanding the Machinery of *erm-1* mRNA Localization in *C. elegans* embryos: Implications for Local Translation and Cellular Regulation** Naly Torres[1], Karissa Coleman[2], Luis Aguilera de Lira[2], Brian Munsky[3], Erin Osborne Nishimura[2] [1]Colorado State University, [2]Biochemistry & Molecular Biology, Colorado State University, [3]Chemical & Biological Engineering, Colorado State University

The precise localization of maternally inherited mRNAs is crucial for establishing cell fate and body axis patterning during the oocyte-to-embryo transition (OET) in *Caenorhabditis elegans*. Because transcription is repressed at these stages, it is possible embryos rely on the localization of maternal mRNA transcripts for precise spatial and temporal control of gene expression and local translation. Indeed, the maternally inherited *erm-1* mRNA within early embryos localizes at plasma membranes (Parker et al., 2020) via translation-dependent localization (Winkenbach et al., 2022). In this study, we aim to understand the machinery of *erm-1*/ERM-1 localization to the plasma membrane, as ERM proteins play a pivotal role in connecting the inner cytoskeleton to the plasma membrane, contributing significantly to various physiological processes. Using a high-yield eggshell permeabilization strategy to impede microtubules (Nocodazole) or actin (Cytochalasin D) followed by single-molecule Fluorescence In Situ Hybridization (smFISH), we demonstrated that the loss of microtubules perturbs *erm-1* mRNA localization to the plasma membrane. Indeed, RNA interference knockdown studies confirm a role for KLP-14 kinesin in proper localization. To determine the significance of microtubule loss on *erm-1* transport, we used the FISHquant analysis pipeline to quantify the total *erm-1* molecules at the plasma membrane. This result suggests that *erm-1/*ERM-1 localization to the plasma membrane depends on microtubules and associated motors for localization, distinguishing between active and passive mechanisms. We hypothesize that translating *erm-1* molecules are transported via microtubules and anchored at the plasma membrane, while non-translating mRNAs remain in the cytoplasm.

1163S **Sexually dimorphic regulation of the PIWI/piRNA pathway impacts heat-induced male infertility in *C. elegans*** Nicole A Kurhanewicz[1], Acadia L DiNardo[1], Hannah R Wilson[1], Jessica A Kirshner[2], Margaret R Starostik[2], John K Kim[2], Diana Libuda[1] [1]Biology/IMB, University of Oregon, [2]Biology, Johns Hopkins University

The maintenance of genomic integrity during sperm and egg development is fundamental for fertility and proper genome inheritance across generations. Germ cells require precise regulation of gene expression to silence deleterious genomic elements, such as transposons, which can cause DNA damage and heritable mutations associated with both infertility and birth defects. During spermatocyte and oocyte development, the conserved PIWI/piRNA small RNA pathway represses transposon activity in part by adding the repressive chromatin mark H3K9Me3. Previous work in *Caenorhabditis elegans* demonstrated that acute heat exposure produces elevated DNA damage associated with transposon activity only in spermatocytes and not oocytes. Here our data indicate a role for the PIWI/piRNA pathway in the sexually dimorphic production of heat-induced DNA damage and Tc1-Mariner family transposon activity in spermatocytes. Using immunofluorescence imaging of PIWI/piRNA pathway master regulator PRG-1, we identify sexually dimorphic and heat-sensitive localization and morphology of PRG-1 within the perinuclear nuage structures of developing germ cells. Further, we reveal that conditional knockdown of PRG-1 knockdown enhances heat-induced DNA damage only in developing sperm. Using chromatin immunoprecipitation of the PIWI/piRNA-related repressive chromatin mark H3K9Me3, we find heat shocked adult hermaphrodites undergoing oogenesis experience a general increase in the repressive chromatin mark H3K9Me3, while H3K9Me3 is largely unaffected in heat shocked males undergoing spermatogenesis. Notably, we observe that heat shock specifically increases H3K9me3 at the DNA transposon Tc1 in adult hermaphrodites. Commensurate with increased H3K9Me3 in adult hermaphrodites, our RNAseq

results also demonstrate heat produces a global repression of transcription in adult hermaphrodites. In contrast, males only exhibit a slight increase in global gene expression. Moreover, we find three-times as many PIWI/piRNA pathway targets are differentially expressed by heat shock in hermaphrodites compared to males. Taken together, these data indicate oocytes have a robust, gene-repressive response to heat that spermatocytes lack. This work provides insight into fundamental differences between the oogenic and spermatogenic developmental and genome maintenance programs, and the broader mechanisms underlying the heat-induced male infertility.

1164S **Roles for fate specifying transcription factors in collective cell migrations and fate transformations in *C. elegans* embryogenesis** Prativa Amom[1], Breana D Anderson[1], Tushar H Ganjawala[1], Radmehr Molaei[1], Jorin T Hanson[1], Amanda L Zacharias[2,3] [1]Developmental Biology, Cincinnati Children's Research Foundation, [2]Developmental Biology, Cincinnati Children's Research Foundation, [3]Pediatrics, University of CIncinnati College of Medicine

In vertebrates, cell fate specification is directly linked with collective cell migrations. In *C. elegans*, the role for lineage determining factors is established in gastrulation, but the role for fate specifying transcription factors in gastrulation and other collective cell movements including ventral cleft closure remained unknown until recently. We previously evaluated the roles of the transcription factors (TFs) that specify neuronal, muscle, skin, and pharyngeal fates to determine their roles in collective cell movements. We found that the skin TFs *elt-1* and *nhr-25* are required to promote mesoderm gastrulation, pharynx organization, and ventral cleft closure, while both muscle fate TFs *hlh-1* and *unc-120* also promote ventral cleft closure. To determine whether fate transformations played a role in disrupting these collective cell movements, we examined the expression of various cell fate markers in mutant embryos. In particular, we wanted to test the hypothesis that cells would express the fate markers of "sister" lineages, since their shared history suggests that they might have the factors necessary to activate these genes.

We found in *nhr-25(jm2389)* mutant embryos, some Caa and Cpa daughter cells that would normally adopt hypodermal fates activate an unc-120 promoter reporter, indicating they have activated the muscle fate of their Cap and Cpp cousin cells. This is consistent with previous reports that utilized RNAi knockdown and microarray to evaluate gene expression. Conversely, in *hlh-1(cc561)* mutant embryos treated with RNAi against *unc-120*, the MSap and MSpp daughters that normally produce muscle do not activate a PHA-4::GFP fosmid reporter, a marker of pharyngeal fate, which is expressed by their MSaa and MSpa cousin cells. These results suggest that different lineages have evolved distinct mechanisms for fate specification. While our findings are consistent with previous reports that the TFs specifying muscle and skin fates are mutally antagonistic in the C lineage, they also suggest that the mechanism(s) for establishing expression of muscle and pharyngeal fate TFs in distinct sister lineages of MS are more complex.

1165S **Exploring the role of *C. elegans* furin proteases in the cleavage of ZP proteins** Chelsea Darwin, Helen Schmidt, Susanna Birnbaum, Meera Sundaram Genetics, University of Pennsylvania

Zona Pellucida (ZP) domain proteins are a highly conserved family of glycoproteins first characterized in the coating of mammalian egg cells. In *C. elegans*, these proteins are important structural components of the precuticle apical extracellular matrix (aECM). When these proteins do not localize to their correct place in the aECM, it results in structural defects in developing organs. Many ZP proteins are cleaved at a dibasic site that resembles the consensus for furin proteases, and we have shown this cleavage to be essential for function and correct localization to the matrix. However, the protease(s) responsible for cleavage of most ZP proteins, in C. elegans as well as mammals, have not yet been identified.

C. elegans has 4 furin proteases: BLI-4, KPC-1, EGL-3, and AEX-5. We recently showed that BLI-4 promotes collagen secretion and cuticle assembly in the embryo. However, despite their dramatic cuticle defects, *bli-4* null mutants still had normal localization of ZP proteins in the embryo pre-cuticle.

Here we used the developing *C. elegans* vulva as a model to investigate the *C. elegans* furins and their relationship to the ZP proteins LET-653 and NOAH-1. Of the four furins, KPC-1 and BLI-4 have been identified as expressed in vulval cells. Our data from *kpc-1* and *egl-3* null mutants, *bli-4* isoform specific knockouts, and *aex-5* reduced function mutants, suggest none of the furins affect the localization of either ZP protein. However, *bli-4* null mutations are lethal, so we have not yet been able to visualize gene knockout in the vulva. Future directions for this project include looking at the phenotypes of double mutants, and screens of other candidate proteases outside of the furin family.

1166S **tab-1, a C. elegans ortholog of BSX, is required for the normal development of the ABalaaa lineage** William Marchese, Eli Preston, Ella Eseigbe, Alexis Garcia, John Murray University of Pennsylvania

The availability of genome-wide lineage-resolved expression atlases and the robustness of C. elegans embryonic cell lineages

create the potential to systematically identify regulators of each sublineage. Here we focus on the ABala lineage, which primarily produces neurons and glia, and for which mechanisms controlling most lineage decisions are unknown.

We screened loss of function mutants of five transcription factors identified in expression databases as expressed in ABala or its sublineages in an attempt to find TFs required for normal ABala development. Using 4-D confocal microscopy and Starrynight cell lineage tracing software, we identified defects in cell division timing, cell death patterns, downstream gene expression or cell positions within the ABala lineage in several transcription factor mutants, including ceh-32, ceh-37 and tab-1.

We focused in more detail on the role of tab-1, since a tab-1 mutant had the most striking impact on division patterns, causing ectopic deaths in the of ABalaaa lineage consistent with an ABalaaa->ABalaap lineage transformation. tab-1 mutants had additional defects in other non-ABala lineages that express TAB-1. This further suggests that tab-1 is responsible for patterning the ABala downstream lineages. Past work from other labs showed that tab-1 is required to generate the ABalaaa-derived neurons AVD, and AIN. We tested whether the ILsoL and ILsoR glia, which are also ABalaaa-derived, are defective in tab-1 mutants and found that they are absent, suggesting tab-1's role in ABalaaa development is not neuron-specific.

To identify potential upstream regulators of tab-1, we explored the upstream regulatory region of tab-1. Using available ChIP-seq and ATAC-seq data we identified two candidate enhancer regions and are currently testing these regions for enhancer activity. We depleted candidate upstream regulators of tab-1 and found that RNAi depletion of ceh-37/Otx causes partially penetrant loss of tab-1::GFP expression.

Future work to better characterize the function of tab-1 in shaping elegans embryonic development will require us to test for the necessity of these modular enhancers by CRISPR deletion of the proposed sites, to test for phenotypic impacts on the embryonic lineage and to identify targets of tab-1 in ABalaaa sublineages. Overall, this work identifies novel functions for a conserved homeodomain TF and supports the feasibility of using large scale imaging and scRNA-seq atlases to identify lineage regulators.

1167S **Sense organ glia secrete extracellular matrix proteins customized for different types of sensory cilia** Wendy Fung[1], Taralyn Tan[1], Irina Kolotuev[2], Maxwell Heiman[1] [1]Boston Children's Hospital, Harvard Medical School, [2]University of Lausanne

We perceive the world through sense organs containing sensory cells with specialized cilia that detect touch, smell, taste, or other stimuli. Importantly, all sense organs are covered with an apical extracellular matrix (aECM) that serves as the interface between cilia and the environment. Electron microscopy studies have revealed an extensive diversity of aECM structures that are customized to sense organ function, from force transducers for touch to nanoscale pores for taste. However, while cilia are well studied, the aECM structures that cover them have been largely ignored. *C. elegans* offers an ideal system for determining the molecular basis of aECM differences at each sense organ. In addition to the major amphid sense organs, the *C. elegans* nose contains 16 minor sense organs with a single mechanosensory neuron (OL; hermaphrodite CEP) or paired mechanosensory and chemosensory neurons (IL; male CEP). In all cases, the ciliated endings of the sensory neurons protrude through a tube formed by two glia, called the sheath and socket. The socket glial cell forms the distal portion of the tube, makes junctions with the skin, and contributes to the cuticle, an aECM body covering. We find that the socket glia of each sense organ (OLso, ILso, CEPso) express different aECM proteins that localize to discrete extracellular domains around specific cilia. For example, using endogenous tags, we find that the collagen COL-56 is expressed exclusively by OLso and CEPso glia and localizes in an extracellular disc over mechanosensory cilia, possibly contributing to force transduction. By contrast, the collagen COL-53 is expressed exclusively by ILso and male CEPso and localizes to the pore through which chemosensory cilia access the environment. Interestingly, we find that COL-53, COL-177, and GRL-18 – a novel aECM protein that we find localizes to transient nanoscale rings during cuticle synthesis – are expressed in male, but not hermaphrodite, CEPso glia. Using genetic screens, we find that this sex-specific difference in CEPso glia is controlled by the known sex identity regulators *mab-3*, *lep-2*, and *lep-5*, as well as novel regulators *nfya-1*, *bed-3*, and *jmjd-3.1*. Finally, by manipulating sex-specific gene expression in CEPso, we find that this switch is necessary and sufficient to pattern the overlying aECM into a nanoscale pore that accommodates the cilium of a male-specific chemosensory neuron. Together, our results suggest that glia secrete modules of aECM components that are customized for different cilia types and that define the interface between each cilium and its environment.

1168S **Understanding how cell fate coordinates localization of myosin activating machinery to drive cell shape changes** Taylor N Medwig-Kinney, Pu Zhang, Bob Goldstein UNC Chapel Hill

Apical constriction is a cell shape change resulting from contraction of actomyosin networks at the cell apex. Apical constriction plays a key role in development of the brain and spinal cord, failure of which is associated with neural tube defects. Polarized contraction of actomyosin networks can also drive cell extrusion, which is required for epithelial homeostasis and can contribute to tumorigenesis and metastasis when dysregulated. Despite the importance of precise coordination

of cell shape changes, how localization of myosin activating machinery is informed by cell fate and cell polarity is not well understood. Internalization of two endoderm precursor cells during *C. elegans* gastrulation provides a visually amenable and genetically tractable model to study apical constriction *in vivo*. Previous work from our group has shown that the myotonic dystrophy-related Cdc42-binding kinase MRCK-1 is a critical regulator of *C. elegans* endoderm internalization. MRCK-1 localizes to the apical surface of the endoderm precursors where it activates actomyosin contractility. Here, we quantify localization of endogenously-tagged myosin (NMY-2) and MRCK-1, and show that they both localize throughout the apical cortex. Surprisingly, we find that MRCK-1's localization pattern is distinct from that of another known CDC-42 interacting protein, WSP-1 (WASP) during apical constriction. We are now developing tools to determine if localization of MRCK-1 is sufficient to induce cell shape change and are investigating the mechanisms downstream of cell fate that coordinate its localization. This research will help draw long-sought connections between developmental patterning mechanisms and force generation.

1169S **The molecular interactions within the fertilization synapse in *C. elegans*** Xue Mei St. John›s University

Fertilization is a culminating event during sexual reproduction. Fertilization involves species-specific interactions between the gametes, including recognition, adhesion, and fusion, to form a zygote. The molecular mechanisms of the interactions are not well understood. Proteins on the surface of the gametes are thought to form complexes that mediate the interactions and eventually bring about fusion, and we call these complexes the fertilization synapse. In *C. elegans*, SPE-51 is one of the sperm secreted molecules that are required for fertilization. Loss of spe-51 results in normal-looking sperm that can migrate to the spermatheca but cannot fertilize the egg. The SPE-51 protein stays associated with spermatozoa, suggesting it is being tethered to the membrane by other molecules. Here, we examine the localization of SPE-51 in the absence of other sperm-surface fertilization molecules. Our preliminary data suggest that SPE-51 localization on the pseudopod is lost in the absence of SPE-38 but not SPE-9. Our findings will provide insights into the assembly and dynamics of the fertilization synapse.

1170S **Mutations affecting the genetic regulation of sperm activation give rise to infertility in the nematode *C. elegans*** Emily K Mincher[1], Allison Ramz[2], Benjamin Khaim[3], Xue Mei[3] [1]Biology, St. John's University, [2]Biology, St. Johns University, [3]Biology, St Johns University

Sperm activation in *C. elegans* is a post-meiotic differentiation process of efficient fertility, in which round spermatids are morphologically and functionally transformed into motile spermatozoa with pseudopods. Initiation of spermiogenesis is known to be genetically regulated by the poorly understood SPE-8 and TRY-5 pathways. Males can use both pathways, while hermaphrodites opt for the SPE-8 pathway. TRY-5 is a protease implicated in extracellular signaling in spermiogenesis. SPE-8 is an intracellular kinase that responds to an unknown activator. These semi-redundant pathways are associated with proteases, cell surface receptors, and intracellular signaling molecules, but other unidentified molecules are believed to be involved. With the use of forward genetic screening, we isolated a temperature-sensitive mutant allele *as47*. Hermaphrodites with the *as47* allele are self-sterile. This infertility defect can be rescued by mating *as47* hermaphrodites with wildtype males, suggesting this defect is sperm-related. Imagin under differential interference contrast (DIC) microscopy showed similar structures of the germline and spermatheca when compared to the control. Mutant hermaphrodites lay unfertilized oocytes. DAPI staining revealed that mutant hermaphrodite sperm were unable to migrate bac into the spermatheca, suggesting a fault in sperm motility. Hermaphrodite dissection showed that sperm were not fully activated *in vivo* in comparison to control sperm. Whole-genome sequencing identified a candidate gene of *as47* with a *tm5344* deletion. These two mutations fail to complement each other, suggesting they are involved in the same gene. The *tm5344* allele was hypothesized to give rise to sterility in *C. elegans*, similar to the *as47* allele. DIC imaging and DAPI staining of the *tm5344* hermaphrodites showed similar results to that of the *as47* allele. A strain called SJM5 was built containing the *tm5344* and *him-5* alleles to better study male fertility. Initial brood counts revealed a low incidence of fertility among these mutant males. We will investigate sperm activation of SJM5 males with *in vitro* sperm activation assays using Pronase, zinc, and zinc ionophore. The gene of interest, implicated in both alleles, encodes a Ser/Thr phosphatase that is most similar to that of the PP1 phosphatase. The goal of this work is to determine if this gene may be part of the SPE-8 or TRY-5 pathways that regulate the initiation of sperm activation.

1171S **LIN-35, the DREAM complex, and inactivation of CED-9 function to promote germline apoptosis under moderate temperature stress in *C. elegans*** Margaret N Davidson[1], Frances V Compere[2], Kristen A Quaglia[1], Lisa N Petrella[1] [1]Biological Sciences, Marquette University, [2]Syracuse University

In *C. elegans*, germline apoptosis occurs regularly to produce healthy oocytes. However, elevated temperature stress along with other stressors leads to an increased rate of apoptosis in the germline, which is likely beneficial for preserving fertility. Previous work has shown that LIN-35 promotes stress-induced apoptosis through regulation of *ced-9* expression. CED-9 protein generally is inactivated in order to promote apoptosis. LIN-35 cannot directly bind to DNA but can regulate gene expression as a member of the DREAM complex. Here, we wanted to determine if LIN-35 and DREAM complex proteins play a role in promoting increased apoptosis in the germline when exposed during moderate temperature stress. We found that

in *lin-35* mutants and two DREAM complex mutants, *lin-54* and *lin-37*, germline apoptosis had a lower level of induction when compared with wild type in temperature stressed animals. We next wanted to investigate whether inactivation of CED-9 function was necessary to induce increased apoptosis during temperature stress. We found that in a constitutively active *ced-9* mutant, germline apoptosis had a lower level of induction when compared with wild type in temperature stressed animals, similar to what was seen in *lin-35* and DREAM complex mutants. Finally, we explored if decreasing the rate of apoptosis during temperature stress would lead to changes in cytoplasmic streaming, oocyte size or ovulation rates. We found that while wild type increased the cytoplasmic streaming rate during temperature stress, neither *lin-35* nor *lin-54* mutants increased their cytoplasmic steaming rate during temperature stress. In addition, *lin-35* and *lin-54* made fewer oocytes than wild type irrespective of temperature treatment. Finally, there was no clear temperature effect on ovulation rate in any strain, including wild type, although *lin-35* and *lin-54* did show a lower number of ovulation events than wild type irrespective of temperature treatment. Overall, our data points towards a model where CED-9 is regulated, maybe both at the mRNA expression level and the protein activation level, to activate increased levels of apoptosis during temperature stress. This activation is, in part, dependent upon LIN-35 and the DREAM complex and results in changes in cytoplasmic streaming and oocyte size and number.

1172S **Functional study of an alternative protein encoded by the dual coding gene *ZYX/zyx-1* with implications for dystrophinopathies** Noémie Frébault[1], Lise Rivollet[1], Benoît Grondin[1], Benoît Vanderperre[1], Claire Bénard[1,2] [1]Dept. Biological Sciences, CERMO-FC Research Center, Université du Québec à Montréal, [2]Dept. Neurobiology, University of Massachusetts Chan Medical School

Translation of alternative ORFs results in the synthesis of at least 30 000 “alternative proteins”. Some of these have been found to physically interact with the canonical protein encoded by the same gene, modulating their expression, cellular localization, and molecular function. Other alternative proteins can function independently of the canonical protein. While alternative proteins tremendously enrich the human proteome, very few have been studied to date. The conserved *ZYX/zyx-1* gene encodes not only the canonical protein Zyxin/ZYX-1 but also -as revealed by mass spectrometry studies in humans and *C. elegans*- an abundant and conserved alternative protein AltZyxin, which is produced from an alternative ORF. The gene *zyx-1* is required for synapse maintenance and dystrophin-dependent muscle degeneration in worms. Moreover, either overexpression or loss of *zyx-1* ameliorates the muscle degeneration phenotype caused by dystrophin deficiency, establishing *ZYX/zyx-1* as a promising therapeutic target for Duchenne muscular dystrophy. Canonical Zyxin is part of adhesion complexes, but the function of AltZyxin is unknown. To decipher the mechanism by which the gene *ZYX/zyx-1* regulates synapse maintenance and muscular degeneration, we investigate the function of the alternative protein AltZyxin in synapse and muscle biology in *C. elegans.* For this, we have generated CRISPR-engineered mutations to specifically disrupt either of the two encoded proteins, and determine the behavioral and anatomical consequences. Neuron- and muscle-specific rescue assays, localization studies, and an *in vivo* TurboID screen to identify AltZyxin interactors will inform on the functions and interplay between Zyxin and AltZyxin.

1173S **Regulated endoplasmic reticulum remodeling inhibits ectopic RNP condensates in oocytes** Jennifer A Schisa, Mingze A Gao, Nicholas A Trombley, Christya A Haddad, Cora A Zoet, Chloe A Munderloh, Victoria A Tice, Ashley A Cichon Biology, Central Michigan University

Infertility is a significant issue among women due to poor oocyte quality; however, factors affecting oocyte quality remain incompletely understood. Our long-term goal is to determine the extent to which the dysregulation of RNA binding protein (RBP) phase transitions contributes to infertility. We are currently focused on dissecting the regulatory pathways that modulate RBP phase transitions during oogenesis and maturation in *C. elegans*. Distinct subunits of the oligomeric CCT chaperonin promote phase separation of three different RBPs in meiotically-arrested oocytes and embryos. We asked if CCT modulates phase transitions and maturing oocytes, and because CCT subunits can function as monomers or an oligomer, we also asked if all subunits are required. We find depletion of an individual CCT chaperonin subunit is sufficient to result in ectopic condensates of MEX-3 and CAR-1/Lsm14 during maturation. These data are the first demonstration of CCT inhibiting RBPs during oogenesis and suggest the CCT chaperonin complex functions to maintain RBP phases during maturation. Because obligate substrates of CCT include actin and tubulin, we asked if *cct* condensation phenotypes are mediated by either cytoskeleton system. Upon depletion of *act-4*, we detected ectopic MEX-3 and CAR-1 condensates, suggesting actin may mediate the *cct(RNAi)* phenotypes. Actin regulates the endoplasmic reticulum in multiple developmental contexts, and the ER undergoes remodeling concomitant with phase transitions in arrested oocytes. Therefore, we hypothesized that CCT and actin modulate RBP condensation via modulation of ER structure. Strikingly, we found that depletion of *cct* or *actin* results in ectopic ER remodeling into sheet-like structures, consistent with the possibility that increased ER surface area promotes ectopic condensation of RBPs. Lastly, we determined the mRNA target of CAR-1, *spn-4*, appears to be translationally derepressed when ectopic CAR-1 condensates form in maturing oocytes. Ultimately, we hope to unravel the complex regulation of RBP condensation during oogenesis and maturation, and the role of regulated RBP condensation on maintaining oocyte quality.

1174S **Novel quasi-living cell morphology in the absence of EOR-1/PLZF, Chromatin Regulators, and WAH-1/AIF1 in a cell that dies via a non-canonical apoptotic program** Nathan Rather, Karen Juanez, Rashna Sharmin, Aladin Elkhalil, Piya Ghose Biology, University of Texas at Arlington

Programmed cell death (PCD) is a genetically programmed and evolutionarily conserved form of cell elimination required for normal development and homeostasis, with important implications for responses to cancer therapies.

We discovered a non-canonical apoptotic developmental cell death program in the *C. elegans* tail spike cell (TSC) called Compartmentalized Cell Elimination (CCE). During CCE the soma (cell body), proximal process, and distal process segments of this specialized cell die differently.

A forward genetic screen for CCE defects recovered a mutant, *ns957,* that shows a persisting enlarged soma alone with nuclear elevation. Genetic analysis of *ns957* revealed that the causative lesion is a mutation in the *eor-1* gene. Here we report a novel role for the EOR-1 transcription factor as well as it›s binding partner EOR-2, the chromatin modifiers MAU-2/MAU2 and SWSN-1/SMARCC1 in CCE. Interestingly, EOR-1 has been implicated in other forms of cell death although its mechanism remains unknown. Importantly, we find that caspase protease activity is normal in *eor-1*(-), suggesting that EOR-1 acts downstream of caspase in CCE.

We probed into the morphology of the remaining cell body on these mutants by generating an *eor-1* and *ced-12* (cell corpse engulfment gene) double mutant to determine if the persisting soma is a dead, but uncleared, apoptotic corpse. Interestingly, the soma remnant of this double mutant does not appear as a refractile cell, nor does it appear as a living cell, suggesting that it is not a persisting apoptotic corpse, but perhaps a quasi-living cell.

Using a candidate gene approach based on putative EOR-1 transcriptional targets we found that mutants for *wah-1*, which encodes a mitochondrial factor homologous to mammalian AIF1, phenocopy *eor-1(-)* soma phenotype. Interestingly, we also find fragmented mitochondria in the *eor-1(-)* persisting soma. Calcium signaling has been linked to cell death as well as the regulation of mammalian AIF1. We also found altered Calcium dynamics during CCE in *eor-1(-)*. Taken together, this suggests a link between EOR-1 regulated WAH-1, mitochondrial dynamics, and Calcium signaling in CCE.

Our study introduces a previously unreported life-to-death cell transition state that takes place during the novel cell death program of CCE. We also describe possible roles of genes implicated in cancer biology and other forms of cell death, as such our study may be highly relevant to developing cancer therapy.

1175S **The regulation of PP1 phosphatase in *C. elegans* sperm development and post-fertilization signalling** Shreyosi Bose, Martin Srayko Biological Sciences, University of Alberta

The fusion of gametic cells is a fundamental process that ensures the survival and propagation of sexually reproducing species. Sperm and oocytes are produced in the male and female germline, respectively, via meiotic divisions. The fusion of sperm and oocyte (fertilization) gives rise to the diploid zygote, which divides mitotically to form a multicellular embryo. Fertilization involves complex signalling pathways and strict regulation of the cell cycle. In most metazoans, oocytes arrest at multiple stages of meiosis to coordinate maturation with fertilization. In vertebrates, oocytes arrest at metaphase of meiosis II, and only complete the MII division after fertilization. This indicates that sperm-derived signals trigger female meiosis completion, though little is known about the molecular mechanism. Using the *C. elegans* hermaphrodite model system, the Srayko lab identified *memi-1/2/3* (meiosis to mitosis), oocyte-specific genes required for completion of female meiosis after fertilization. Loss of *memi* function causes embryonic lethality due to a “skipped MII” phenotype. Since this phenotype is also observed when a mature oocyte is not fertilized, the MEMI proteins likely represent a maternal component of the sperm-derived post-fertilization signal required for the proper meiosis-to-mitosis transition. In contrast to the *memi* loss-of-function phenotype, a gain-of-function mutation, *memi-1(sb41)* demonstrates entry into MII but a failure to exit MII. Genetic screens for *memi-1(sb41)* suppressors identified two nearly identical sperm-specific PP1 phosphatases, GSP-3/4. GSP-3/4 have been previously implicated in sperm meiosis and motility, but we found that these PP1s also contribute to the female MII program in the fertilized oocyte. Our suppressor screen also revealed a putative regulatory subunit of PP1 phosphatase. A FLAG-tagged version of this regulatory protein localized to the plasma membrane of activated sperm. Interestingly, this localization was restricted to the sperm cell body membrane, rather than the pseudopod, suggesting a model for how PP1 activity could be spatially regulated within crawling sperm. In fertilized embryos, the protein was tightly restricted to a zone around the condensed sperm DNA. A molecular and cellular characterization of this gene will be presented, as well as a model for its role in post-fertilization signalling.

1176S **An EMS screen for suppressors of *C. elegans memi-1(sb41)* reveals oocyte and sperm-specific pathways required for proper post-fertilization events** Rim Daher, Shreyosi Bose, Ish Jain, Rudra Banerjee, Jens Herzog, Caitlin Slomp, Martin

Srayko Biological Sciences, University of Alberta

Before fertilization, the *C. elegans* oocyte responds to an external, sperm-derived signal provided by major sperm protein (MSP). This signal releases the oocyte from its arrest, initiating the meiosis I division (MI). Normally a sperm enters the oocyte within a few minutes, but if fertilization does not occur, the MSP-stimulated oocyte aborts anaphase I, skips meiosis II (MII), and enters mitosis. This indicates that a second signal is provided upon sperm entry to specify the MII program. The paralogs, *memi-1*, *2,* and *3* (meiosis-to-mitosis transition) encode oocyte proteins that likely represent maternal components of this post-fertilization signal, because loss of all three paralogs also results in a skipped-MII phenotype. In contrast to the loss-of-function phenotype, a gain-of-function mutation, *memi-1(sb41ts),* results in fertilized embryos that complete MI, enter MII, but do not exit MII properly. In a previous RNAi screen, we identified a *gsp-3/4* as a suppressor of *memi-1(sb41)*. These genes encode sperm-specific PP1 phosphatases required for spermatogenesis and sperm motility (pseudopod treadmilling), but their involvement in the suppression of maternal *memi-1(sb41)* suggested that they also represent part of the sperm-derived signal.

A subsequent EMS-based screen recovered both intragenic and extragenic suppressors of *memi-1(sb41)*. Consistent with results from the RNAi-based screen, the EMS screen identified 4 alleles of *gsp-4*. In addition, the screen identified sperm-specific GSK3 kinases, *gskl-1* and *gskl-2*, which seem to act within the GSP-3/4 pathway. For example, like *gsp-3/4*, these genes are required for spermatogenesis and sperm motility via pseudopod treadmilling. In addition, we found that *gskl-1* and *gskl-2* cooperate with *gsp-3/4* for post-fertilization functions that involve MEMI. Using CRISPR gene editing, we have now confirmed most of the remaining extragenic suppressor mutations from this screen. Interestingly, these suppressors fall into two groups: 1) genes required for sperm-specific functions, which likely represent some component of the post-fertilization signal, or 2) maternal genes that function as genetic activators of *memi,* and thus, could modulate MEMI activity or levels within the fertilized oocyte. Current progress on the intragenic and extragenic suppressors will be presented.

1177S **The Transcription Factors PAL-1 and SEX-1 drive Ventral Nerve Cord Assembly in *C. elegans*** Nathaniel Noblett[1,2], Tony Roenspies[2], Stephane Flibotte[3], Antonio Colavita[1,2] [1]University of Ottawa, [2]Ottawa Hospital Research Institute, [3]University of British Columbia

The development of complex tissues requires the regulation of coordinated cell movements, including convergent-extension (CE). Common among processes that involve CE, including gastrulation and neural tube development, cells undergo coordinated intercalations that narrow and elongate the tissue. These movements require complex actomyosin organization and are facilitated by the formation and resolution of multicellular rosettes. We have previously shown that aspects of rosette-mediated CE are conserved within the embryonic *C. elegans* nervous system, where the process regulates assembly of the ventral nerve cord (VNC). During embryonic development, VNC assembly involves the intercalation of DA, DB and DD neurons at the midline to form a single nerve tract consisting of a stereotypical pattern and spacing of neurons. A genetic screen for VNC assembly defects identified PAL-1, a homolog of the CDX family, and SEX-1, a nuclear hormone receptor, as important players in VNC assembly. Mutation in these genes results in worms with anterior displacement and mis-ordering of VNC neurons at hatching, suggesting that VNC assembly in the embryo may be abnormal. We used timelapse microscopy to visualize VNC development in live embryos and assessed terminal neuron positions in larvae. New alleles of *pal-1* and *sex-1* were also generated using CRISPR-Cas9. We observed defects in *pal-1* mutant embryos that are characteristic of disrupted CE, including rosette resolution delays. These defects are independent of cell fate changes previously described in *pal-1* mutants, as the number of VNC neurons and terminal cell fate markers are normal. Additionally, we knocked GFP into the endogenous *pal-1* and *sex-1* loci. PAL-1::GFP is expressed in a number of posterior embryonic cell lineages, including a subset DA, DB and DD neurons. We found that point mutations and a small deletion approximately 10kb upstream of the *pal-1* start site resulted in loss of PAL-1::GFP expression in DA and DD neurons. *sex-1* is widely expressed during early embryogenesis but less so after the comma stage. Interestingly, *sex-1* mutants result in a similar loss of PAL-1 expression in DA and DD neurons suggesting that *sex-1* regulates *pal-1* transcription. Both *pal-1* and *sex-1* mutants display similar VNC neuron spacing defects at hatching. Together, this data highlights a role for the transcription factors PAL-1 and SEX-1 during VNC assembly and serve as the basis for further study into their regulatory targets.

1178S **DUO-1 plays multiple roles in meiotic prophase chromosome dynamics** Charlotte P Choi, Liesl Strand, Anne Villeneuve Developmental Biology, Stanford University School of Medicine

Meiosis is a crucial developmental process that generates haploid gametes from diploid germ cells, an essential feature of reproduction in eukaryotes. During prophase of meiosis I, germ cells undergo multiple major state transitions, involving massive remodeling of chromosome architecture and nuclear organization, without any intervening cell divisions. This dynamic program of changes in chromosome architecture involves a complex series of associations and dissociations of multiple different protein complexes that drive assembly, remodeling, and disassembly of meiosis-specific chromosome structures and dramatic changes in chromosome compaction. Failure to properly coordinate these processes can result in improper

segregation of chromosomes, resulting in aneuploid gametes and inviable zygotes. We are investigating the roles of DUO-1, a putative deubiquitinating enzyme, in mediating these dynamic chromosomal events of meiotic prophase.

We identified two mutations in *duo-1* in our recent "Green eggs & Him 2.0" screen for mutants defective in meiotic chromosome segregation, implicating DUO-1 as an important component of the meiotic machinery. *duo-1* mutants were notable in exhibiting highly decompacted chromatin at the end of meiotic prophase when chromosomes normally condense into compact bivalents in preparation for the meiotic divisions. Immunofluorescence analyses of *duo-1* null mutants indicate that DUO-1 is required for normal appearance of meiotic chromosome axes and synaptonemal complexes (SCs), for timely completion of meiotic DNA repair, and for late-prophase chromosome compaction. Further, by using a dual-AID-tagged allele to deplete DUO-1 for different durations during meiotic development, we were able to demonstrate distinct roles for DUO-1 in both assembly and stability of axes and SCs, indicating that the SC is a structure that requires active maintenance. Moreover, we demonstrated a separate and independent role for DUO-1 in promoting chromosome compaction at the end of meiotic prophase. Consistent with multiple roles in chromosome dynamics during meiotic development, 3xFLAG::DUO-1 and DUO-1::GFP localize predominantly in the nucleoplasm of meiotic prophase germ cells, increasing markedly in abundance during prophase progression. We are currently pursuing partners and targets of DUO-1 using the GFPnanobody::TurboID system. We are optimistic about this approach based on preliminary results showing that DUO-1::GFP is sufficient to direct Nanobody::TurboID to the nucleus.

1179S **Exploring the Complexity of the *kayak* Locus in Development** Juan R Riesgo-Escovar[1], Manuel Alejandro Zúniga-García[2] [1]Neruobiología del desarrollo y Neurofisiología, Universidad Nacional Autónoma de México, [2]Universidad Nacional Autónoma de México

The *kayak* locus consists of the gene '*kayak'* alongside two intronic genes— an uncharacterized long non-coding RNA and a predicted serine/threonine phosphatase. Through the generation of mutant clones and the overexpression of two distinct *kay* isoforms, we employed optical and scanning electron microscopy (SEM) to assess the resulting phenotypes. Our findings reveal that the overexpression and loss-of-function for *kayak* generates defects in imaginal structures. We observed a spectrum of phenotypic outcomes across different alleles. While some alleles exhibited pronounced defects, others displayed almost no consequences. Remarkably, all investigated alleles share a common trait—embryonic lethality. Notably, the insertion of a P-element into the lncRNA also resulted in embryonic lethality and displayed a phenotype strikingly similar to *kayak* mutant alleles. These results shed light on the multifaceted nature of the *kayak* locus and its impact on development.

1180S **Understanding the relationship between soluble histone supply and gene regulation in the early embryo** Reyhaneh Tirgar, Mohit Das, Jared T Nordman Vanderbilt

Histones are essential for chromatin packaging and histone supply must be tightly regulated as excess histones are toxic. To drive the rapid cell cycles of the early embryo, however, excess histones are maternally deposited. Therefore, soluble histones must be buffered by histone chaperones. We have identified the chaperone necessary to stabilize soluble H3-H4 pools in the Drosophila embryo to be NASP. We observed NASP localization in the nucleoplasm throughout embryogenesis. In the absence of NASP, H3 levels are depleted in the early nuclear cycles until cycle 14, where H3 levels are stabilized. Although *NASP* null mutants are viable in Drosophila, *NASP*is a maternal effect gene. Embryos laid by *NASP* mutant mothers have a reduced rate of hatching and show defects in early embryogenesis. Since NASP is a H3-H4 specific chaperone, we hypothesize that reduced H3 and H4 levels in the absence of NASP may lead to differential chromatin packaging in the early embryo and consequently aberrant transcription. To test our hypothesis, we have generated NASP mutants that do not bind H3 and are using both FISH and RNA-seq based approaches to measure transcription. This work will could provide direct evidence that soluble H3 in the early embryo modulates transcriptional activity.

1181S **Homeostatic control of intestinal stem cell renewal by two transcriptional regulators** Victoria Placentra[1], Shilpi Verghese[2], Ken Moberg[1] [1]Cell Biology, Emory University, [2]Emory University

As organisms age, the proliferative capacity of stem cells declines, which in turn impairs tissue renewal and can lead to organ dysfunction and disease. How local and systemic cues precisely regulate stem-cell based tissue renewal remains unclear, particularly in the rapidly cycling intestinal epithelium. A pair of transcriptional coactivator proteins that promote intestinal stem cell renewal – the Hippo pathway protein YAP1 and the nuclear receptor (NR) interactor NCOA3 – are each implicated in the progression of colorectal cancers and have orthologs in the fruit fly, *D. melanogaster*: the nuclear coactivator proteins Yorkie (Yki; YAP1 in humans) and Taiman (Tai; nuclear receptor coactivator-3, NCOA1-3 in humans). Prior studies have established that a physical interaction between Yki and Tai mediated via respective WW (tryptophan-tryptophan) domains and PPxY (proline-proline-x-tyrosine) motifs allows these factors to cooperatively induce target genes associated with regenerative growth of disc epithelia (e.g., *Ilp8*). As Tai and Yki each drive intestinal stem cell (ISC) proliferation in the

adult *Drosophila* midgut, we sought to test the hypothesis that Tai:Yki binding is required for this gut renewal function, and that this interaction allows the Hippo and NR pathways to cooperatively regulate gut homeostasis via a set of as yet undefined target genes in midgut cells, e.g., absorptive enterocytes (ECs) and ISCs. To address this question, we have generated a CRISPR mutant fly stock in which the PPxY motifs of endogenous Tai are converted to PPxA, blocking Tai's binding to Yki. Remarkably, these animals are alive, but show evidence of susceptibility to chemical agents that induce gut damage. We will present evidence of cellular and molecular defects that underlie this defect, including analysis of changes in chromatin state in wildtype and *tai*^{PPxA} following gut damage.

1182S **Roles for *CG5755* in the testis and nervous system, and possible interactions with *Ant2* and cardiolipin** Linden Patterson[1], Maggie Woodward[1], Amelia Roselli[1], Claire Olson[1], Karen G Hales[2] [1]Department of Biology, Davidson College, [2]Biology, Davidson College

Dramatic mitochondrial morphogenesis during spermatogenesis makes the *Drosophila* testis a useful context in which to explore mechanisms of mitochondrial dynamics. We previously found that *CG5755,* also known as *SLC25A46b*, is required for mitochondrial shaping during late spermatid elongation. Its human ortholog, *SLC25A46*, is associated with several human neurodegenerative conditions. The expression pattern of *CG5755* suggests testis specificity, but another group reported neurological phenotypes in a knockdown. Our *CG5755/deficiency* flies indeed exhibited hyperactivity in climbing assays, with speeds faster than their wild type*, CG5755/CG5755, or +/deficiency* counterparts. We introduced a wild type *CG5755* transgene to *CG5755/deficiency* flies to ask whether the hyperactivity phenotype could be attributed to *CG5755* loss. The *CG5755* spermatogenesis phenotype was rescued, but hyperactive climbing remained in *CG5755/deficiency; CG5755*$^{+}$, indicating the hyperactivity is not due solely to loss of functional *CG5755* and may instead stem from interactions with a neighboring gene. Conversely, *CG5755* homozygous females but not males showed a reduction in climbing ability. To investigate additional functional aspects of *CG5755*, we used RNA interference (RNAi) to explore connections between *CG5755* and two other genes, *Ant2* and *cardiolipin-synthase (CLS)*. The human ortholog of Ant2 (SLC254A4/5) has been shown by others to interact with SLC254A46. *Ant2* knockdown revealed its role in male fertility, sperm motility, and normal testes development. We are further investigating whether RNAi knockdown of *Ant2* affects the localization of *CG5755*-GFP. The *CG5755* human ortholog's structural similarity to another protein previously predicted a possible interaction with the mitochondrial membrane-specific lipid cardiolipin. We found that localization of CG5755-GFP was unaffected by depletion of cardiolipin via *CLS* knockdown. However, *CLS* knockdown impaired testis development and size to varying extents, suggesting that cardiolipin may be important for germ cell proliferation and maintenance. Overall, these results suggest roles for *CG5755*, *Ant2*, and *CLS* in spermatogenesis though functional connections are still unclear.

1183S **Epithelial cell fusion is required for wound healing following UV-A irradiation** Minqi Shen, Lydia W Boer, Vicki Losick Biology, Boston College

Polyploid cells are life's stress responders. The more than doubling of a cell's genome is often an adaption that enables cells, tissues, and organisms to survive in response to injury, including from sources of genotoxic stress. Cell cycle dependent (endoreplication) or independent (cell fusion) mechanisms lead to the generation of mononucleated and multinucleated, polyploid cells. While endoreplication has been shown to enable polyploid cells to survive in presence of DNA damage, it remains unknown whether cell fusion leading to the multinucleated ploidy state provides equal protection. Here we utilize the adult *Drosophila* epithelium which we found responds to stress, including UV-A irradiation via the generation of mono- and multinucleated, polyploid cells. Exposure to UV-A irradiation results in cell loss and a corresponding wound healing response characterized by the generation of polyploid cells by cell fusion (dBrainbow color mixing) and endoreplication (nuclear ploidy $\geq$4C). In the adult *Drosophila* epithelium, cell fusion is the prominent response to UVA irradiation and essential for tissue repair. Epithelial specific expression of a dominant negative Rac GTPase via Gal4/UAS system blocks cell fusion post UVA exposure and impairs epithelial survival resulting in apoptosis. Whereas blocking endoreplication via epithelial specific knockdown of E2F1 or CycE does not appear to delay epithelial wound healing as cells are still able to fuse and restore tissue integrity. In conclusion, we have found that multinucleation via cell fusion is another strategy to protect against genotoxic stress. Thus we are aiming to elucidate whether these distinct ploidy states enable cell survival via similar or distinct molecular mechanisms in response to life's insults.

1185S **Live imaging reveals stepwise signaling and cytoskeletal changes underlying de-differentiation in the *Drosophila* testis** Carlie Relyea, Kari F Lenhart Biology, Drexel University

Tissue homeostasis requires continual maintenance of adult stem cells over the lifetime of an organism. These stem cells produce progenitors that go on to specialize and populate the tissue in which they reside. Yet, in many cases, insult, injury, and lifelong stress cause significant depletion of the stem cell pool which, in turn, produce insufficient progenitors to maintain the health of the tissue. Thus, the mechanisms that tissues employ to retain a robust stem cell pool are vital for prevention

of tissue degeneration and atrophy. One key method to renew the stem cell population is de-differentiation; the process by which differentiating cells of a tissue physically move back to the specialized stem cell niche and adopt self-renewing capabilities. The *Drosophila* testis is an ideal model to study the cell biology of de-differentiation as a number of both genetic and environmental perturbations induce this process to replenish the germline stem cell pool. Under homeostatic conditions, differentiating germ cells are released from the niche and go on to complete four rounds of mitosis with incomplete cytokinesis, forming interconnected units termed cysts. Each cyst is tightly encased by two quiescent somatic cells which co-differentiate, facilitating spermatogenesis and tissue maintenance. Work from our lab and others suggests a three-step model by which de-differentiation is achieved: 1. Somatic cells lose contact with adjacent germ cells 2. Germ cell cysts complete cytokinesis to release individual cells 3. Migration of germ cells back to the niche. Preliminary studies utilizing genetic analyses and longitudinal live imaging of germ cells have revealed the signaling and cell biological changes that promote two of these events, cytokinesis completion and migration. First, we find that completion of cyst cytokinesis is preceded by loss of F-actin at typically stable germ cell intercellular bridges, allowing for germ cell abscission outside of the niche. Moreover, subsequent migration back to the niche is mediated by Jak/STAT signaling, which promotes germ cell polarization and leading-edge cytoskeletal rearrangement. Current work is focused on live imaging somatic cells during de-differentiation to fully elucidate the mechanisms governing each step of de-differentiation to maintain the germline stem cell pool.

1186S **The *Drosophila* testis compensates for catastrophic germ cell loss by altering stem cell cytokinesis** Christie Campbell, Tiffany Roach, Kari F Lenhart Biology, Drexel University

Tissue homeostasis requires a balance in production of self-renewing stem cells and differentiating daughters, or progenitors. The specialized microenvironment, or niche, in which stem cells reside provide regulatory signals to control this balance. Diminished niche signals and subsequent progenitor loss, or atrophy, is a hallmark of aging. However, the mechanisms by which stem cells and their progenitors respond to tissue atrophy remain elusive. Using the *Drosophila* male germline as a model system, we explored a genetic model that depletes progenitors to mimic tissue atrophy through ablation by expression of an apoptotic factor, Hid. During homeostasis, germline stem cells (GSCs) engage a delayed cytokinesis program, the timing of which is controlled by niche derived Jak/STAT signaling. Following contractile ring disassembly, GSCs pause cytokinesis progress through formation of a secondary F-actin ring. The lifetime of that ring is controlled by Jak/STAT signaling and determines the timing of cytokinesis completion and release of daughter cells from the niche. While it is known that GSCs can increase their mitotic rate to compensate for progenitor loss, this compensatory mechanism comes with a cost due to the long duration of GSC cytokinesis. Previous work from our lab has shown that fast cycling GSCs are significantly more likely to exhibit failed cytokinesis, and thus, mitotic rate may be deleterious as a compensatory mechanism. Here, we elucidate a novel mechanism used by the testis niche to compensate for tissue atrophy. Ablation of germ cells leads to compensatory feedback to the niche, inducing faster secondary actin ring disassembly and significantly shortening the cytokinetic pause in GSCs. This altered cytokinesis timing is likely achieved through increased Jak/STAT signaling in the niche, mediated by increased niche size. We are currently investigating the hypothesis that differentiating somatic cells move back to the niche and transdifferentiate to increase niche size. Together, this data supports a model whereby under catastrophic germ cell loss, a larger niche is formed, providing increased STAT signal to support a faster release of progenitor cells. Future work will investigate the mechanistic steps underlying this feedback and subsequent change in niche architecture to better understand how stem cell niches attempt to prevent tissue atrophy.

1187S **Misregulation of germ cell cytokinesis drives tumorigenesis in the *Drosophila* testis** Beth Kern, Kari F Lenhart Biology, Drexel University

Tissue homeostasis requires a tight balance between maintenance of the stem cell pool and production of specialized daughter cells. This balance is accomplished by restriction of the stem cell microenvironment, or niche, such that only stem cells receive self-renewal cues. Dysregulation in the stem cell niche and surrounding tissues can induce progenitors to revert in identity, express stem cell-specific markers, and initiate tumorigenesis. Yet how progenitors on the path to specialization initially respond to pro-oncogenic signals, and the degree to which they convert to true stemness, remains elusive. Under homeostasis, the *Drosophila* male germline is maintained by a group of mitotically dividing germline stem cells (GSCs). Using a modified, but complete, cytokinetic program, GSC daughters are released from the niche and spatially displaced from niche cues. Outside of the niche, differentiating germ cells execute a highly conserved incomplete cytokinetic program. Here, formation of stable intercellular bridges termed ring canals (RCs) creates germline cysts that share cytoplasm and differentiate as synchronous units. Homeostasis of this tightly controlled system is disrupted by expansion of niche Jak/STAT signaling, which promotes formation of stem-like germ cell tumors (GCTs). Yet, the temporal events underlying transformation, and degree to which GCTs execute GSC programming, is unknown. Here, I find that initial reception of the Jak/STAT ligand Unpaired (Upd) by germline cysts does *not* promote full re-acquisition of GSC cytokinesis. Instead, GCTs have disrupted incomplete cytokinesis, exhibiting dynamic instability of F-actin at normally stable RCs. Persistent depletion of F-actin permits inappropriate completion of cytokinesis through abscission. Moreover, just as in mammalian GCTs, we find that defects in adjacent somatic

cells are sufficient to induce GCTs characterized by RC F-actin instability. This indicates that integrity of incomplete cytokinesis may require co-differentiation of somatic support cells. Our preliminary work suggests that somatic-derived FGF is required for fidelity of incomplete cytokinesis, is attenuated at tumor onset, and that aberrant cytokinetic completion drives germline tumorigenesis.

1188S **Exploring the complex signaling between a transcription factor, *dve* and a morphogen involved in establishing eye vs head fate.** Soumya Bajpai[1], Anuradha V Chimata[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

Organogenesis is the development of a highly organized tissue from just a cluster of few cells. Although it sounds quite simple, but it involves interaction of multiple factors and signaling pathways. Morphogens and axial patterning factors are two important players in organogenesis. As morphogens impart positional information to determine cell fate while axial patterning drives the transformation of those cells present as a monolayer tissue into a 3-dimentional organ by establishing Dorsal-Ventral (DV), Anterior-Posterior (AP) and Proximal-Distal (PD) axes, among which DV axis is the first to form during eye development. Any aberration in establishment of either these axes or the morphogen gradient fosters craniofacial birth defects. And to better understand the development of these defects it is important to investigate the complex signaling that is involved in establishment of a normal eye vs head fate. *defective proventriculus* (*dve*), previously identified as a dorsal selector gene, is a K-50 homeodomain containing transcription factor, a *Drosophila* ortholog of human SATB1. Dve plays a crucial role in eye development since it›s loss-of-function of results in dorsal eye enlargement while gain-of-function results in complete eye suppression. The Hedgehog (Hh) family of molecules are an important class of morphogens and render a crucial part in eye development as it regulates formation of the retina in *Drosophila* by orchestrating a differentiation wave that allows for the rapid and precise differentiation of the fly retina. We found out that these two individually important players in eye development do associate with each other and affect the eye vs head fate. We further want to explore the signaling that comes into action because of this association and understand the cause of the aberrant establishment of eye vs head fate, a common problem observed in craniofacial birth defects. Here, we present our results from modulating Hh signaling pathway in *dve* expression domain and how it affects eye development.

1189S **Real-time brain lineage modulation in pregastrulation neural primordium *in vivo*** Kelli D Fenelon, Priyanshi Borad, Theodora Koromila Biology, University of Texas at Arlington

Cell differentiation, which drives embryonic development, is initiated by pioneer transcription factors (PTFs) that prime cells to shift their external roles by transforming their transcriptional landscapes. Neural progenitor specification and differentiation occur early in development with detectable neuroblasts arising a mere hour post gastrulation in the *Drosophila* embryo. Pre-gastrulation, pioneer factors activate a multitude of genes simultaneously to produce antecedent cells for burgeoning common lineages of distinct germ layers or tissue primordia. The roles of early PTFs involved in brain development, such as Odd-paired (Opa)/Zinc finger in the cerebellum (ZIC3) and Ocelliless (Oc)/OTX1/2, are largely conserved across the animal kingdom. Despite ongoing efforts, the synergistic functionality of PTF spatiotemporal cycles and their rippling long-term effects are poorly characterized. We have previously demonstrated a pregastrulation spatiotemporal niche of co-regulation by these two factors spatially confined to the early embryonic region of the future brain and occupying distal elements proximal to a panoply of brain genes. We develop *in vivo*, optogenetic and real-time transcription observation tools to modulate expression of these genes pregastrulation to interrogate the primordial fate determining events which specify the earliest brain lineages. Specifically, we are employing and engineering LEXY and LANS optogenetic transgenic control tools on endogenous and exogenous Opa and Oc allowing us to modulate pre- and post-gastrulation expression of novel real-time MS2 transcriptional reporters for brain genes (e.g. *hb, Dll*) *in vivo* in real-time with spatiotemporally precision. This work is vital to understanding the cell fate determinations which beget the coordinated cellular diversity of mature animalia.

1190S **Exploring Myoblasts and Muscle Development: The Impact of MEF2 Overexpression** Elizabeth Trujillo[1], Richard Cripps[2] [1]Biology, San Diego State University, [2]San Diego State University

The Myocyte enhancer factor-2 (MEF2) transcription factor plays a vital role in orchestrating the muscle differentiation program. While MEF2 cannot effectively induce myogenesis in naïve cells, it can potently accelerate myogenesis in mesodermal cells. This includes Drosophila imaginal disc myoblasts, where triggering premature muscle gene expression in these adult muscle stem cells has become a paradigm for understanding regulation of the myogenic program. Here, we investigated the global consequences of MEF2 overexpression in the imaginal wing disc myoblasts, by combining RNA-sequencing with RT-qPCR and immunofluorescence. We observed the formation of sarcomere-like structures that contained both muscle and cytoplasmic myosin, and significant upregulation of muscle gene expression, especially genes essential for

myofibril formation and function. These transcripts were functional, since numerous myofibrillar proteins were detected using immunofluorescence. Interestingly, muscle genes whose expression is restricted to the adult stages were not activated in these adult myoblasts. These studies confirm a broad activation of the Drosophila myogenic program in response to MEF2 expression, and suggest that additional regulatory factors are required for promoting the adult muscle-specific program. Our findings contribute to understanding the regulatory mechanisms governing muscle development, and highlight the multifaceted role of MEF2 in orchestrating this intricate process.

1191S **Nemp, a conserved IDR containing nuclear transmembrane protein, is essential for oogenesis** Ruichen C Cao[1], Yonit Tsatskis[2], Helen McNeill[1] [1]Developmental Biology, Washington University in St. Louis, [2]Cell Biology, The Hospital for Sick Children

The nuclear envelope is a highly regulated and organized double membrane that separates the nucleus from the cytoplasm in all eukaryotes. It is embedded with numerous regulatory and transport proteins. Nuclear envelope membrane protein (*Nemp*) is a highly conserved multipass inner nuclear membrane protein. Though *Nemp* is ubiquitously expressed in all examined tissues across mouse and fly, it exhibits strongly tissue specific phenotypes: one of the most striking results of *Nemp* loss is sterility, conserved across flies, female mice, zebrafish, and worms. In addition, point mutations in *Nemp* have been associated with early onset of menopause in humans. In plant homologs, Nemp family proteins have been implicated in chromatin tethering. The reasons for the strong tissue specific phenotypes of Nemp loss are unknown. *Nemp* genetic null flies are infertile, with atrophied ovaries that are incapable of producing eggs. Preliminary data shows early germline specific knockdown of Nemp leads to almost total loss of early egg chambers, while late knockdown has no apparent effect, indicating that Nemp functions in early oocyte development. Remarkably, egg laying can be partially rescued by concurrent knockdown of the cell cycle checkpoint protein Chk2, implying that the shrunken ovaries from Nemp loss of function are related to DNA damage checkpoint. I will present data characterizing the effects of inducible Nemp knockdown in meiosis and oocyte determination with the Gal4/Gal80 system. In addition, I will determine whether oocyte loss can be mitigated by loss of meiotic DNA breaks, and look for markers of DNA damage in Nemp loss of function.

Recent work in the lab has shown that Nemp contains intrinsically disordered regions (IDR) in its nucleoplasmic tail and forms puncta in mouse oocytes. Live imaging in mouse oocytes reveals these puncta to be dynamic and sensitive to mechanical stress. My preliminary data indicates that Nemp also forms puncta in *Drosophila* salivary glands, muscle and ovary. However, it is still unclear if these puncta are phase separated bodies, what the mechanism of Nemp phase separation is, if there are other components involved in these condensates, and what the biological function of these condensates are. I use *Drosophila* to explore some of these questions.

1192S **Systematic rectification of planar orientation angle leads to interface behavior switching and replenishment during epithelial remodeling** Timothy E Vanderleest[1], Liam J Russell[1], Katie E Linvill[1], Miao E Hui[2], Xie E Yi[2], Dinah E Loerke[3], Todd E Blankenship[2] [1]Molecular and Cellular Biophysics, University of Denver, [2]Biological Sciences, University of Denver, [3]Physics and Astronomy, Cellular and Molecular Biophysics, University of Denver

Tissue elongation through morphogenetic epithelial remodeling is a fundamental process that is used across a variety of multicellular animals and occurs through dynamic cell behaviors. In the early Drosophila embryo, tissue elongation is driven by the modification of local topologies through oriented cell intercalation. Previous work has shown that a system of planar polarity produces net contractile behaviors at vertical cell-cell contacts (or interfaces), i.e. those that are aligned along the dorsal-ventral axis. These interfaces contract fully to produce higher-order vertices, which then resolve into new horizontal (anterior-posterior aligned) interfaces through so-called T1 transitions. Here, we show that contractile events produce a continuous “rectification” of cell interfaces, in which interfaces systematically and continuously rotate towards more vertical orientations. Intriguingly, as interfaces rotate in angle, their behaviors change, often transitioning from stable to contractile regimes. This observation demonstrates that the planar polarized identities of cell-cell interfaces are continuously re-interpreted in time depending on their orientation angle. These behavioral transitions are observable at the molecular level, with interfaces acquiring higher levels of Myosin II motor proteins as they become more vertical. Disruptions to the contractile molecular machinery (F-actin and Myosin II) cause reduced rates of rotation, consistent with this dynamic rectification mechanism being driven, at least in part, by interface contraction. Importantly, as a result of this rectification scheme, the available pool of contractile interfaces is continuously replenished as new interfaces acquire contractile identities through rotation. This means that over time cells in the germband epithelium acquire additional interfaces that are capable of undergoing T1 transitions, thus allowing cells to participate in multiple staggered rounds of intercalary events, and thereby producing higher net tissue extension than would be possible in a system with only a single round of contractile vertical interface specification.

1193S **Competing for survival: Taiman controls fitness status by a mechanism involving glypican-dependent diffusion and capture of the Wg morphogen** Colby K Schweibenz, Ken H Moberg Cell Biology, Emory University School of Medicine

Cell competition ensures that the fittest cells populate developing primordia but is also postulated to underlie the phenomenon of "field cancerization," in which cancer cells expressing 'super-competitor' genes eliminate slow growing neighbors and take over an epithelial tissue. Our prior work demonstrated that cells overexpressing the *Drosophila* protein Taiman (Tai; human NCOA3/AIB1), a transcriptional co-activator of both the Ecdysone receptor and the Hippo pathway effector Yorkie, kill wildtype neighbors within the larval wing epithelium in a manner dependent on production of the Toll ligand Spätzle (Byun et al., 2019). Here we use the reciprocal finding that cells with reduced Tai expression (Tai^{low}) are competitive 'losers' as the basis of a genetic screen for mutations that rescue elimination of 'loser' cells . This screen recovered 'hits' in pro-apoptotic genes (*hid*, *reaper*), confirming a dependance of the 'loser' phenotype on apoptosis, and also recovered the *Drosophila* Adenomatous polyposis coli (APC) tumor suppressor homologs, *Apc1* and *Apc2*, which are conserved inhibitors of the Wg (Wnt) pathway. Notably, *tai* loss reduces expression of the Wg target gene *nkd* in wing discs while *tai* overexpression has the opposite effect, indicating that Tai normally promotes expression of a Wg pathway component(s). Subsequent work determined that *tai* promotes expression of the GPI-linked glypican *dally-like* (*dlp*), which localizes to the apical ECM to facilitate Wg spread from source cells and acts as a Wg coreceptor. tai^{low} regions of wing discs are depleted of Dlp protein and block extracellular spread of Wg protein from source cells, leading to the hypothesis that Tai^{low} cells are at a competitive disadvantage with wildtype cells for 'capture' of extracellular Wg. Ongoing experiments examine Tai effects on *dlp* RNA transcription and Dlp protein trafficking, with the goal of defining how Tai control of the apical extracellular matrix modulates competitive status.

1194S **Investigation of the genes and gene regulatory networks activated during regeneration** Noah C. Fryling, Rebeccah L. Messcher, Keisha Roldán Báez Roldán Báez, Shireen T. Shah, Gloria Uduehi, Lydia Driggers, Josh Pazin, Nikhil Reddy, Melanie I. Worley Department of Biology, University of Virginia

For the field of regenerative biology, there remain many unanswered questions, including when an organism regenerates, to what extent is regeneration accomplished via activating the same molecular mechanisms required for normal development versus regeneration-specific processes? To start to address this question, we use the model organism Drosophila melanogaster, which provides a wide availability of powerful genetic tools to support dissection of gene function in vivo, including the ability to screen gene interactions and quantify them through regenerative growth assays. Specifically, we study regeneration in imaginal discs, the larval precursor to adult structures such as eyes and wings. In larval organisms, imaginal discs are capable of robust regeneration with characterized stages, including the formation of a localized zone of proliferation and enhanced plasticity, called a blastema. Through single-cell analysis and genetic approaches, we previously identified a Gene Regulatory Network (GRN) that is critical for sustaining the pro-regenerative state of the blastema. This GRN is driven by the stress-responsive JNK/AP-1 pathway and the transcription factor Ets21C, which together form a feedforward loop that induces and sustains the expression of several key downstream effector genes, including genes that encode for several secreted ligands such as the unpaired cytokines. Ets21C is required for effective regeneration, as in the absence of Ets21C regenerative growth is prematurely terminated. Single-cell transcriptomic data was also used to identify potential genes of interest, including those significantly up-regulated during the regeneration of the wing disc that are not widely expressed during normal development. We show a pair of genes, wun/wun2 to be expressed spatially and temporally in the imaginal disc during regeneration. Current work consists of the characterization of regenerative growth in the absence of these genes, as well as other candidate genes shown to have altered expression during regeneration. Additionally, since a number of these candidate genes are implicated in cellular movement, a process likely essential for the early initiation of regeneration, we are determining the role of these genes in cell movement via tissue-specific knock-out. Our future work aims to elucidate the manner in which these candidate genes impact mechanisms necessary for regeneration.

1195S **The long chain fatty-acyl CoA reductase *waterproof* is required for eye and head development** Ashleigh Ogg[1], Amber Reynolds[1], Nia Harris[1], Adriana Visbal[2], Mardelle Atkins[3] [1]Sam Houston State University, [2]University of Houston-Downtown, [3]Biology, Sam Houston State University

In *Drosophila melanogaster*, many external adult structures arise from epithelial sac-like tissues known as imaginal discs. One such disc, the eye-antennal disc, gives rise to the adult eye, antennae, and head epidermis. Our lab performed an *in-silico* screen that identified 96 potential candidate genes for eye and head development. From this list, the gene *waterproof (wat)* was selected for further analysis. *Wat* encodes a fatty acyl CoA reductase (FAR), which is responsible for reducing very long chain fatty acids. Defects in FAR1, the human ortholog, can cause cataracts, spastic paraparesis, or fatty acyl-CoA reductase 1 disorder. The specific FAR encoded by *wat* is known to be involved in lipid metabolism. Current research demonstrates that *wat* is crucial for a functional embryonic tracheal system, however it has not been characterized in the eye-antennal imaginal disc. Using a *wat::GFP* fusion protein, we observed a restricted expression pattern in the eye-antennal imaginal disc that included Bolwig's nerve and photoreceptor axons. Surprisingly, knockdown of *wat* results in headless progeny when using *ey-Gal4* or *c311-Gal4*. Subsequent experiments were performed using the UAS-GAL4 transgenic system and immunohistochemistry to assess the tissue-specific requirements for *wat* expression. These experiments revealed

requirements for *wat* in cells of both the peripodial epithelium (PE) and disc proper (DP) cells, each producing a distinct phenotype affecting disc growth and differentiation. We will present these results as well as ongoing work to assess the role of *wat* in Bolwig's nerve and if this is important for structural integrity of the PE.

1196S **Subcellular Mechanisms of Programmed Cell Death in *Drosophila* Ovarian Nurse Cells** Georgette-Vanelle Wandji, Kristen Harder, Kimberly McCall Boston University

Cell death and clearance of cellular debris is essential to the development and homeostasis maintenance of an organism. These phenomena in *Drosophila* oogenesis play critical roles in ensuring the proper development of the female reproductive system and the formation of functional eggs. In the *Drosophila* ovary, germline-derived nurse cells (NCs) undergo non-apoptotic programmed cell death as part of normal development. We have found that NC death is controlled largely non-autonomously by the surrounding somatic stretch follicle cells (FC), and that the phagocytic machinery is required for the final steps of NC death: acidification, nuclear membrane breakdown, and DNA fragmentation. Lysosomal machinery acting in the surrounding FCs non-autonomously promotes the acidification and DNA fragmentation of nurse cells. Through candidate gene screens and confocal microscopy, we determined that V-ATPases (proton pumps) are enriched and localized to the plasma membrane of the FCs as they surround the nurse cells. Using a pH-sensitive reporter, we found that NC nuclei were not engulfed in vesicles, but instead acidification was observed outside the FCs. We propose that the FCs do not engulf the NC nuclei, but instead the V-ATPases promote extracellular acidification and the FCs release cathepsins to eliminate the NCs. To gain a comprehensive view of the molecular network that controls NC death non-autonomously, we will further elucidate how the cells' endoplasmic reticulum and plasma membrane are eliminated. We find that the NC membrane begins to break down prior to acidification and we hypothesize that the NC plasma membrane undergoes trogocytosis by the neighboring FCs. By observing the interaction between the plasma membranes of FCs and NCs during late-stage oogenesis, NC death and clearance will be better understood. This work sheds light on mechanisms of phagocyte-dependent cell death.

1197S ***cupid*, a spontaneous mutation affecting proximodistal patterning in *Drosophila*** Cory J. Evans[1], Juliana Venegas[2], Zoe Wong[2] [1]Biology, Loyola Marymount University, [2]Loyola Marymount University

A spontaneous mutation was isolated that behaves recessively, is located on Chromosome 3, and causes the formation of small adult wings and short forelegs. We have named this mutation *cupid* (*cpd*) because the appearance of these flies is reminiscent of Renaissance-era depictions of Cupid, often cherubic deities with small wings and short limbs. Recombination mapping with dominant markers place *cpd* within the 46-53 cM interval. Morphometric analysis indicates that wings of *cpd* homozygotes are approximately 68% of the size of wild-type (Oregon R) wings. Comparison of L3 vein length from its origin at the hinge to the anterior cross vein (ACV) and then to the wing margin indicates that *cpd* predominantly affects proximal wing development. From hinge to ACV, *cpd* flies average 38% of the length in wild-type flies, whereas from ACV to the margin, *cpd* flies average 86% of the length in wild-type flies. Additionally, most *cpd* flies (85%) have an incomplete or missing ACV, and vein L5 fails to reach the wing margin 60% of the time. In terms of length, complete L5 veins in *cpd* flies average only 75% that of wild type, whereas incomplete *cpd* L5 veins average 54% of wild type. Regarding legs, the major phenotype of *cpd* flies is shortening of the tarsus (78% of wt), apparently caused by the partial or complete loss of two or more of the five tarsal segments present in wild-type flies. This loss includes the distal region of tarsal segment T1 and is most noticeable in males because sex combs, which develop in this region, are always missing or strongly reduced in *cpd* male flies. In *cpd* flies, the tarsus appears to be composed of three segments, with the proximal region of T1 fused with T4 and followed by a normal T5 segment containing the tarsal claw. During our analysis, we became aware that mutations in *rotund* (*rn*), encoding a zinc-finger transcriptional regulator known to control proximodistal patterning, exhibit *cpd*-like phenotypes. Furthermore, *rn* maps to 48 cM on the third chromosome, coincident with the *cpd* interval. We find that null alleles of *rn* fail to complement *cpd*, with *cpd*/*rn* heterozygotes reproducing the *cpd* phenotype. Additionally, we find that a duplication of the *rn* locus carried on the second chromosome is sufficient to rescue the *cpd* phenotype. Collectively, our results indicate that *cpd* is allelic with *rn* and is likely a genetic null. We are currently analyzing the molecular nature of the *cpd* mutation in the *rn* locus.

1198S **Stem cell mitophagy-dependent quiescence involves regulation of CycE levels and its localization at the mitochondria** Anne-Marie Pret[1,2,3], Miriam Gonzaga[2,3], Shelly Caisley[2,3], Sahiti Peddi[2,3], Cheryl Chan[2,3], Riya Keshri[2,3], Beatriz Estrada[2,4], Julie Mathieu[2,3], Hannele Ruohola-Baker[2,3] [1]Institute of Integrative Biology of the Cell Gif-sur-Yvette/ University of Versailles, [2]Biochemistry, University of Washington, [3]Institute for Stem Cell and Regenerative Medecine, University of Washington, [4]Institute of Stem Cell and Regenerative Medecine, University of Washington

Cells can undergo cell-cycle arrest, quiescence or diapause, at the G1/S transition to avoid apoptosis under stress conditions. This state is reversible when the stress is removed allowing cell-cycle reentry. Recently our lab has shown a common mechanism by which two different types of stem cells, *Drosophila* Germline Stem Cells (GSCs) and human induced Pluripotent Stem Cells (iPSCs), enter stress-induced quiescence. Surprisingly, unlike in other cell types, high levels of CycE are localized

at the outer mitochondrial membrane during the G1/S transition in the stem cells studied. Quiescence in these stem cells involves reduction of CycE, as well as that of mitochondria via mitophagy driven by the Ser/Thr kinase Pink and the ubiquitin ligase Parkin.

Presently, we are testing several mechanisms by which CycE regulation might occur during stem cell quiescence:

1. In order to determine whether direct CycE degradation is involved, we expressed CycE deleted of its PEST domain in *Drosophila* GSCs and found that irradiation stress permits the cells to remain in the cell cycle rather than entering quiescence unlike the control. This suggests that CycE must be degraded via the proteasome pathway involving ubiquitin E3 ligases. Therefore, we are testing whether CycE in *Drosophila* GSCs is ubiquitinylated and, if so, is Parkin responsible for CycE ubiquitinylation. We are presently using a similar strategy to test whether the degron domains in human CycE are necessary for quiescence of human iPSCs undergoing rapamycin-induced stress.

2. A candidate gene approach of genes involved in mitophagy, mitochondrial dynamics, and vesicular trafficking in *Drosophila* is being used to screen for those having a role in GSC quiescence. We will present localization of CycE in positive candidate gene loss and/or gain of function conditions. Positive candidate genes will also be knocked out in human iPSCs using the CRISPR/Cas9 methodology.

Determining the mechanism for CycE regulation in stem cells is critical to understand how diapause-like cancer cells can be made to re-enter the cell cycle and thus remain amenable for cancer chemotherapy.

1199S **The Gut-Brain Axis Unveiled: Aging and Tauopathy Models Reveal a Novel Impact of the Brain on Intestinal Stem Cell Differentiation** Tyler Jackson[1,2], Ye-Jin Park[2,3], Tzu-Chiao Lu[2,4], Christina Ko[5], Lindsey Ran[5], Yanyan Qi[2,4], Hongjie Li[2,4] [1]Cancer and Cell Biology Program, Baylor College of Medicine, [2]Huffington Center on Aging, Baylor College of Medicine, [3]Development, Disease Models, and Therapeutics Program, Baylor College of Medicine, [4]Department of Molecular and Human Genetics, Baylor College of Medicine, [5]Department of Neuroscience, Rice University

Complex eukaryotic organisms are composed of specialized organ systems that must participate in cross-tissue communication to ensure proper responses to environmental stimuli. The gut-brain axis plays a pivotal role in inter-tissue communication, crucial for organismal adaptation and homeostasis. This bidirectional interaction involves neuronal signals regulating digestion and hunger responses. While functional assays dominate gut-brain axis research, understanding molecular mechanisms impacting gut stem cell homeostasis remains limited. Leveraging aging and neurodegenerative disorders as models, we explore the gut-brain axis using Drosophila melanogaster, a model organism sharing incredible orthology with mammalian gut features. Preliminary data from the Aging Fly Cell Atlas revealed age-associated dysplasia in intestinal stem cells (ISCs), prompting investigation into the contribution of brain aging to this phenotype. Our lab generated single-cell sequencing data using a neuron specific Tauopathy model, providing a resource to decipher the effects that neuronal dysfunction may have on cell function in the gut. Data from this resource recapitulated the age-associated accumulation of gut ISCs and additionally revealed a unique subset of immature enterocytes (absorptive cells in the gut). These findings underscore the nervous system's direct influence on cell differentiation in the gut. Furthermore, I found there was dysregulation of well-characterized signaling pathways during ISC differentiation using cell-cell communication prediction software to produce additional support for this finding. In summary, our work uncovers novel consequences of brain dysfunction on gut homeostasis, prompting deeper exploration of cross-tissue communication.

1200S **Having a Heart: Biological and Mechanistic Roles for Slit Fragments in *Drosophila* Heart Development** Sahara C Harrington[1], Riley Kellermeyer[2], Ria Anand[1], Jonathan Taasan[1], Laureline Lequint[1], Thomas Kidd[1] [1]University of Nevada, Reno, [2]Stowers Institute

Congenital heart defects (CHDs) affect around 1% of live births in the United States, making it the most common birth defect. Interestingly, mutations in axon guidance genes lead to congenital heart defects in humans. *Drosophila melanogaster* is an excellent cardiac model for understanding the biological roles that conserved axon guidance genes, *slit*, *robo1*, *Dscam1*, and *tok,* play in heart development. While full-length Slit is required to repel the cardiac cells generating the lumen, little is known about the function of the Slit proteolytic fragments generated by the Tok protease. We have characterized the heart defects of *tok* mutants, and those of new CRISPR alleles of *slit.* The new alleles, Slit-Uncleavable (*slit-UC*) and Slit-N (*slit-N* only fragment), allow for fragment-specific genetic manipulations that provide insights into their roles in development.

Genetic rescue and molecular experiments show that the N-terminal Slit fragment, Slit-N, mediates cell-cell adhesion through heterodimerization with Dscam1 and Robo1 receptors. Remarkably, both *slit-N* and *slit-C* can rescue the migration and adhesion heart defects of *tok* null mutants. However, preliminary data shows that *slit-N* does not rescue *slit* null mutant

phenotypes. Preliminary data also indicates strong interactions with collagen-IV (Pericardin) and collagen-XV (Multiplexin) in the extracellular matrix may be leading to disorganization across heart-specific cells.

Our work establishes molecular and biological mechanisms for these genes and suggests they may function in the collective migration of the cells that generate heart valves in humans.

1201S **Antagonistic interactions between Dpp signaling and defective proventriculus determines eye versus head fate.** Anjali Sangeeth[1], Neha Gogia[1], Anuradha V Chimata[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

Axial patterning, a crucial process during development, involves the delineation of three axes, such as Antero-Posterior (AP), Dorso-Ventral (DV), and Proximo-Distal (PD), is required for the transition of a monolayer organ primordium to a three-dimensional organ. Axial patterning involves the participation of morphogens, transcription factors, and regulatory genes. Any deviations in this process result in birth defects. We have identified a K-50 homeodomain-containing transcription factor, *defective proventriculus* (*dve*, an ortholog of SATB1), as a dorsal fate selector gene during eye development. Using genetic approaches, we found that Dve interacts with various signaling pathways during eye development to determine eye versus head fate. Among these, a highly conserved Decapentaplegic (Dpp)/Bone Morphogenetic Protein (BMP) signaling pathway, which forms a morphogen gradient in the developing *Drosophila* eye, acts antagonistically to *dve* to regulate retinal differentiation and thereby determines eye versus head fate. Here we present our studies on molecular genetic interactions between the members of Dpp signaling pathway and *dve* during eye development. Interestingly, SATB1, a mammalian homolog of *dve*, exhibits similar interaction with Dpp signaling pathway members suggesting that these interactions may be conserved.

1202S **Characterizing anterior somatic muscle specification in the *Drosophila* embryo** Lauren Kraker[1], Josue Merida[2], Dalia Fainberg[2], Kristelle Capistrano[1], Krista Dobi[2,3] [1]Natural Sciences, Baruch College, [2]Baruch College, [3]Molecular, Cellular and Developmental Biology, CUNY Graduate Center, City University of New York

Muscle wasting is a progressive decline in tissue mass and strength that occurs due to disuse, muscle diseases, cancer (cachexia) and aging (sarcopenia). Prevention and treatment of these disorders depends on our ability to generate different sizes and shapes of muscles, so that we: 1) understand why certain muscle types are affected and 2) can repair or generate new muscle tissues *in vitro* that match those affected muscles. Fruit flies make an ideal system to study muscle function because both fly and human systems feature multinucleated, striated muscles that form indirect attachments to tendons or direct attachments to skeletal structures. Over 20 identity gene transcription factors have been shown to regulate muscle properties in the *Drosophila* embryonic abdominal hemisegments. A few of these transcription factors have been examined in the T2 and T3 thoracic hemisegments, but almost no work has examined the development of the T1 muscle pattern that connects the somatic musculature to the mouthhooks used for feeding. One of the challenges of this muscle subset is that the embryonic head segment invaginates during head involution; the thoracic musculature correspondingly moves forward so that the most anterior external hemisegment becomes T1. We have begun our analysis of T1 using the live transgene *twist-actin-GFP* to follow the movements of the dorsal pharyngeal mesoderm and somatic mesoderm during head involution. These movies show that myoblast fusion continues during tissue rearrangement. A preliminary mutant analysis has shown that overexpression of *ap* or *muscle segment homeobox* using *twist-Gal4* leads to mispatterning of T1. In vertebrates, muscles can form indirect attachments to tendons or direct attachments to bone. We are particularly interested in the T1 subset of muscles to determine whether *Drosophila* larvae have these two types of attachments. We are using antibody staining and microscopy to determine whether muscle attachments to the internal cephalopharyngeal skeleton are structurally similar to muscle attachments to the external cuticle via tendons.

1203S **Ets21C-dependent gene regulatory network shared between regeneration and tumorigenesis** Keisha M Roldan Baez[1], Rebeccah L Messcher[2], Noah C Fryling[1], Shireen T Shah[1], Gloria Uduehi[1], Lydia Driggers[1], Josh Pazin[1], Nikhil Reddy[1], Melanie I Worley[1] [1]Department of Biology, University of Virginia, [2]University of Virginia

Regeneration is the process by which damaged or lost tissues are replaced with functionally equivalent tissues. Tumors share many characteristics with regenerating tissues, including increased cellular proliferation and loss of differentiation markers. We aim to better understand the molecular and cellular mechanisms that regulate growth during regeneration and tumorigenesis. To this end, we investigate regeneration and tumorigenesis in Drosophila imaginal discs. Through single-cell analysis and genetic approaches, we have previously identified a Gene Regulatory Network (GRN) that is critical for sustaining the pro-regenerative state of the blastema and demonstrated that this pro-regenerative GRN is co-opted to promote tumorous growth in a neoplastic-tumor model. This GRN is driven by the stress-responsive JNK/AP-1 pathway and the transcription factor Ets21C, which together form a feedforward loop that induces and sustains the expression of several key downstream

effector genes, including genes that encode for several secreted ligands such as the unpaired cytokines. We show that Ets21C is required for effective regeneration and that in the absence of Ets21C regenerative growth is prematurely terminated. The mammalian orthologs of Et21C, Ets-related gene (ERG) and friend leukemia integration 1 transcription factor (FLI1), are recognized proto-oncogenes that are associated with Ewing Sarcoma. Therefore, we were interested in characterizing the Ets21C-dependnet GRNs activated both during tumorigenesis and regeneration. To address this question, we compared single-cell data from an imaginal disc neoplastic tumor model to regenerating tissue. The tumor model is based on the loss of the apicobasal polarity regulator and forms disorganized and multilayered tumors. In these tumors, we identified subpopulations of cells that were blastema-like and demonstrated that Ets21C-/- mutants had reduced tumor growth, suggesting that these tumors hijack pro-regenerative pathways to promote their own cell proliferation and growth. We are currently investigating how overexpression of Ets21C impacts tissue growth and the function of several genes that are upregulated in subpopulations of cells in both regeneration and tumorigenesis. Our future work aims to elucidate the cellular and molecular mechanisms that regulate shared growth properties during regeneration and tumorigenesis.

1204S **Investigating the role of ecdysone signaling in dorsal closure using Halloween genes.** Jae Ho Lee[1], robert q ward[2] [1]Case Western Reserve University, [2]Biology, case western reserve university

20-hydroxyecdysone (20E) is a well-characterized steroid hormone required for major development changes in Drosophila. 20E surges before each larval molt, before pupariation, and during terminal differentiation of the adult structures. During molting and metamorphosis, 20E binds to its receptor to directly activate a group of early genes such as Broad-Complex (BR-C), E74, and E75, which activate late genes that are performing stage- and tissue-specific functions. There is also a less well-characterized pulse of 20E during mid-embryogenesis. Previous studies indicate a role for 20E signaling in germband retraction, head involution, dorsal closure, and cuticle secretion during embryogenesis. Here, we are focusing on the role of 20E signaling during dorsal closure in mid-embryogenesis. To gain a mechanistic understanding of the function of the 20E during dorsal closure we are characterizing phenotypes associated with loss of *disembodied* (*dib*) and *shroud* (*sro*), two “Halloween” genes that encode biosynthetic enzymes required for 20E synthesis. Our immunostaining images on *dib* and *sro* mutant embryos during dorsal closure show that JNK and Dpp signaling, which are initial signaling pathways of dorsal closure, appear normal. Likewise, the formation of the actomyosin cable on the leading edge is normal in mutant embryos. However, our time-lapse imaging of Ecad and Sqh marked *dib* and *sro* mutant embryos show poor formation of the canthus and zippering of the contralateral epidermal sheets. Also, we observe that mutant embryos show significantly slowed germ band retraction, abnormal shape and behavior of aminoserosa cells during dorsal closure, and reduced filopodia activity at the leading edge. Based on our observation, ecdysone seems to work in both the amnioserosa and epidermis for some aspects of actomyosin dynamics. To confirm this, we are also conducting tissue-specific expression of a dominant negative Ecdysone receptor (EcR-DN) to compare with the Halloween mutants. Preliminary data shows that ubiquitous expression (daughterless GAL4) of EcR-DN shows a strong dorsal closure phenotype. Surprisingly, expression in the amnioserosa via 332.3 GAL4 does not show dorsal closure defects by cuticle preparations. We plan to conduct Ecad and sqh live imaging in the ECR-DN lines to compare to our current results.

1205S **Lipid accumulation promotes loss of homeostasis in the male germline stem cell niche through differentiation** Rafael S Demarco Biology, University of Louisville

The capacity of stem cells to self-renew or differentiate has been attributed to distinct metabolic states. In the Drosophila testis, both germline stem cells (GSCs) and somatic cyst stem cells (CySCs) employ strategies to control lipid levels to promote stem cell maintenance. When lipid catabolism is impaired, neutral lipids accumulate in lipid droplets (LDs) and GSCs and CySCs exit the niche to differentiate, suggesting a role for lipid metabolism in the control of maintenance versus differentiation. We are currently investigating the role of LDs in stem cell maintenance, as well as the impact of lipid accumulation in the overall stem cell niche. Recent data suggests that lipid accumulation is detrimental for the maintenance of hub cells, a main component of the stem cell niche in the testis, by promoting hub-to-CySC conversion. Our findings highlight a critical role for lipid homeostasis in stem cell maintenance, providing a framework for investigating the impact of metabolic diseases on stem cell function and tissue homeostasis.

1206S **Molecular genetic dissection of a transcription factor Defective proventriculus in growth versus cell fate decisions** Anuradha V Chimata[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration & Engineering (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

Defective proventriculus, a homeodomain containing transcription factor acts as a dorsal fate selector during *Drosophila* eye development. It is highly conserved across species and its human ortholog SATB1 is highly upregulated in cancer. Earlier,

we have shown that *dve* is crucial to establish dorsal fate which is required to promote growth and cell fate decisions. Furthermore, the *dve* expressing cells (~150-200) are responsible for expression of a morphogen *wingless (wg)/Wnt* in the developing eye. These *dve* expressing cells provide an inductive signal to determine eye vs head fate specification. Since *dve* is involved in growth regulation and cell fate decisions, we wanted to dissect these two independent functions during eye development. We employed structure-function analysis because *dve* has two isoforms and the Dve protein has multiple functional domains such as ULD domain, two Hox domains and a PPP4R2 domain. We hypothesized that different domains of Dve might be involved in regulating different functions. We present our results from studies on the role of these domain(s) on eye development and regulation of Wg expression in the developing eye. Here, we present results from individual functional domain(s) of Dve, combination of domain(s) and chimeras with SATB1. SATB1, human ortholog of *dve*, has similar domains and such studies can shed light on how SATB1 might function in diseases.

1207S **Dorsal fate selector gene *defective proventriculus (dve)* interacts with JNK pathway to determine dorsal eye fate** Sunanda Yogi[1], Anuradha V Chimata[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration & Engineering (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

Organogenesis occurs in a highly coordinated manner by regulating several cellular processes. The c-Jun N-terminal kinase (JNK) signaling pathway is an evolutionary conserved pathway that provides crucial signals for cellular process like proliferation, growth, survival and cell death during development and disease. JNK pathway is also a master cell death regulatory pathway that is at the node of several cell death mechanisms. We have previously identified *defective proventriculus (dve)* (SATB1, mammalian ortholog of *dve*), a K50 homeodomain transcription factor as a novel dorsal fate selector gene. We have demonstrated that the *dve* expressing cells (~150-200) are a crucial signaling center that is required for the transcription of a negative regulator of eye development, *wingless (wg)* morphogen. Loss of these cells resulted in change of developmental fates and impacted organogenesis significantly. Therefore, we hypothesized that *dve* might interact with JNK signaling pathway members to regulate cell survival and growth during development. We have used classical Gal4-UAS system to perform gain-of-function and loss-of-function studies to misexpress JNK pathway members in the *dve* expression domain. Here, we present our results to demonstrate the interaction between the conserved JNK pathway and a dorsal patterning gene. This study might help to shed light on how a patterning gene might interact with other pathways to provide survival cues to regulate growth and development.

1208S **Glucose 6 phosphatase is required for male fertility and sperm-induced activation of embryonic development** Sheida Hedjazi[1], Tetsuya Miyamoto[2], Hubert Amrein[2] [1]Nutrition, Texas A&M Uinversity, [2]Cell Biology and Genetics, Texas A&M Uinversity

Maternal genes expressed during oogenesis play critical and well-defined roles in fertilization and early embryonic development. In contrast, much less is known about paternally expressed genes during spermatogenesis in fertilization and early embryogenesis. Here, we describe a novel role for Glucose-6-phosphatase (G6P) in male fertility and/or the initiation of early embryonic development. G6P is mainly known for its role in hydrolyzing glucose-6-phosphate to glucose during gluconeogenesis and glycogenolysis in the mammalian liver and kidney. Since trehalose, but not glucose, is the main circulating sugar in insects, and conversion of glucose-6-phosphate to trehalose requires the enzyme Trehalose phosphate synthase and not G6P, the latter has become dispensable in this process. Surprisingly, some insect genomes, including that of, have maintained a functional *G6P* gene. We previously showed that *Drosophila G6P* has a non-canonical role in a small subset of peptidergic neurons in the fly CNS, where it is required for neuropeptide signaling. We now report a second critical and non-canonical function for *G6P* in spermatogenesis. *G6P* mutant males produce phenotypically normal sperm and mate with the same frequency as wild-type males but produce virtually no progeny. Using the sperm marker *don juan-GFP,* we find that while *G6P* mutant sperm is deposited in female's spermathecae, and can penetrate eggs, its localization within the egg is disturbed compared to wild type sperm. Moreover, we find that *G6P* mutant sperm have an upregulated stress response, assessed by increased splicing of the unfolded protein response marker *Xbp1*. Taken together, we propose that G6P plays a pivotal role in fertilization and possibly the subsequent commencement of embryogenesis.

1209S **Novel role of miRNA-137 in Drosophila eye development** Radhika Padma[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration & Engineering (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

During organogenesis various players including genes non-coding RNAs like microRNA (miRNA) are involved in differentiation and development. miRNA are involved in post-transcriptional regulation of gene expression in a tissue-specific manner and

thereby fine tune the expression of their target gene(s). Therefore, miRNAs play a crucial role in regulation of the cell fate and differentiation during development. In a forward genetic screen, we identified a miRNA which exhibits reduced eye phenotype upon overexpression in the developing eye. Here, we present our characterization of the role of this new miRNA-137 (miR-137) in growth and development of an eye-antennal imaginal disc of Drosophila. Our results illustrate the novel role of miR-137 in eye development and growth. The results from our studies on molecular characterization of the role of this miR-137 during eye development will be presented.

1210S **Me31B function is required during adult muscle myogenesis in *Drosophila*** Harry Manning[1,2], Maria L Spletter[1] [1]Biological and Biomedical Systems, University of Missouri Kansas City, [2]University of Bath

RNA-binding proteins play important roles during myogenesis, both in directing alternative splicing to produce multiple isoforms of fiber-type specific proteins as well as in regulating the nuclear export, trafficking, stability, and translation dynamics within the muscle cell. This determines the balance in isoform expression of sarcomere proteins, enabling muscles to fine-tune their morphologies and contractile properties. Misregulation of RNA-binding protein function is observed in muscle aging and disease. Indirect flight muscles (IFMs) in *Drosophila melanogaster* are a powerful model to study RNA-binding protein function in muscle development. We identified a novel muscle-specific role for the DEAD-box RNA-helicase Me31B in adult myogenesis in an RNAi screen. Me31B has been previously reported to localized to P-bodies and mediate repression of maternal transcripts through translation repression and regulation of mRNA stability in the fly embryo. We show that me31B is expressed at a high level in muscle cells and localized at the nuclear membrane in distinct punctate structures in the indirect flight muscles (IFMs), consistent with a role in IFM development. Knockdown of *me31B* using Mef2-Gal4, which drives in all muscles, as well as with drivers Act88F-Gal4 and UH3-Gal4 that drive in early stages of IFM development result in pupal lethality. Late-stage IFM-specific knockdown driven by Fln-Gal4 did not produce a strong behavioral or cellular phenotype, suggesting Me31B function is important during early stages of IFM development. Structure-function analysis using CRISPR alleles targeting distinct Me31B domains further reveals Me31B function in muscle. Our data suggest a critical role for DDX6 homolog me31B in pupal muscle development, emphasizing the importance of RNA regulation during myogenesis.

1211S **Dose-dependent Effects of Lead Exposure on Development and Behavior in Drosophila melanogaster** Gabriella Zegarelli, Anna Arzeno, Sarah John, Dylan Koproski, Vanessa Yap, Rhea Datta Hamilton College

Lead (Pb) is a toxic metal that has adverse effects on neurological and reproductive development in various animal systems. In humans, the burden of lead exposure is not evenly distributed across the population, with low-income individuals and minority groups facing a disproportionately higher risk of exposure. In our research, we use Drosophila as a model to investigate the impact of dose-dependent exposure to Pb on various locomotive and reproductive behaviors, including sleep, hyperactivity, light sensitivity, fecundity, and egg-laying. We first assessed the effects of Pb exposure on larval and adult viability. Our findings reveal that both F0 and F1 control groups consistently produced more pupae and adult flies compared to all treatment groups. We then conducted assays on locomotion and activity. We found that Pb-exposure increased hyperactivity in flies during the masking-transition period from night to day and resulted in disruptions to circadian rhythms. Finally, we assessed the effects of Pb on fecundity and ovarian morphology. Notably, ovarioles in Pb-exposed experimental flies exhibited qualitative differences, with higher Pb concentrations causing increased fragility, compared to control and lower-dose experimental groups. However, fecundity increased at exposure to low concentrations of Pb and decreased at higher levels of exposure. Our data suggest that Pb exerts a dose-dependent influence on the development and behavior of Drosophila melanogaster. It remains unclear however, how Pb affects the genome. We are currently examining the potential mechanisms underlying Pb's impact on the behaviors we outlined above by looking directly at the effects of Pb on loci that regulate locomotion and oogenesis.

1212S **Different Bru1 isoforms play functionally distinct roles during IFM myogenesis in Drosophila** Maria L Spletter[1,2], Jenna DeCata[3], Aaron Morgan[3], Elena Nikonova[4], Tobias Straub[4] [1]Biological and Biomedical Systems, University of Missouri Kansas City, [2]Physiological Chemistry, Ludwig-Maximilians-University Munich, [3]University of Missouri Kansas City, [4]Ludwig-Maximilian-University Munich

CELF (Bruno) family members are important regulators of RNA processing in muscle. Muscles fine-tune their morphological characteristics and contractile abilities through regulation of gene expression and alternative splicing. The balance in splice-isoform expression of sarcomere genes varies between muscle-fiber types and is disrupted in muscle diseases such as myotonic dystrophy (DM1). Misregulation of CELF activity is thought to pathogenically underly contractile defects and muscle atrophy in DM1, highlighting the importance of RNA regulation for muscle homeostasis. CELF proteins are themselves alternatively spliced, but isoform-specific functions are currently unknown. We previously demonstrated that Bruno1 (Bru1), a CELF homolog in *D. melanogaster*, is required for indirect flight muscle (IFM) development. Bru1 is required early in muscle development for cytoskeletal rearrangements to support myogenesis and controls a later switch in fiber-type specific alternative splicing that enables sarcomere growth and maturation. Here we report that different Bru1 isoforms play

distinct roles during IFM myogenesis. We show using RT-PCR that the majority of Bru1 splice isoforms are expressed in IFM. Unexpectedly and in contrast to null alleles, an isoform-specific mutant affecting long *bru1* isoforms progressed normally through early stages of myogenesis but then underwent hypercontraction in adult IFM. This phenotype can be rescued by expression of longer Bru1 isoforms with Fln-Gal4 during later maturation stages, indicating that a novel short Bru1 isoform with only two RRM domains is sufficient during early myogenesis, but longer three RRM containing Bru1 isoforms are necessary during later myogenesis. We further demonstrate differences in overexpression phenotypes as well as subcellular localization of Bru1 isoforms Bru1-RA, Bru1-RB and Bru1-RD. Our data are consistent with isoform-specific functions for Bru1 and challenge models suggesting that all three RRM domains in CELF proteins are necessary for target binding. We propose that alternative splicing of CELF proteins is a conserved mechanism to fine-tune regulatory activity and developmental splice-isoform transitions.

1213S **The transcription factor Xrp1 regulates organ size in Minute (Ribosomal Protein heterozygous mutant) flies** Amit Kumar[1], Nicholas E Baker[2] [1]Genetics, Alber Einstein College of Medicine, [2]Genetics, Albert Einstein College of Medicine

A complex interplay of genetic, cellular, and environmental factors regulates organ size during the development of an organism. The genetic pathway that controls organ size during the development of an organism is well studied, but how organ size is regulated upon altered growth is not yet well studied. We are working on mutants of the ribosome protein-encoding genes in *Drosophila*, commonly known as *Minute* mutants. The $Rp^{+/-}$ (heterozygous mutant) animals are slow-growing but attain the size of wild-type flies after a developmental delay. We have previously identified a transcriptional pathway, regulated by the bZip AT hook protein Xrp1 controlling multiple aspects of the $Rp^{+/-}$ phenotype, particularly cell competition, the cellular fitness sensing mechanism that eliminates sporadic $Rp^{+/-}$ cells in mosaics. Xrp1 also controls growth rate, translation, and gene expression changes in $Rp^{+/-}$ cells. Here we examined the development of $Rp^{+/-}$ mutant wings. Our results show that $Rp^{+/-}$ mutant wings need Xrp1 to attain the normal size. We are currently investigating if Xrp1 regulates wing size in $Rp^{+/-}$ mutants through Yki, or through any of its transcriptional target genes, and will present a model of Xrp1 function in organ size regulation.

1214S **Shared and divergent roles for Bithorax-Complex miRNAs in regulating reproductive behavior across *Drosophila* species** Binglong Zhang, Daniel L Garaulet, Eric Lai Developmental Biology Program, MSKCC

We have long-standing interest in the biogenesis and function of ~22nt miRNAs encoded by the *Drosophila* Bithorax Complex (BX-C), which is most well-known for encoding homeodomain transcription factors that specify anterior-posterior segmental identity (Hox factors). Curiously, bidirectional transcription of the same hairpin locus generates miR-iab-4 and miR-iab-8, which both obey core regulatory principles for Hox genes, namely colinearity and posterior prevalence. In particular, both miRNAs directly repress more anteriorly-expressed/5›-located BX-C Hox genes *Ultrabithorax* (*Ubx*) and *abdominal-A* (*abd-A*), as well as the Hox cofactor *Homothorax* (*Hth*). The miRNA knockout (*Δmir*) exhibits profoundly defective reproductive behaviors, and is completely sterile in both sexes. Recently, we used precision genetic engineering to demonstrate that specific miRNA binding sites in the Hth 3'UTR are required for female sexual receptivity. Now, we engineered additional miRNA resistant alleles of *Ubx* and *abd-A* to examine their contributions to reproductive behaviors. To address if BX-C miRNAs are required in other species, we generated the first *Drosophila* miRNA knockout outside of *D. melanogaster*, namely in *D. simulans*. These mutants phenocopy overall anatomical and behavioral defects, but also exhibit certain differences. We wish to know if these may potentially relate to divergent circuitry underlying reproductive behaviors between these closely related species (Ruta lab). Finally, we wish to elucidate the circuit and target basis of incomplete male copulatory behaviors in (*Δmir*), which accounts for male sterility. Altogether, there are shared and divergent roles for BX-C miRNAs that are manifest in the CNS, and are fully required for fertility in both sexes in multiple species. The paradigm of BX-C miRNA function is of general interest to regulatory biology, given the vast majority of miRNA knockouts have only subtle phenotypes.

1215S **Investigating the development of key somatic cells in the *Drosophila* ovary** Joanna Portillo[1], Mark Van Doren[2] [1]Biology, Johns Hopkins University, [2]Johns Hopkins University

Throughout the animal kingdom, male and female gonads develop differently in a process that is regulated by the Doublesex and mab-3 related (DMRT) family of transcription factors. Our lab studies how *Drosophila* Doublesex (Dsx) controls development of the somatic gonad of the ovary and testis. A great deal is known about testis development, while much less is known about development of the ovary. Therefore, to understand how Dsx controls sexual dimorphism in the somatic gonad, we first need to understand how the somatic stem cells and support cells of the ovary form and attain their distinct identities. Our current theory is that the somatic support cells, Escort Cells (ECs), and the somatic stem cells, Follicle Stem Cells (FSCs), develop from a set of somatic cells known as "intermingled cells" (ICs) in the larval ovary. Single-cell RNA sequencing from the Lehmann lab demonstrated that the ICs in the larval gonad have distinct anterior vs. posterior identities. Recently, our lab has characterized the development of the FSCs using the FSC marker, Castor. We found that a pool of FSC precursors form from posterior ICs during early pupal stages and the JAK/STAT pathway is required for cells to take on FSC precursor identity at this time. Based on these observations, this work aims to investigate the role of signaling pathways on ECs and FSCs differentiation

from ICs. We have begun examining how the JAK/STAT and Hedgehog (HH) pathways influence EC and FSC development. Through the UAS/GAL4 system, we have manipulated different factors that influence the level of autonomous signal the cells receive from these pathways. We then visualized the change in cell identity and characteristics with confocal imagining through immunofluorescence and in-situ hybridization. We started by inducing a gain of function phenotype of in both the JAK/STAT and HH pathways. Overexpression of both results in over proliferation of ICs in larval gonads. Manipulating HH signals to ICs changes the expression levels of posterior IC marker, *bond*, suggesting that HH affects the identity of ICs. While the loss of JAK/STAT results in ovaries with no FSCs, loss of HH produces ovaries with small amounts of total cells. The gain of function in both pathways results in Castor expressed anteriorly in the germarium and EC marker, PZ1444-lacZ, expressed more posteriorly. The confusion in somatic cell identity suggests that both pathways are involved in the development of these cells.

1216S **Elucidating the non-autonomous role of macrophages in tumor growth regulation in *Drosophila*** Eri Hirooka, keisuke Iksawa, Shizue Ohsawa Biological Science, Graduate school of Science, Nagoya University

Tumor progression is not only driven by sequential acquisition of genetic mutations, but also regulated by interactions between oncogenic cells and surrounding normal cells in the tumor microenvironment. Growing evidence indicate that macrophages exert dual functions on tumorigenesis by both enhancing anti-tumor responses and antagonizing the anti-tumor immune cells. However, the underlying mechanisms remain elusive.

Using a Drosophila model system, We genetically analyzed the mechanisms of tumor progression through cell-cell communications. We found that malignant tumors, induced by Ras activation with cell polarity defects (Ras^{V12}/$scrib^{-/-}$) markedly recruit *Drosophila* macrophages, termed hemocytes, in the imaginal epithelia. Genetic ablation of hemocytes significantly reduced the size of Ras^{V12}/$scrib^{-/-}$ tumors, suggesting that hemocytes promote overgrowth of Ras^{V12}/$scrib^{-/-}$ cells. To explore the role of hemocytes in promoting Ras^{V12}/$scrib^{-/-}$ tumor growth, we genetically inhibited various signal pathways by expressing *RNAi* in hemocytes. The mechanism by which hemocytes non-autonomously regulate tumor growth will be presented.

1217S **Direct and indirect regulation of EGFR target genes by opposing gradients of BMP and JAK/STAT signaling patterns the follicular epithelium of the Drosophila ovary.** Laura Nilson[1], Kelvin Ip[2], Scott De Vito[3], Baptiste Rafanel[4], Kaitlin Mac Donald[2] [1]McGill Univ, [2]Department of Biology, McGill University, [3]Department of Pharmacology, McGill University, [4]Institute of Molecular Biotechnology, Austrian Academy of Sciences

A relatively small number of signaling pathways drive a wide range of developmental decisions involving distinct target genes. This versatility points to a role for cellular context in generating diversity in signaling outcomes, but how targets are chosen is not well understood.

Context-dependent signaling outcomes occur during patterning of the Drosophila follicular epithelium, where activation of epidermal growth factor receptor (EGFR) signaling by its localized ligand Gurken (Grk) induces distinct cell fates depending on its location. Posterior follicle cells respond to Grk by expressing the T-box transcription factors Midline (Mid) and H15, while anterior cells respond by expressing the homeodomain transcription factor Mirror (Mirr). The choice between these alternative EGFR targets depends on input from additional localized ligands. At the posterior, activation of JAK/STAT signaling by the ligand Upd is required for Mid/H15 expression, while at the anterior activation of BMP signaling by the ligand Dpp is required for Mirr expression. This choice is reinforced by mutual repression between Midline/H15 and Mirror, and through the ability of both Dpp and Upd to repress their “opposing” target (i.e. *mid/H15* and *mirr*, respectively).

The integration of these multiple localized positional cues suggests that crosstalk between these signaling pathways generates mutually exclusive EGFR signaling outcomes, but at what level this occurs remains unclear. To approach this question, we identified genomic regions from the *mid* and *mirr* loci that, in a transgenic reporter, recapitulate the expression patterns and regulation of endogenous *mid* and *mirr* genes. We have shown that these regions contain STAT92E and MAD binding sites that are required for Upd- and Dpp-mediated repression of *mirr* and *mid* reporters, respectively. Further mapping of these genomic sequences suggests that these repressive elements silence the ability of nearby sequences to positively regulate reporter expression. Interestingly, activation of *mid* reporter expression does not require putative STAT92E binding sites, suggesting that the positive regulation of *mid* expression by Upd is indirect. Indeed, we find that Upd positively regulates *mid* by increasing levels of the EGFR effector Pointed (Pnt), suggesting crosstalk in which Upd ensures levels of Pnt adequate to allow EGFR to induce mid expression. Dpp and Upd therefore influence EGFR target gene expression through both direct and indirect mechanisms.

1218S **A conserved Immunoglobulin cell adhesion junction module maintains epithelial integrity** Tara M Finegan[1], Dan T Bergstralh[2] [1]Biology, University of Missouri, [2]Division of Biological Sciences, University of Missouri

Epithelial tissues are sheets of cells that line animal body compartments to protect organs mechanically and chemically. Epithelial cells often move apically during mitosis with respect to the tissue layer and daughter cells can be born misplaced from the plane of the tissue. We found that misplaced cells can reincorporate back into the parental tissue layer through a process we call cell reintegration. Reintegration appears to be a general property of epithelia to protect their integrity and is likely to be a protective mechanism against carcinoma. In fruit flies, reintegration relies on a suite of evolutionary-conserved Immunoglobulin cell adhesion (IgCAM) proteins called Neuroglian (Nrg), Fasciclin II (Fas2), and Fasciclin III (Fas3). These proteins are well-studied for their roles in axon fasciculation, and we have previously demonstrated mechanistic overlap between this process and reintegration. Nrg, Fas2 and Fas3 are also identified at neuromuscular junctions (NMJs), synapses that appear subsequent to fasciculation, and in epithelia at septate (occluding) junctions, which do not develop in the follicular epithelium until after proliferation has ceased. These observations suggest both a mechanistic and an evolutionary relationship between neural and epithelial tissue development. We are currently exploring this possibility using structure-function analysis, genetic rescue experiments, quantitative analysis and advanced imaging techniques.

1219S **Investigating how niche shape coordinates stem cell behavior** Gabriela Vida, Elizabeth Botto, Stephen DiNardo University of Pennsylvania

Stem cells are important for repairing and regenerating our tissues, and often reside in a niche that controls their behavior. The testis niche has been a paradigm for niche-stem cell interactions. Recently, our lab has focused on the construction of this niche. Examining initial assembly of the niche in embryonic gonads has revealed both how extra-gonadal signals drive niche assembly (Anllo and DiNardo, 2022), and begun illuminating the cell mechanics involved in first forming a compact, functional niche (Warder et al. 2023). Here we use the adult testis niche to address the cell biological features that maintain niche structure and function during its steady-state operation. The niche resides at the testis tip and is comprised of a group of quiescent cells that send renewal signals to the neighboring stem cells. These quiescent cells are organized spherically, and are radially surrounded by two stem cell populations, the germline stem cells (GSCs) and the cyst stem cells. Additionally, this niche helps orient GSC divisions by centrosome anchoring at the niche to produce a renewing GSC and a differentiating daughter cell to achieve stem cell balance. Proper centrosome orientation is ensured by the centrosome orientation checkpoint (COC), which stalls GSCs in G2 until the centrosomes are properly oriented for mitosis. Our preliminary evidence suggests that acto-myosin contractility (AMC) is important for the maintenance of the spherical nature of the stem cell niche. This abolishment of this spherical structure reduces the effectivity of niche signaling per GSC, and instead allows for more germ cells to respond to signaling. This is accomplished by differentiating daughter cells making contact with the niche, potentially disrupting the differentiation program. Finally, this loss of niche structure causes the GSCs to misorient their centrosomes, bypass the COC, and execute misoriented divisions. Ultimately, this work shows a novel way in which niche structure ensures a proper balance of stem cells and is crucial for their behavior.

1220S **FMRP is a target of TDP-43 and mitigates morphological and functional phenotypes in striated muscle** Brijesh S Chauhan[1], Samantha Macklin[2], Daniela Zarnescu[3] [1]Cellular and Molecular Physiology, Penn State College of Medicine, [2]Cellular and Molecular Physiology, Penn State college of Medicine, [3]COM, Penn State COM

Amyotrophic Lateral Sclerosis (ALS) and Fronto-Temporal Dementia (FTD) comprise a spectrum of neurodegenerative disorders for which there is no cure. A major hallmark of pathology in ALS/FTD is the presence of cytoplasmic TDP-43 inclusions, which are linked to 97% of ALS and 45% of FTD cases. TDP-43 is a DNA/RNA binding protein with multiple roles in RNA processing including mRNA localization and translation. In axons, TDP-43 was shown to regulate the transport and translation of specific mRNAs while puromycin incorporation experiments show that cytoplasmic TDP-43 inhibits translation globally. Using ribosomal tagging approaches, we have recently shown that TDP-43 affects the association of mRNAs with ribosomes causing alterations in translation itself, cellular energetics, and synaptic function among other pathways. These findings underscore TDP-43's involvement in translation, however, its targets, and their impact on the homeostasis of neuromuscular synapses remain a poorly understood aspect of TDP-43 biology and its relationship to neurodegeneration in ALS/FTD. Here we explored the muscle side of the neuromuscular junction (NMJ) where local translation is known to occur. We examined TDP-43's impact on new protein synthesis using Non-Canonical Amino-acid tagging (NCAT) *in vivo,* in the context of Drosophila models of TDP-43 proteinopathy. These experiments show that overexpression (OE) of wild-type TDP-43 in muscles reduces new protein synthesis globally, with mutant TDP-43 showing a more pronounced reduction in translation. Using biotinylation and mass spectrometry in conjunction with NCAT (BONCAT) we identified several candidate targets of TDP-43 in muscles including the Fragile X mental retardation protein (dFMRP). Immunofluorescence experiments show that FMRP levels are significantly reduced in muscles overexpressing TDP-43 in flies. Interestingly, deletion of endogenous TDP-43 (TBPH) causes reduced FMRP expression consistent with TDP-43 OE mimicking a loss of function phenotype in muscles. Notably, FXR1 the muscle specific ortholog of dFMRP in humans exhibits a significant reduction in ALS patient muscles compared to control, consistent with our findings on dFMRP in flies. Lastly, overexpression of FMRP in muscles mitigates TDP-43 associated phenotypes including

locomotor deficits, reduced survival and sarcomere abnormalities, and suggest that restoring FMRP expression in muscles provides a potential therapeutic strategy for TDP-43 proteinopathies.

1221S **The Drosophila DPP/BMP-4 gradient formation in the embryo is dependent on cell constriction mediated by Frazzled and E-Cadherin** Aravindan Krishnan, Runze Ni, Hainvi Gullapalli, Rui Sousa-Neves, Claudia Mizutani Case Western Reserve University

A long-standing problem in developmental biology is how cells acquire positional information from morphogen gradients while being displaced in space. We showed that the DPP/BMP gradient attracts cells and precisely control their movements in the blastoderm through an interaction between the epithelial polarity genes *frazzled* (*fra*) and *guk-holder* (*gukh*), and the cell junction protein E-cadherin (ECAD). These stereotyped movements fine-tune the shape of the BMP gradient and establish precise cell fates (Xue et al., 2023, PLoS Biol). These results show that cell movements enable precision, rather than hinder cell fate specification. These findings open exciting new perspectives. For example, we showed that the formation of a peak level of BMP signaling in the dorsal midline, visualized by the intense dorsal stripe of pMAD, involves the contraction of dorsal cells, but the molecular mechanisms involving FRA, GUKH and E-CAD in this process remain unclear. Another question is how FRA maintains high levels of ECAD in the dorsal region of the embryo in an environment with high BMP signaling, which like in cancer, normally disrupts cell junctions and cause cell invasion. To answer the first question, we are testing whether ECAD form complexes with BMP receptors that become spatially denser as cells contract, leading to higher BMP activation. Using super-resolution microscopy, we found that ECAD and the BMP receptor TKV indeed co-localize in the dorsal region of the embryo. Cells within the pMAD stripe have less numbers of ECAD-TKV complexes compared to adjacent cells. This is a similar pattern to the developing wing disk, where TKV levels are lower within peak regions of the gradient, and higher in regions of low BMP. We are testing two possibilities to explain how a lower number of ECAD-TKV complexes can transduce higher levels of BMP signaling within the pMAD stripe region. First, we are determining whether ECAD-TKV complexes form high density clusters at the dorsal midline where the cells are more constricted and more disperse clusters in lateral regions. We are also testing whether ECAD-TKV complexes are more internalized due to TKV activation within the pMAD stripe and therefore located within the cell rather than the membrane. Finally, to answer how FRA maintains high ECAD levels, we hypothesize that FRA/ECAD are targets of Presinilin and FRA protects ECAD from excessive cleavage by competition. We show that Presinilin loss-of-function embryos have the expected increase in BMP activity compared to controls. We are testing if this effect agrees with less cleavage of FRA and/or ECAD, and with higher cell constriction. In sum, our results bring a previously unexplored regulatory component in the DPP signaling cascade and gradient regulation.

1222S **Characterization of Juvenile hormone esterase and Juvenile hormone epoxide hydrolase mutants** Rebecca Spokony[1], Harry Siegel[2], Said C Yashaev[3], Creehan Healy[2], Lacy Barton[2] [1]Natural Sciences, Baruch College, [2]University of Texas at San Antonio, [3]Baruch College, CUNY

Juvenile hormone (JH) is one of the most important regulators in insect development. It is synthesized through a series of enzymatic reactions and degraded by three classes of enzymes. Two of these are JH esterase (Jhe) and JH epoxide hydrolase (Jheh). Jhe and Jhe duplicate (JheDup) are next to each other on the right arm of the 2nd chromosome. Jheh is triplicated in tandem on the same chromosome. We developed new CRISPR mutants that are null for all copies of each class of gene, *Jhe, JheDup* and *jheh1,2,3*. *Jhe, JheDup* grow larger, while *jheh1,2,3* are smaller and pupariate 3 days after wildtype larvae. Here we examine if these phenotypes can be genetically rescued; if these phenotypes are epistatic to JH synthesis and if knock-down of a single enzyme is sufficient to cause these phenotypes. We used P[acman] BAC clones with approximately 80 kb of genomic DNA covering the deleted regions, inserted back into a complementary chromosome (3rd). Both size and timing phenotypes were rescued. JH acid methyltransferase (Jhamt) is the rate limiting enzyme converting inactive JH precursors into bioactive molecules. To test if a lower concentration of JH could reduce or eliminate the degredation enzyme phenotypes, we generated *Jhe, JheDup; Jhamt* and *jheh1,2,3; Jhamt* stocks. Elimination of Jhamt eliminated overgrowth of Jhe, JheDup. Preliminary results suggest an effect on *jheh1,2,3* timing defects. Lastly, we are currently testing a variety of RNAi lines ubiquitously driven by da-Gal4. Knock-down of Jhe alone lead to an increase in pupal size. Surprisingly, we preliminarily found that knocking down just one of any of the Jheh paralogs leads to an increase, rather than a decrease in size. We are currently checking efficiency of the knock-down with qPCR, and any compensatory changes in Jheh expression. We plan to examine which tissues are responsible for these phenotypes next.

1223S **Grainyhead regulates wound-induced polyploidization in Drosophila** Lydia M Bischoff, Erin C Bailey, Vicki P Losick Biology, Boston College

In Drosophila, adult epithelial wounds heal by cell growth instead of cell division. Cells grow orders of magnitude through polyploidization, which in fruit flies arises by both cell fusion and endoreplication at a puncture wound site. Previous studies have found that wound-induced polyploidization is required for epithelial wound healing as it permits wound closure in the

presence of genotoxic stress, restores tissue mass, and maintains tissue tension post-injury. What remains poorly understood are the genes that regulate polyploid growth in response to injury. The transcription factor, Grainyhead (Grh), is known to play a conserved role in regulating epithelial differentiation and wound healing by controlling the expression of cell cycle and extracellular matrix genes. Therefore, we investigated whether Grh contributes to the regulation of wound-induced polyploidization. Indeed, we have found that Grh regulates entry and the extent of endoreplication. Grh overexpression appears to be sufficient to induce endoreplication even without injury in epithelial cells. Previous research in our lab identified another transcription factor, Yorkie (Yki) which also regulates the extent of epithelial endoreplication. Thus, we are investigating whether Grh and Yki genetically interact to regulate endoreplication during wound healing.

1224S **Complementary Volume Electron Microscopy-based approaches reveal ultrastructural changes in germline intercellular bridges** Irina Kolotuev[1], Abigayle Elsbury[2], Stephanie Pellegrino[2], Lindsay Lewellyn[2] [1]University of Lausanne, [2]Butler University

Intercellular bridges are essential for the development of eggs and sperm in many organisms; however, despite their importance, there is still much to be learned about how their structure changes through development. The egg chamber is an excellent model system to study intercellular bridges. Within the egg chamber, the germ cells are connected to each other by relatively large intercellular bridges, or ring canals, which expand ~20-fold in diameter through oogenesis. Many proteins have been identified that localize to the germline ring canals and regulate their formation, growth, or stability, but a more extensive analysis of ultrastructural changes is lacking. Electron microscopy is a valuable tool that can be utilized to monitor structures through development or following genetic or other manipulations. Here, we provide an extensive ultrastructural study of the developing egg chamber using a combination of Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) and Array Tomography Scanning Electron Microscopy (AT-SEM). We have rendered multiple large data sets collected using FIB-SEM to generate 3D models of multiple early-stage germ cell clusters. This analysis revealed interesting structural differences in the germline ring canals through development as well as within a single cluster; however, we quickly approached the functional upper limit (spatially and computationally) of FIB-SEM. Therefore, to monitor ring canal structure at later stages of development, we turned to AT-SEM. This approach allowed us to easily screen through the array of sample sections to identify the position of the ring canals within a much larger sample volume. Because we collect serial sections, we are still able to generate 3D reconstructions using this approach. Therefore, the combination of FIB-SEM and AT-SEM allowed us to monitor ring canal structure in 3D throughout oogenesis. Although the focus of this work has been on the germline ring canals, because electron microscopy reveals the entire morphome of the sample, we envision that this dataset could be utilized by other researchers in the field to answer a variety of questions.

1225S **Yorkie Activation Restores Epithelial Integrity in Neoplastic Tumors in Drosophila Wing Discs** Vanessa Ghorayeb, Gayaanan Jeyanaathan, Meggie Cao, Parama Talukder, Ulrich Tepass University of Toronto

Our recent work has established a link between mitosis and tumor progression in epithelial tissues. Using the Drosophila wing disc epithelium as a model, we have found that enhancing cell division by overactivation of E2F1, a cell cycle regulator, not only causes an increase in tissue size, but also exerts morphogenetic stress on the epithelium resulting in permanent loss of epithelial integrity, leading to neoplasia. This is seen in different conditions as well such as in neoplastic tumor mutants like *scribbled (scrib)* or with *crumbs (crb)* overexpression. We have also shown that decreasing cell proliferation in classic neoplastic models such as *scrib* knockdown rescues neoplasia and restores the epithelium, further implicating enhanced cell proliferation as the driving force of not just tumor growth but also neoplastic tumor progression. In contrast, accelerated cell proliferation mediated by Yorkie (Yki) activation does not result in loss of epithelial integrity, causing hyperplasia rather than neoplasia. Yki is a downstream effector of the Hippo pathway and promotes tissue growth via transcription of pro-proliferative and anti-apoptotic genes such as CyclinE and Diap1, respectively. Dysregulation of the Hippo pathway and increased activity of Yki or its mammalian homologs YAP/TAZ have been implicated in numerous epithelial cancers. In the Drosophila wing disc, overexpression of Yki (Yki-WT), or its constitutively active form (Yki-3A) results in dramatic hyperplastic tissue overgrowth and significant epithelial folding.

To explain this discrepancy between neoplastic tumors and Yki-mediated hyperplastic tumors, both driven by excessive cell proliferation, we hypothesize that Yki has target genes that can stabilize and restore epithelial polarity, counteracting proliferation-induces morphogenetic stress. To test this hypothesis, we have expressed Yki-WT and Yki-3A in various neoplastic backgrounds and examined both epithelial integrity and levels of JNK signaling, another signature of neoplasia. Preliminary observations indicate that Yki activation can strongly suppress neoplastic development and rescue epithelial polarity in neoplastic tumor mutants. A significant reduction of JNK signaling is also observed. These findings suggest that Yki plays a dual role, enhancing proliferation and protecting epithelial integrity at the same time.

1226S **Characterization of muscle survival induced by nutrient modulation after traumatic injury in *Drosophila*** Yutian Li California Institute of Technology

Muscles can repair daily wear-and-tears and minor strains. However, in more serious injuries, for reasons not well understood, injured muscles degenerate. While large muscle loss has been modeled in mammalian models, invertebrate models have a track record in helping discoveries of basic mechanisms. Toward developing an invertebrate model for studying large muscle injury, in this work, we assessed in adult *Drosophila* how limb muscle responds to dramatic injury, i.e., amputation, and identify a condition that can modify that response. As expected, muscle in the amputated limb rapidly degenerates within a week after injury. Muscle degeneration, we further find, can be significantly inhibited by administering the growth hormone insulin and the amino acids leucine and glutamine to the fly amputees. Consistent with the muscle survival, reporter of Notch signaling, known to be essential in muscle regeneration, is indeed activated in treated limbs. Finally, transcriptomic analysis suggests that the day-scale muscle survival is underlined by modulation in gene regulation occurring within hours, including modulation in genes involved in ecdysone signaling, immune response, and reproductive behavior. This work provides a starting point for investigating in a genetically tractable system the mechanisms that normally limit muscle survival upon severe injuries, and the molecular strategies that can overcome those limitations.

1227S **Mechanistic basis of germ-layer emergence by Polycomb Repressive Complex 1 in stem-cell derived embryonic organoids.** Shreyasi Mukherjee[1,2], Robert E. Kingston[1,2] [1]Department of Molecular Biology, Massachusetts General Hospital, [2]Department of Genetics, Harvard Medical School

Polycomb repressive complexes [PRC] are critical regulators of lineage fidelity across embryonic development, organogenesis, and tissue homeostasis; and their dysregulation is frequently associated with developmental disorders and cancer. PRC1 members have well-defined functions in maintaining pluripotency, and yet, how they spatiotemporally regulate the lineage commitment potential of stem cells remains unknown. During gastrulation, PRC1 members are highly expressed in the epiblast and primitive streak before exhibiting distinct expression patterns in the three germ-layer derivatives, indicating functional roles in regulating key decision points during lineage segregation. Here, we use embryonic stem-cell derived 3D organoid models of mouse gastrulation [gastruloids] to define the molecular consequences of PRC1 loss during germ layer specification. Our data indicates that loss of the PRC1 catalytic component RING1B inhibits axial elongation and significantly disrupts the progression of epithelial to mesenchymal transition upon gastrulation onset. In addition, RING1B-null gastruloids exhibit delayed WNT signaling responses and fail to spatially segregate the expression domains of mesendodermal markers. In contrast, loss of CBX and PHC family members lead to delayed gastrulation defects and ectodermal expansion. These results identify multiple complex and subunit-specific contributions of distinct PRC1 members in initiating gastrulation and specifying cellular identities in distinct germ-layers. Collectively, these data have the potential to shed light on how Polycomb complexes integrate spatiotemporal cues to direct critical lineage segregation decisions during early embryogenesis.

1228S **Non-ciliary roles for the cilia-motility associated gene *Cfap298*(*Kurly*) in zebrafish and mouse** Marvin Cortez, Rebecca Burdine, Danelle Devenport Princeton University

Cfap298 (*Kurly*) is important for regulating cilia/flagellar motility and is conserved across ciliates. Disrupting *Cfap298* function leads to ciliopathy-related disorders in both humans and zebrafish. Additionally, *Cfap298* has also been shown to be important for motile cilia polarity in some tissues in *Xenopus* and zebrafish through the Planar Cell Polarity (PCP) mechanism. To investigate the role of CFAP298 in mouse we generated two alleles. The $Cfap298^{delta3aa}$ affects cilia motility and left-right patterning as expected. Surprisingly, our $Cfap298^{null}$ mutant results in early embryonic lethality between E4.5-E5.5 perimplantation stages due to a failure to maintain epiblast cells. This suggests that *Cfap298* plays important roles in development prior to the emergence of motile cilia. *Cfap298* mutants are not embryonic lethal in zebrafish. However, we observe that maternal c*fap298* mutants have abnormal cell divisions beginning from 4-cell stages to ~256 cell stages, likely as a result of mis-oriented, asynchronous mitotic spindles, yet embryos recover by MZT. To further investigate the role of CFAP298 in tissues without motile cilia, we developed a *Cfap298* floxed allele for tissue-specific knockouts in mouse. Upon conditionally removing *Cfap298* function in the developing mouse epidermis using Tg(RT14-cre)1Efu, we observed skin formation to be severely impaired in P0 pups, leading to post-natal death by dehydration. From E15.5 -E17.5 stages, we observed embryos to have reduced stratification, reduced skin barrier function, and increased cell death, likely leading to impairment of skin morphogenesis. We are currently investigating whether effects on spindle orientation and function may underlie the non-motile cilia associated phenotypes we observe in our different systems. Overall, our work uncovers novel functions for *Cfap298* in vertebrate development that extend beyond cilia motility.

1229S **The KAT6A-NCOA2 (MOZ-TIF2) fusion protein drives aberrant gene expression in a mouse model of Acute Myeloid Leukemia (AML)** Daniel W Sullivan[1,2], Anne Smolko[1,2], Naomi Olsen[3,4], Florian Perner[3,4], Jonathan Baell[5], Scott Armstrong[3,4], Mtizi Kuroda[1,2] [1]Genetics, Brigham and Women's Hospital, [2]Harvard Medical School, [3]Dana Farber Cancer Institute, [4]Boston Children's Hospital, [5]Monash University

Many cancer types exhibit aberrant genome regulation due to improperly activated chromatin, which has made targeting

chromatin modifiers a potential strategy in cancer therapeutics. KAT6A (MOZ) is a histone acyltransferase that is required for normal embryogenesis and hematopoiesis and is recurrently fused to transcriptional co-activators Ep300, CREBBP (CBP), or NCOA2 (TIF2) to drive Acute Myeloid Leukemia (AML). Two major goals of our research are to understand how MOZ leukemic fusion proteins alter transcription to drive leukemia and how MOZ normally regulates gene expression during development. Using pharmacological inhibition and targeted protein degradation, we show that MOZ enzymatic activity and the MOZ-TIF2 fusion protein are necessary for indefinite proliferation in a murine primary leukemia cell line expressing a human MOZ-TIF2 transgene. Inhibition of MOZ activity results in decreased histone acylation, including the understudied Histone 3 Lysine 23 propionylation (H3K23pr) modification. By integrating chromatin binding profiles of MOZ-TIF2 and H3K23pr with RNAseq datasets, we show that MOZ-TIF2 directly targets a set of developmental genes that are potential drivers of AML. In parallel, we are investigating MOZ function in a normal developmental context. For these studies we are utilizing murine embryonic stem cells as a model system, aiming to (A) epitope tag endogenous MOZ to map its genome localization pattern, and (B) determine how MOZ inhibition and degradation affect genome-wide acylation levels and gene expression. Overall, our findings will complement our previous analyses in the MOZ-TIF2 leukemia model to provide a greater understanding of MOZ function in both normal and disease states.

1230S **Role of *Mirc5* (aka *Mir 290-295)* and *Mirc20* (aka *Mir-302/367)* Clusters in Testicular Germ Cell Tumor Development** Harlie Cope, Olga Medina-Martinez, Matthew Gonzalez, Denise Lanza, Ronald Parchem, Jason Heaney Molecular and Human Genetics, Baylor College of Medicine

Testicular germ cells tumors (TGCTs) originate during development as a result of germ cells failing to complete differentiation. Understanding how these tumors originate and develop is important as TGCTs are the most prevalent form of solid cancer in young men, and the incidence has increased in recent years. Sequencing studies show that several miRNA clusters are upregulated in both tumor samples and serum from patients with TGCTs, including the *MIR371* family, aka *MIR371-373* and *MIR302* family, aka *MIR302/367* clusters. These clusters are important regulators of pluripotency in early embryonic development, with the *Mirc5* aka *Mir290-295* (murine equivalent of human *MIR371-373*) expressed during naïve pluripotency and *Mirc20* aka *Mir302/367* expressed slightly later when the embryo is in a primed pluripotent state. We evaluated the expression of these miRNA clusters and their effects on TGCT development in the M19 mouse, which has a high rate of spontaneous testicular tumor development. In this model embryonal carcinoma (EC) cells, which are the precursors to tumors seen in adulthood, are identifiable at embryonic day 15.5 (E15.5). Using a *Mirc5* reporter mouse, we have shown that germ cells express *Mirc5* as early as E12.5, and that this expression is maintained through post-natal day 2 (PND2), as well as in EC foci seen at E15.5 and E16.5. Using a *Mirc20* knockout/reporter line, we visualized expression of the *Mirc20* cluster at different embryonic timepoints in germ cells and EC foci. Expression of the *Mirc20* cluster is not detectable in germ cells using this reporter line; however, it is expressed in EC cells as early as E15.5 through PND2. The timing of the *Mirc20* GFP reporter expression in EC foci corresponds with immunofluorescent staining for OTX2, a transcription factor expressed in primed pluripotent EC cells. We assessed EC foci/tumor incidence in *Mirc20* heterozygous mice at E16.5 and at 8-12 weeks of age. At E16.5, 88% of heterozygous embryos had EC foci compared to 100% of wildtype littermates (N=8 per genotype, P=0.3017, Chi-square). In the 8-12 week old adults, 42% of heterozygotes had tumors compared to 76% of wildtype littermates (Het N=26, WT N=21, P=0.020, Chi-square). This reduction in tumor incidence along with the correlation of miR-302/367 and primed pluripotency marker OTX2 suggests that *Mirc20* expression may be important in maintaining the proliferative state needed for the EC foci to fully differentiate into teratomas. We will continue to characterize the *MIrc5* cluster in later EC cells. As homozygous knockout of each cluster is embryonic lethal at stages prior to EC cell development, we have generated conditional knockout lines for each cluster to determine the impact of homozygous knockout specifically in the germ cells on tumor incidence. We plan to isolate wild-type *Mirc5* knockout and *Mir302a/b/c/d* knockout germ cells to extract RNA for differential expression analysis of mRNA targets.

1231S **CRISPR Induced Overexpression of Placental *Igf-1* Causes Sex Specific Changes in Placental and Fetal Development in Mice** Annemarie Carver[1], Robert Taylor[2], Faith Fairbairn[2], Hanna Stevens[2] [1]Psychiatry, University of Iowa, [2]University of Iowa

Insulin-like growth factor 1 (IGF-1) is an essential hormone that is primarily produced in the placenta prior to birth. IGF-1 has a significant impact on fetal growth directly but also through other placental functions it regulates at the transcriptional level. IGF-1 levels impact the expression of IGF binding proteins, other growth factors, and nutrient transporters all localized in the labyrinth zone or transport region of the placenta. Altering placental IGF-1 may have significant effects on the developing fetus, particularly tissues that require GF-1 for growth of the brain and all elements of the body. We hypothesized that overexpression of placental *Igf1* would promote expression of its downstream targets subsequently accelerating overall growth of the fetus. We created a placental targeted overexpression of *Igf1* using an *in utero* CRISPR activation technique developed in our lab and assessed with qPCR and ELISA, as well as placental and fetal growth as developmental outcomes. Interestingly, we found that males and females responded differently to this manipulation. At E14 and E18, female overexpression placentas displayed the expected increased placental *Igf1* gene expression and protein levels compared to controls. Males did not show

these changes with the overexpression manipulation but had higher placental *Igf-1* than control females generally which may reflect a ceiling effect limiting the impacts of the CRISPR manipulation. Furthermore, males with placental CRISPR activation had increased fetal body IGF-1 protein at E14. This suggested a previous temporary placental overexpression as a source for higher E14 body IGF1 that was then downregulated in placenta to control levels by E14. In females, IGF binding proteins, placental growth factor, and amino acid transporter placental gene expression was higher after *Igf1* overexpression. Male placentas after the CRISPR activation showed only decreases in these outcomes. Despite these changes, placental size and zone areas were not altered in either sex. Female body mass was larger at E14 but unchanged at E18, while male body mass showed no change at E14 but was decreased at E18. These sex-specific growth changes were consistent with the sex-specific changes found in other placental genes, regulated by placental IGF-1 levels. Overall, these studies demonstrate how male and female placental *Igf1* may be differentially constrained, affecting its regulation of gross fetal development.

1232S **Pumilio proteins interact with UPF1 to promote degradation of a subset of pumilio-target mRNAs in mouse embryonic stem cells** Yuedong Huang, Yiying Yang, Haifan Lin Yale University

Post-transcriptional regulations play crucial roles in mammalian embryogenesis yet have not been well studied. Our lab discovered that pumilio RNA-binding family member 1 (PUM1) and PUM2, the two murine members of the RNA-binding Pum protein family, are essential for early embryogenesis and embryonic stem cell (ESC) function. To explore the underlying mechanism, we identified 543 direct mRNA targets of PUM1 and 508 direct mRNA targets of PUM2 in mouse ESCs by enhanced crosslinking and immunoprecipitation (eCLIP). Among them, 330 mRNAs are PUM1-PUM2 common targets, including key pluripotency factors such as *Sox2*, *Nanog*, *Tbx3*, and *Esrrb*. RNA-seq of *Pum1*-knockout (*Pum1*-KO), *Pum2*-KO, *Pum1/2*-DKO, and wild-type ESCs before and after inducing differentiation revealed that, among the 107 Pum-target mRNAs down-regulated in wild-type ESCs during differentiation, the down-regulation is overall reduced in *Pum*-KO ESCs. This reduction is especially significant for 42 mRNAs, which includes mRNAs of pluripotency factors such as *Tbx3*, *Nanog*, and *Esrrb*. These results indicate that PUM1 and PUM2 may promote the degradation of these 42 target RNAs. In addition, for the 58 PUM-target mRNAs that are up-regulated in wild-type ESCs during differentiation, the up-regulation is variably affected in *Pum*-KO ESCs. This implicates that PUM proteins can exert different regulatory effects on different targets. To investigate how PUM proteins mediate target mRNA degradation, we performed immuno-precipitation and mass spectrometry of PUM1 protein in ESCs and identified UPF1, a key factor in nonsense-mediated decay (NMD) pathway, as a novel protein partner for PUM1. Disrupting the UPF1-interaction region of PUM1 abolished its regulatory effect. This result indicates that PUM1 and UPF1 function together to degrade target mRNAs. Overall, our work reveals a novel and complex mechanism of gene regulation at post-transcriptional levels that is essential for ESC pluripotency.

1233S **Genetics and genomics in planarians and geckos** Longhua Guo University of Michigan

The decreasing cost and increasing power of sequencing allowed unprecedented accessibility to the secrets of genomes from a wide range of species. In my laboratory, we combine traditional genetics and modern genomics to study traits in two non-traditional laboratory animal models, the planarians, and leopard geckos. For planarians, we use established inbred lines to build laboratory mapping populations. For leopard geckos, we collaborate with breeders to collect DNA samples from a large collection of breeding populations. These approaches allow us to identify casual genotype and phenotype relationships in non-traditional animal models.

1235S **Defining a role for Hedgehog signaling in zebrafish left-right patterning** Cullen B Young, Rebecca D Burdine Molecular Biology, Princeton University

Underneath the exterior of a bilaterally symmetric vertebrate is an internal body plan characterized by distinct left-right (LR) asymmetries in organ structure and position. LR asymmetry arises at a structure referred to as the left-right organizer (LRO) that is required for proper LR axis specification. Errors in LR axis specification result in birth defects such as heterotaxy, and congenital heart disease. While the initial symmetry breaking event at the LRO varies across vertebrates, amplification of the transforming growth factor β (TGFβ) morphogen Nodal at the LRO and followed by asymmetric Nodal signaling is highly conserved. The Hedgehog (Hh) pathway, the first pathway to be implicated in vertebrate LR patterning, is known to be required for asymmetric organ development in a variety of organisms such as mice and chick. However, its specific influence on *nodal* has been controversial due to temporal adaptation mechanisms in the absence of Hh activity and Hh effects on morphological structures such as the midline which indirectly impacts asymmetry of *nodal* expression. To address this, we sought to investigate whether Smoothened-mediated hedgehog signaling is required for LR patterning in zebrafish. Surprisingly, while all Hh pathway components are expressed in or around Kupffer's vesicle (KV), the zebrafish LRO, a requirement in LR patterning has yet to be described. To avoid the confounding variables brought by genetic mutants and exogenous over-expression, we turned to pharmacological manipulation using agonists and antagonists of Smoothened (Smo), the key transducer of the pathway during critical periods of LR development to delineate any temporal requirements.

-Strikingly, we find a minimal period where embryos are sensitive to Smo perturbations, preventing the establishment of proper asymmetric markers. Our findings suggest that Smoothened-mediated Hh signaling has a previously uncharacterized role in zebrafish LR patterning and requires further mechanistic investigation. Overall, our work highlights the importance of modulating signaling strength and duration during embryonic development and provides insight to the molecular players instructing asymmetric organogenesis.

1236S **Investigating the Role of the Adaptor Protein Enkurin in Zebrafish Left-Right Patterning** Billie M Reneker[1], Vanessa Gonzalez[1], Triveni Menon[2], Rebecca Burdine[1] [1]Molecular Biology, Princeton University, [2]HHMI Janelia Research CampuS

Vertebrates are externally symmetric but have critical internal asymmetries in organ placement and patterning. Asymmetries along the left-right (LR) body axis are established within embryonic structures known as LR organizers, which in zebrafish is Kupffer's vesicle (KV). Current models propose that motile cilia within KV generate a leftward flow of extracellular fluid that is sensed by KV cells via the cation channel complex Polycystin 2 (Pkd2) and Polycystin 1 Like 1 (Pkd1L1), leading to an increased flux of Ca^{2+} in cilia. Increased ciliary Ca^{2+} would then signal through unknown mechanisms to culminate in asymmetric posttranscriptional regulation of the Nodal inhibitor, *dand5*, which would restrict Nodal signaling to the left side of the embryo to accomplish proper LR patterning. However, the precise targets of flow and/or calcium signaling that connect the Polycystin complex to regulation of *dand5* mRNA are entirely unknown. To identify these effectors, we carried out single-cell RNA sequencing of zebrafish KV cells. From this dataset I identified the gene *enkurin* as highly enriched in KV cells when *dand5* asymmetry is being established. Based on published work in Mouse sperm flagella (Sutton et al., *Dev Biol*. 2004; Jha et al., *Can. J. Physiol. Pharmacol*. 2015.), I hypothesize Enkurin acts as an adaptor protein to link Pkd2 to downstream Ca^{2+} signaling effectors which regulate the downregulation of *dand5* in response to flow. To test my hypothesis, I have generated *enkurin* CRISPR/Cas9 mutants and will present my characterization of the mutant phenotypes. I am currently testing binding of Enkurin to Pkd2, Calmodulin, and other proteins involved in the LR patterning pathway and determining localization of Enkurin within KV cells. My work will provide insight into the mechanisms downstream of flow in the zebrafish LRO that controls *dand5* asymmetric expression.

1237S **Urotensin Signaling Controls Development of Muscle and Spine Morphology** Johnathan O›Hara-Smith, Elizabeth Bearce, Samuel Bertrand, Rachael Giersch, Daniel Grimes Biology, University of Oregon

As animals mature, the body grows rapidly and must properly scale its tissues and organs to maintain the right shape. Failure to properly develop the musculoskeletal system can result in scoliosis, that is the breakdown of the morphology of the spine. Idiopathic scoliosis (IS), defined by acquisition of spinal curves during adolescence in the absence of explicative neuromuscular or vertebral structure defects, is highly prevalent, affecting about 3% of humans, yet poorly understood. Using zebrafish genetic models of IS, we have identified 2 cyclic neuropeptides, the Urotensin II-related peptides 1 and 2 (Urp1 and Urp2), which are secreted from within the spinal cord and control spinal morphology as well as muscle development. When Urp1 and Urp2 are deleted, spine morphology breaks down severely during juvenile growth, producing scoliosis-like phenotypes. To understand the molecular developmental mechanisms leading to this spinal dysmorphology, we performed bulk RNA-sequencing of Urp1/Urp2-deficient embryos, identifying multiple dysregulated transcripts encoding proteins critical for the basic function of muscle. Confocal microscopy to observe embryonic and larval somitic musculature revealed subtle structural defects including cavities in muscle tissues as well as waviness of muscle fibers. Additionally, spinal dysmorphology occurred when we mutated the muscle-expressed Urp1/Urp2 receptor, Uts2r3. We hypothesize Urotensin signaling controls spine morphology by controlling the way trunk muscle tissue grows and matures, where mismatched growth or maturation with vertebral structures, organs, and other tissues results in breakdown of spine morphology.

1238S **Optic Fissure Morphogenesis and the Mechanisms Driving Coloboma** Ryan Clough, Keith Carney, Kristen M Kwan Human Genetics, University of Utah

Tissue morphogenesis is a critical process that creates the three-dimensional tissue shape necessary for its proper function, and birth defects can arise when these processes go awry. Coloboma, an ocular birth defect and a significant cause of childhood blindness worldwide, manifests due to structural developmental defects in the optic fissure, a transient embryonic eye structure. The optic fissure forms as two tissue margins at the ventral face of the embryonic eye and optic stalk, creating an avenue for blood vessels to supply the developing eye as well as for retinal axons to exit and innervate the brain. After the optic fissure forms, the margins subsequently fuse, enwrapping these blood vessels and axons. Defects in either the formation or fusion of the optic fissure can lead to coloboma. Coloboma research has heavily focused on mechanisms of optic fissure fusion, but morphogenetic studies of optic fissure formation remain comparatively unexplored. Previous work has uncovered the developmental origin of the cells that form the optic fissure; however, little is known of the cell morphology changes and movements underlying optic fissure formation. Here, we combine multidimensional imaging of zebrafish embryos as well as custom software tools developed in our lab to segment and track cells in 4D to characterize the cell movements and cell morphologies driving optic fissure formation.

Our preliminary analyses reveal some potentially surprising behaviors: cells populating the optic fissure margins may undergo lateral constriction, suggesting an unexpected invagination, or folding event that is responsible for optic fissure formation. Moving forward, we aim to comprehensively define the cell behaviors directing this process, which will serve as a foundation to understand the molecular mechanisms controlling optic fissure formation and its disruption in coloboma. We previously found that overactive Hedgehog (Hh) signaling, as found in the zebrafish *ptch2* mutant, disrupts optic fissure formation. In the future, we will determine the specific molecular mechanism by which overactive Hh signaling, and its downstream effectors, alter the morphogenetic processes underlying optic fissure formation.

1239S **The role of chemokine signaling in the projection of habenular axons in zebrafish** Catherine Stress, Ryan Anderson, Sara Roberson Applied Science, Bluefield State University

The dorsal habenulae (dHb) are a conserved, bilateral region of the forebrain responsible for behaviors such as fear, anxiety, and comprehension of reward versus punishment. Axons of dHb neurons project posteriorly to synapse with neurons of the interpeduncular nucleus, an unpaired region of the midbrain. During development of the dHb, its precursor cells express the *chemokine (C-X-C motif) receptor 4b* (*cxcr4b*). Active chemokine signaling through Cxcr4b is detected at the distal ends of newly developing axons. Two chemokine ligands, *chemokine (C-X-C motif) ligand 12a* and *12b* (*cxcl12a* and *cxcl12b*) are expressed in the region of the developing dHb. Previous work has shown loss of either *cxcr4b* or *cxcl12a* results in the defasciculation and anterior projection of dHb axons. A similar axon phenotype is detected in a mutant where overexpression of ligand *cxcl12b* is observed in the region of the developing dHb. The individual roles of *cxcl12a* and *cxcl12b* in directing dHb axons to their midbrain target is not fully understood. Relative expression patterns of the two ligands and axon phenotypes in zebrafish larvae lacking *cxcl12b* are currently being explored. Preliminary data suggests that global overexpression of *cxcl12a* does not phenocopy the loss of *cxcl12a* or overexpression of *cxcl12b*. Together, this suggests that *cxcl12a* and *cxcl12b* play distinct, non-redundant roles in directing dHb axons to their midbrain targets.

1240S **The Role of *tango6* in Embryonic Zebrafish Development** Sydney Versen[1], Hannah Herron[1], Kelli Carroll[2] [1]Austin College, [2]Wofford College

The Undiagnosed Diseases Network (UDN) is a collection of clinicians and researchers that diagnose individuals with rare or previously uncharacterized diseases. Mutations in *TANGO6* were identified in a child with neurological and cardiovascular defects. While data from The International Mouse Phenotyping Consortium indicated that TANGO6 is required for development, the function and expression patterns of TANGO6 are largely unknown. To understand the role that *tango6* plays in development, we utilized embryonic zebrafish to analyze its quantitative and spatial expression. *tango6* is expressed most highly between 0 and 12 hours post fertilization (hpf) but continues to be expressed at low to moderate levels from 24-120 hpf. *In situ* hybridization demonstrated that *tango6* is broadly expressed in zebrafish embryos from the 256-cell stage through early somitogenesis. In older embryos, *tango6* showed more restricted localization with expression in the brain beginning at 24 hpf and in a specific region of the lower jaw by 72 hpf. Furthermore, by 96 hpf, *tango6* is expressed in the developing gastrointestinal system and swim bladder. Preliminary data of mosaically edited *tango6* knockdowns generated using CRISPR (CRISPANTS) show a transient accumulation of blood around the gut by 120 hpf, suggesting defects in gut morphogenesis or vascular permeability. Additionally, *tango6* CRISPANTS present with craniofacial malformations and potential liver abnormalities. Intriguingly, knockdown of *tango6* using a morpholino showed a more dramatic phenotype, with high rates of lethality and broad morphological defects, indicative of a potential maternal mRNA contribution. In total, these data suggest that *tango6* is involved in early zebrafish development, and further analysis of knockdowns and spatial expression patterns is underway to determine the precise role of *tango6* in development and disease.

1241S **Maternal Osbpl7 factor controls cleavage furrow formation during the embryonic first cell division** Ingrid del Pilar Pinto-Borguero[1,2], Natalia Benavente-Cabrera[1], Felipe Aguilera[3], Mary C. Mullins[4], Ricardo Fuentes[5] [1]Cell biology, Universidad de Concepcion, [2]Cell and developmental biology, University of Pennsylvania, [3]Biochemistry and Molecular Biology, Universidad de Concepcion, [4]Cell and Developmental Biology, University of Pennsylvania, [5]Cell Biology, Universidad de Concepcion

After fertilization, the initial stages of embryonic development involve the orchestration of the first round of cell division, a highly regulated process guided by genetic products—RNAs and proteins—loaded by the mother and stored into the oocyte during oogenesis. Despite the increasing awareness of the pivotal role maternal products play in vertebrate development, only a limited number of them have been discovered.

We have isolated the maternal-effect zebrafish mutant that harbors a mutation in the *osbpl7* gene, which encodes a lipid transporter associated with the oxysterol-binding protein family. Employing techniques such as microscopy, immunostaining, and bioinformatic analyses, we found that the mutant phenotype completes meiosis post-fertilization. However, it exhibits notable aberrations in egg activation and cleavage furrow formation during both initial and subsequent cell divisions.

Furthermore, there is plasma membrane instability leading to subsequent cell lysis, indicating that the mutation is highly penetrant and lethal in the offspring of a mutant female fish. Our initial studies of differentially expressed genes also reveal that the mutation impacts on factors related to lipid homeostasis and cytoskeletal rearrangement.

This research not only establishes a novel link between a member of the oxysterol lipid transporter family and the first embryonic cell division but also identifies it as a pivotal maternal factor crucial for early developmental processes. Ongoing studies are in progress to understand the mechanisms of how Osbpl7 participates in the meiosis-to-mitosis transition.

1242S **Systematic analysis of temperature-sensitive alleles uncovers new functions for essential genes in yeast filamentous growth** Atindra N Pujari[1], Zhijian Li[2], Ankita Priyadarshini[1], Deanna Williams[1], Dale Climie[2], Sondra Bahr[2], Helena Friesen[2], Michelle Li[1], Joshua Oken[1], Brenda Andrews[2], Charles Boone[2], Paul J Cullen[1] [1]Biological Sciences, State University of New York at Buffalo, [2]Terrence Donnelly Center for Cellular and Biomolecular Research, University of Toronto

Through the process of differentiation, cells specialize into unique types with distinctive shapes and specific functions. Many fungal species, including pathogens, differentiate to adherent, pseudohyphal, and hyphal cell types, which are collectively referred to as filamentous growth, in response to environmental cues. Certain strains of baker's yeast *Saccharomyces cerevisiae*, such as the Σ1278b background, also undergo filamentous growth. Studying filamentous growth in yeast has facilitated the identification of many genes and regulatory pathways that control these behaviors. A group of genes yet to be systematically analyzed for their role in filamentous growth are those that perform essential functions. We generated a collection of temperature-sensitive (ts) alleles in 325 essential genes in the Σ1278b strain to interrogate their roles in filamentous growth. Ts mutants were examined at semi-permissive temperatures for phenotypes in different aspects of filamentous growth, such as invasive growth, pseudohyphal growth, and biofilm/mat formation. More than half the alleles tested showed phenotypes by at least one assay. New connections to filamentous growth and splicing, kinetochore assembly, and chromosome segregation were identified. We also found that the Wiskott-Aldrich Syndrome protein homolog Las17p regulated the Cdc42p-dependent MAP kinase pathway (the fMAPK) that controls filamentous growth. Las17p was required for the localization and levels of Sho1p, a tetraspan sensor of the fMAPK pathway. Our results, including identification of new roles for essential genes in cell differentiation and variation in essential processes across populations, may improve the understanding of essential gene functions in eukaryotes.

1243V **The AP-1 clathrin adaptor complex differentially regulates Notch signaling** Tatsuya Kato[1,2], Olga Skorobogata[1,2], Haojun Zhu[1,2], Edouarda Taguedong[1,2], Christian Rocheleau[1,2,3] [1]Research Institute of the McGill University Health Center, [2]Department of Anatomy & Cell Biology, McGill University, [3]Department of Medicine, McGill University

Notch signaling relies on interactions between transmembrane Notch receptors and ligands expressed on neighboring cells to influence cell differentiation and proliferation. Consequently, its roles in diseases such as cancer are varied, and it is vital to further understand how Notch signaling is regulated in different tissues to shed light on their pathologies. *C. elegans* vulval development is a powerful system to study tissue-specific Notch signaling regulation since it is controlled by Notch-dependent cell fate specifications in the gonad and vulval epithelium. A somatic gonad precursor cell with low LIN-12/Notch activity is specified to become the anchor cell (AC). AC function is critical for subsequent induction of vulval precursor cells (VPCs), two of which are specified to the secondary fate through high LIN-12/Notch activity. Modulations of Notch signaling cause observable developmental defects such as ectopic secondary fate inductions or lack of VPC inductions called the vulvaless phenotype. AP-1 is a conserved clathrin adaptor complex known to regulate transmembrane protein sorting from the Golgi to the plasma membrane. We previously reported that double mutants of the AP-1 subunit *unc-101/ap1m1* and the Rab GTPase *rab-7/rab7a* exhibited ectopic VPC inductions with secondary fate morphologies, suggesting a role of AP-1 in Notch signaling.

To investigate, I analyzed effects of the *unc-101(sy108)* loss-of-function mutant in a *lin-12(n302)* background. *lin-12(n302)* is a partial gain-of-function mutant which inhibits AC specification but does not ectopically induce secondary fates, resulting in a vulvaless phenotype. I observed that *unc-101(sy108)* suppressed the *lin-12(n302)* vulvaless phenotype through restoration of the AC fate, indicating that AP-1 activity promotes Notch signaling in the AC. Interestingly, *unc-101(sy108); lin-12(n302)* animals also exhibited ectopic secondary fate inductions in the VPCs, suggesting that UNC-101/AP1M1 inhibits LIN-12/Notch in the VPCs. Furthermore, expression analyses of a LIN-12/Notch reporter showed that AP-1 promotes and inhibits LIN-12/Notch membrane expression in the AC and the VPCs respectively. These results point to differential Notch signaling regulation by AP-1 in the somatic gonad and vulval epithelium. I am currently testing if AP-1 differentially regulates Notch signaling through tissue-specific LIN-12/Notch sorting and/or cell polarity maintenance.

1244V **Understanding the development and function of Drosophila descending neuron controlling motor programs** Alex Le[1], Kristen Lee[2], Chris Doe[2], Matthew Clark[3] [1]Bucknell University, [2]Institute of Neuroscience, University of Oregon, [3]Department of Neuroscience, Bucknell University

While research on Drosophila melanogaster has yielded substantial knowledge about neuronal differentiation, synaptogenesis, and more, there's limited understanding of the specific genes forming the neural circuit during metamorphosis. Our study investigates the roles of transcription factors (TFs) and cell-surface molecules (CSMs) in the moonwalking descending neurons (MDN) circuit, pivotal for fruit flies' locomotion. Using techniques like genetic screening, optogenetics, and confocal microscopy, we examined the impact of different genotypes on the MDN circuit post-metamorphosis and aimed to reconstruct the descending neurons (DNs) circuits. Our findings highlight that specific TFs, CSMs, and some known descending neurons are integral to MDN circuit formation, as observed through the altered locomotion behaviors and atypical neuronal morphology. Considering the genetic parallels between fruit flies and humans, this research holds significant ramifications for developmental neurobiology. Furthermore, the insights offer potential avenues for enhanced human disease screening, underscoring the interplay between genetics, neural connectivity, and health.

1245V **Arrowhead, a LIM homeodomain protein plays critical role in Notch mediated wing and neuron development in *Drosophila*** Jyoti Singh, Ashim Mukherjee Molecular and Human Genetics, Banaras Hindu University

Notch pathway is an evolutionarily conserved signaling pathway that tends to influence an astonishing array of cell fate decisions in different developmental contexts. To identify novel effectors of Notch signaling, the whole transcriptome of the *Drosophila* wing imaginal discs was analysed in which an activated form of Notch was overexpressed. Among the candidate genes, a LIM-homeodomain protein encoding gene, *Arrowhead* (*Awh*) was identified as a novel candidate which plays an important role in Notch-mediated developmental events. A strong genetic interaction between the alleles of Awh and Notch pathway components was also observed. Immunocytochemical analyses revealed that Awh overexpression downregulates Notch targets, Cut and Wingless (Wg). This reduction of targets is regulated through the downregulation of the ligand, Delta without altering Notch receptor levels. As a consequence the expression of Wg effector molecule Armadillo, and its downstream targets Senseless and Vestigial also gets downregulated. Further, *Awh* overexpression resulted in ectopic expression of *engrailed*, a segment polarity gene in anterior region of wing disc, leading to duplication of the wing. We also observed that Awh overexpression significantly rescues neuronal defects caused by activated Notch. Interestingly, activated Notch inhibits Awh activity, indicating a regulatory loop between Awh and Notch. In addition, the defects caused by Awh overexpression were significantly rescued by Chip, a LIM-interaction domain containing transcriptional co-factor. The LIM domain of Awh is crucial for the Awh-Chip interaction. The present study highlights the feedback regulation between Awh and Notch and elucidate their significance in *Drosophila* wing and neuronal development.

1246V **Epigenetic Avoidance of *Drosophila* Egg Chambers with an Excessive Number of Oocytes** Laura Castro, Talia Feijao, Joao Rede, Rui Gonçalo Martinho University of Aveiro

Oocyte determination occurs in many organisms within a germ line cyst, a multicellular structure composed of interconnected germ cells. In *Drosophila*, mouse and many other organisms, each cyst forms a single oocyte, whereas the remaining interconnected cells of the cyst differentiate as supporting nurse cells, which will ultimately die by programmed cell death.

Interestingly, early on, multiple cells of the cyst enter meiosis, but only one is capable of remaining in meiosis and avoiding a nurse cell fate as the cyst differentiates. This suggests that the mechanisms required for oocyte determination are likely to go hand-in-hand with poorly understood restriction mechanisms that avoid the formation of multiple oocytes within a single germ line cyst.

Recently, we and others observed that Polycomb-group proteins (PcG proteins) have a critical function in the repression of early prophase I genes during mid/late prophase I (PMID: 32773039 and 36215502). We therefore hypothesized that such transcriptional repressive activity within the female germ line cyst is likely to contribute for the avoidance of *Drosophila* egg chambers with supernumerary oocyte formation.

In order to test this hypothesize, we screened for genes whose misexpression, in the context of defective Polycomb silencing, could facilitate the formation of *Drosophila* egg chambers with excessive number of oocytes. We identified a chromatin-related protein whose expression up-regulation dramatically increase the frequency of *Drosophila* egg chambers with multiple oocytes. Interestingly, and although the viability of such egg chambers is reduced, we could easily detect egg chambers with multiple oocytes until mid/late oogenesis (stage 9).

We will present our ongoing work, where we try to mechanistically understand the way supernumerary oocyte formation is avoided in *Drosophila*. Our working hypothesis is that highly conserved oocyte-fate restriction mechanisms are likely to exist in the female germ line cyst.

1247V ***ztf-16* is a novel heterochronic modulator that opposes adult cell fate in dauer and non-dauer life histories in *Caenorhabditis elegans*** Mark A Hansen[1], Anuja Dahal[1], Taylor A Bernstein[1], Chani Kohtz[1], Safiyah Ali[1], Aric L Daul[2], Eric

Montoye[1], Ganesh P Panzade[3], Amelia F Alessi[4], Stephane Flibotte[5], Marcus L Vargas[2], Jacob Bourgeois[1], Campbell Brown[1], John K Kim[4], Ann E Rougvie[2], Anna Zinovyeva[3], Xantha Karp[1] [1]Central Michigan University, [2]University of Minnesota, [3]Kansas State University, [4]Johns Hopkins University, [5]University of British Columbia

To increase the chance of survival in adverse environments, *C. elegans* can enter dauer diapause, a stress-resistant, developmentally arrested stage adopted after the second larval molt. If dauer larvae find favorable conditions, they can exit dauer and complete development. To study the effect of dauer diapause on development, we focus on the epidermal seam cells. Seam cells are multipotent during larval development but differentiate in adults, a process that is regulated by the heterochronic genes. Interestingly, many heterochronic genes are required only during non-dauer development, suggesting that novel genes may control post-dauer seam cell development. To identify such genes, we conducted a genetic screen for mutants displaying precocious expression of the adult-specific *col-19p::gfp* marker in post-dauer larvae. We found that *ztf-16*, encoding a C2H2 zinc finger transcription factor, is required to prevent precocious *col-19p::gfp* expression beginning in the L1 stage in both dauer and non-dauer life histories. Comparative mRNA-seq analysis also identified 306 differentially expressed genes between wild-type and *ztf-16(-)* larvae. In non-dauer development, *col-19* expression is regulated by a genetic pathway including the *let-7* microRNA, the LIN-41 RNA binding protein, and the LIN-29 transcription factor that directly activates *col-19* transcription. We used genetic and molecular analyses to place *ztf-16* within this pathway. Expression of *ztf-16::gfp* was strongly upregulated in *let-7(-)* mutant larvae, indicating that *ztf-16* acts downstream of *let-7*. Genetic epistasis experiments further supported this interpretation. However, mutation of the *let-7* site in the *ztf-16* 3'UTR did not affect *ztf-16::gfp* expression, suggesting that *let-7* regulates *ztf-16* indirectly. *lin-41* is a target of *let-7*, and we hypothesized that *lin-41* may mediate regulation of *ztf-16* downstream of *let-7*. Surprisingly, RNAi of *lin-41* did not suppress the upregulation of *ztf-16::gfp* and in fact enhanced this phenotype. Finally, *lin-29* was not required for precocious *col-19p::gfp* expression in *ztf-16(-)* larvae, suggesting that additional players are involved in regulating *col-19p::gfp* expression. Taken together, our work describes a novel heterochronic regulator that functions after dauer diapause.

1248V **Drosophila REV7 Promotes Genome Stability Independently of Pol ζ** Lara R Maggs, Mitch McVey Tufts University

REV7 is best known as a component of DNA translesion polymerase ζ. This specialized polymerase is involved in synthesis past DNA lesions at replication forks and single-strand gaps during postreplication repair. It's also a subunit of other protein complexes involved in genome stability, including the Shieldin complex, which regulates double-strand break repair pathway choice in mammals, and the mitotic spindle assembly checkpoint complex, which prevents premature onset of anaphase. REV7, a HORMA domain protein, uses its characteristic safety belt region to interact with other proteins in these complexes.

Although the Drosophila REV7 protein shares the same HORMA domain as its orthologous counterparts, it remains unknown whether it functions beyond its canonical role as a Pol ζ constituent. To test this, we used mutant stocks with transposon insertions in the REV7 coding sequence, along with CRISPR-generated mutants, and compared them to flies lacking REV3, Pol ζ's catalytic subunit. We assessed the mutants for their response to innate endogenous damage, including adult viability, hatching rate, and eggshell abnormalities. Strikingly, REV7 loss decreases homozygote viability, impairs hatching rate, and hinders eggshell development to a greater extent than REV3 loss. Additionally, we conducted mutagen sensitivity assays with the alkylating agent methyl methanesulfonate (MMS) to evaluate these mutants' response to exogenous damage. MMS induces replication-blocking adducts that, if not swiftly addressed, cause deleterious outcomes like fork collapse or aberrant checkpoint activation. At all MMS concentrations tested, REV7 loss caused greater hypersensitivity than REV3 loss.

The divergent data obtained using rev3 and rev7 mutants indicates the observed defects are not solely due to Pol ζ loss. Instead, these data suggest REV7 interacts with proteins other than REV3 to coordinate damage response and to promote proper development. We are currently conducting proteomic studies to identify REV7's uncharacterized protein interactors. These studies will provide deeper insight into the mechanism(s) by which Drosophila REV7 promotes genome stability in response to endogenous and exogenous damage.

1249V **Single cell genomic strategies for prioritizing candidate genes in *Sox10^{Dom}* Aganglionosis Modifier Intervals** Joseph T Benthal, Justin A Avila, E Michelle Southard-Smith Genetic Medicine, Vanderbilt University

Enteric nervous system (ENS) development requires coordinated gene expression that regulates enteric neural crest-derived cell (ENCDC) migration, enteric gliogenesis, and enteric neurogenesis. Perturbations in genes involved in these initial processes can result in gastrointestinal motility disorders, including Hirschsprung's disease (HSCR). The *Sox10^{Dom}* mouse model of HSCR recapitulates the variable penetrance of the aganglionosis phenotype. To identify the genetic loci that modify severity and penetrance of the *Sox10^{Dom}* aganglionosis phenotype, our group conducted a genome-wide linkage study on *Sox10^{Dom}* F_2 progeny from a cross of C3HeB/FeJ and C57B6/J mice. These strains exhibit differential severity of the *Sox10^{Dom}* aganglionosis phenotype. Five modifier loci intervals were identified from this cross, three of which are novel and

do not coincide with known aganglionosis susceptibility loci or intervals containing genes known to participate in neural crest development. We have since conducted a genetic scan of an extended pedigree of *Sox10^{Dom}* mice which identified 3 additional modifier intervals. We hypothesize that genes within these *Sox10^{Dom}* modifier loci will contain genes or genomic elements that are differentially regulated in ENS progenitors from wild type and *Sox10^{Dom}* fetal intestine and that intervals around these differentially expressed genes will exhibit differential chromatin accessibility. To address this, we have utilized bulk RNA-seq of enteric neuronal progenitor cells including the migrating wavefront, single cell RNA-seq and single nucleus ATAC-seq of fetal enteric nervous system cells, previously mapped modifier intervals, and our updated modifier intervals from the extended pedigree to identify and prioritize the most relevant candidate genes in ENS development. Our approach has identified candidate genes and regulatory elements that are likely to impact the severity of the *Sox10^{Dom}* aganglionosis phenotype and may point to new mechanisms in which SOX10 interacts with genetic elements to produce phenotypes relevant for human disease.

1250V **The mechanism of of head-tail connection in sperm formation** Danielle B Buglak, Kathleen HM Holmes, Brian J Galletta, Nasser M Rusan National Institutes of Health

During spermiogenesis, spermatids undergo dramatic morphological changes to develop into mature sperm. The final architecture of the sperm requires the lateral attachment of the axoneme (sperm tail) to the needle shaped nucleus (sperm head). Secure attachment is mediated by the head-tail coupling apparatus (HTCA) and its failure results in male sterility due to sperm decapitation. How the HTCA forms and remodels over time is not well understood, and the molecular architecture of the HTCA is an ongoing question in the field. Here, we describe a four stage process of HTCA development: 1. Search and capture of the nucleus by the centriole, 2. Centriole attachment to the nucleus, 3. Centriole insertion into the nucleus, and 4. Centriole lateralization. Using structured illumination microscopy, we identified two unique structures at the HTCA during late spermiogenesis: the “centriole cap” and “nuclear shelf”. We found that the centriole cap is associated with centriole insertion into the nucleus, while the nuclear shelf is associated with centriole lateralization. Two important HTCA components, the testis-specific SUN-domain protein Spag4 and the gravitaxis protein Yuri Gagarin, both localize to the centriole cap and nuclear shelf. Furthermore, we found that the centriole cap and nuclear shelf are closely associated with two additional sperm centriole structures, the proximal centriole-like (PCL) and centriole adjunct (CA). Mutant analysis led to a model whereby the PCL acts as an anchor to maintain centriole positioning at the HTCA during late-stage spermiogenesis. Thus, we identify two unique structures in the sperm HTCA and a novel role for the PCL in male fertility. We are currently working to identify a role for the CA at the head-tail connection and to expand the list of components important for HTCA function.

1251V **Sensory neurons and insulin signaling modulate oogenesis and fertilization in *C. elegans*** Shashwat Mishra[1], Mohamed A Dabaja[1], Asra Akhlaq[1], Bianca Pereira[1], Kelsey Marbach[1], Mediha Rovcanin[1], Rashmi Chandra[1], Antonio Caballero Reyes[2], Diana Fernandes de Abreu[2], QueeLim Ch’ng[2], Joy A Alcedo[1] [1]Department of Biological Sciences, Wayne State University, [2]Centre for Developmental Neurobiology, King’s College London

The survival of an animal species, including those of the worm *C. elegans* and of humans, depends on the physiological state of their oocytes. We have recently shown that specific sensory neurons in the worm can promote a diet-dependent early onset of oogenesis and a faster rate of oocyte fertilization. The chemosensory neurons ASJ stimulate early oogenesis onset through the insulin-like peptide (ILP) INS-6 when *C. elegans* are fed a specific type of bacterial diet. In contrast, the olfactory neurons AWA regulate food type-dependent differences in *C. elegans* fertilization rates but have no role in early oogenesis. AWA neurons modulate fertilization at least partly in parallel to insulin receptor signaling, since the insulin receptor DAF2 regulates fertilization independently of food type, which requires ILPs other than INS-6. Thus, our findings suggest that diverse food-derived cues modulate oocyte biology through different neural signals that optimize an animal’s reproductive program in a given environment.

1252T **New models of transcriptional adaptation in *C. elegans*** Yuntao Charlie Song, Vahan Serobyan, Didier Stainier Max Planck Institute for Heart and Lung Research

Transcriptional adaptation (TA) is a newly identified cellular response whereby a mutation in one gene triggers the transcriptional modulation of other genes, named adapting genes, independent of protein feedback loops. TA has been observed in multiple species, including zebrafish, mice, and *C. elegans*, suggesting a conserved underlying mechanism. However, the current TA models in *C. elegans* have several limitations including the lethality of homozygous mutants and multiple isoforms of the mutant gene. Also, the mRNA splicing and degradation factors required for TA diverge between these models. Hence, more models are needed to study TA in *C. elegans*. A distinct feature of TA is the differential expression of adapting genes in the presence of mRNA decay (e.g., PTC alleles) versus in the absence of transcripts of the mutant gene (i.e, RNA-less alleles). Thus, we explored Wormbase to identify candidate genes with existing promoter-less and premature termination codon (PTC) alleles. So far, we have selected 40 genes that meet these criteria for further investigation. Among

these candidates, two genes, *maco-1* and *agmo-1*, are not expressed in the promoter-less alleles while showing reduced expression in the PTC alleles based on our RNA-seq data. Interestingly, among the *maco-1* PTC alleles, the one with highest level of mRNA reduction displays the highest number of potential adapting genes (i.e., differentially expressed in the PTC allele compared with wild type, but not in the promoter-less one). Moreover, the set of potential adapting genes may depend on the precise location of the PTC (i.e., different PTC alleles might be associated with different adapting genes). Currently, we are trying to narrow down the list of potential adapting genes by impairing essential TA factors, such as *ergo-1*, that were identified using existing TA models. In summary, the initial goal of this project is to discover new TA models that should allow further studies on the underlying mechanisms.

1253T **Analyzing chromatin accessibility using ATAC-seq in *C. elegans*** Nadia Sadri Biology, New York University

Investigating the process of dosage compensation in *C. elegans* provides insights into how chromatin is packaged within the nucleus of a cell. The *C. elegans* dosage compensation complex (DCC) is a multi subunit structure that binds to both X chromosomes of hermaphrodite worms and reduces their transcription. Previous research has shown that the DCC preferentially binds to the regulatory elements of active genes and the level of binding correlates with chromosome accessibility measured by ATAC-seq. However, it is unknown whether accessibility mediates DCC binding or if DCC binding controls accessibility .

To address this question, we aim to perform ATAC-seq upon DCC knockdown. Although routine in many other systems, we found that the ATAC-seq protocol in *C. elegans* produces variable signal to noise profiles for nucleosome presence. The variability comes in part due to the nuclei preparation step yielding compromised nuclei. To prepare intact nuclei, we optimized the current protocol, eliminating the harsh grinding step and reducing the number of pestle strokes used to break the larvae apart. We incorporated a nuclei quality check and input estimate step using a hemocytometer to control the ATAC reaction.

To knock down DCC, we tagged the DPY-26 (a subunit of condensin I and DC) using degron-GFP. This was crossed to a TIR1 strain expressed under the control of the eft-3 promoter for auxin-inducible degradation in somatic cells. We will present our progress in using this strain to knock down DCC and perform ATAC-seq to measure the effect of DCC binding on the accessibility of active gene regulatory elements on the X chromosomes. If there is no change in accessibility following the depletion of DPY-26, we can conclude that DCC binding to the active regulatory elements does not control accessibility. If there is an increase in accessibility, we will test if this is a direct cause of DCC depletion or an indirect effect of increased transcription.

1254T **Poly (U) polymerase activity in *C. elegans* regulates expression and tailing of sRNA and mRNA** Leanne H Kelley[1], Ian V Caldas[1], Matthew T Sullenberger[1], Kevin E Yongblah[1], Anoop Iyer[1], Adnan M Niazi[2], Yini Li[1], Patrick M Tran[1], Eivind Valen[2], Yasir H Ahmed-Braimah[1], Eleanor M Maine[1] [1]Biology, Syracuse University, [2]University of Bergen

Uridylation, the addition of uridine to the 3' end of RNAs (U-tailing), is a conserved post-transcriptional modification documented in many organisms to promote mRNA turnover and implicated in regulating small RNA (sRNA) function. Our previous work showed that poly(U) polymerase (PUP) activity is critical for germline development and embryonic viability, especially under temperature stress. Given this developmental role, we identified the sRNA and mRNA targets of the four known *C. elegans* PUPs and determined the effect of U-tail loss on RNA expression. Ultimately, we aim to determine how the PUPs coordinate proper germline development.

We obtained RNA U-tailing data for adult hermaphrodites carrying *pup* null mutations and raised at 22°C. mRNA data were obtained with a Nanopore-based approach and sRNA data with a high-throughput method. mRNA U-tailing is notably reduced only in the absence of all four PUPs. In contrast, most U-tailed sRNAs are targeted by PUP-1, and distinct subsets of those sRNAs are also targeted by PUP-2, PUP-3, or PUP-4. Surprisingly, PUP-4 apparently *limits* U-tailing of a subset of PUP-1 sRNA targets. Moreover, PUPs have distinct functions in promoting sRNA mono- vs oligo-uridylation. Notably, reduced U-tailing correlates with increased expression of some sRNAs and reduced expression of others.

Numerous siRNAs are differentially expressed in *pup* mutants, and they tend to target genes with germline-enriched or ubiquitous expression. We obtained high-throughput mRNA-seq data for comparison with sRNA-seq data. In the adult, PUP loss correlates with sets of elevated and depleted mRNAs whose products are enriched for several functional classes active in the adult germline and/or early embryo. PUP loss in the early embryo correlates with elevated ribosomal protein mRNAs. Intriguingly, down-regulated siRNAs in the adult include a set that target ribosomal protein genes. Perhaps a diminished contribution of maternal siRNAs leads to higher expression of these mRNAs in the embryo. We will expand on these and other consequences of PUP-mediated regulation in our presentation.

1255T **Transcriptional analysis of *xol-1* mutant hermaphrodites reveals changes in developmental plasticity during embryogenesis** Eshna Jash[1,2], Hector Mendoza[1], Anati Alyaa Azhar[1], Zoey M Tan[1], Halle N Esher[1], Gyorgyi Csankovszki[1] [1]Molecular, Cellular and Developmental Biology, University of Michigan - Ann Arbor, [2]Molecular, Cellular and Developmental Biology, University of Michigan

xol-1, a gene located on the X chromosome, is the master regulator of sex determination and dosage compensation in *C. elegans*. *xol-1* is essential for normal development of XO males, where it promotes the expression of male-specific developmental genes. Additionally, *xol-1* inhibits genes important for hermaphrodite development, which include genes related to X chromosome dosage compensation. While *xol-1* is expressed at very low levels in hermaphrodite embryos, it is thought to be turned off at a very early stage, allowing male-specific developmental genes to be repressed. However, several aberrant phenotypes in *xol-1* mutant hermaphrodites suggest that it does have a function in hermaphrodites as well. We present evidence from bioinformatic analysis in wild-type and *xol-1* mutant embryos showing that the male-specific transcriptional program is active during early hermaphrodite embryogenesis. Immunofluorescence experiments show that the dosage compensation complex, responsible for balancing gene products from the two X chromosomes in hermaphrodites, is activated earlier in embryogenesis in the absence of *xol-1*. We also show that *xol-1* mutant embryos significantly overexpress *met-2*, which is a histone methyltransferase responsible for depositing the H3K9me2 mark. Overexpression of *met-2* and subsequent changes in H3K9me2 can provide an explanation for the differential embryonic developmental plasticity seen in our *xol-1* mutants.

1256T **GPCR Signaling, ACY-4, and acto-myosin contractility in *Caenorhabditis elegans* spermatheca** Maria Khalid[1], Erin Cram[2] [1]Biology, Northeastern university, [2]Biology, Northeastern University

Correct regulation of smooth muscle cell Ca^{2+} release and contractility are vital for the function of various biological systems, including the lungs and cardiovascular system. In the hermaphroditic nematode *Caenorhabditis elegans,* the reproductive system contains a contractile tube composed of smooth muscle-like cells called the spermatheca which stores sperm and is the site of oocyte fertilization. Regulated contractions of the spermatheca push the embryo into the uterus. Previous data suggest that GPCR signaling through the Gα subunits (GOA-1 and GSA-1), presumably upstream of adenylyl cyclase, plays a key role in regulating Ca^{2+} release in the spermatheca. Here, we describe the role of ACY-4/ADCY6, an enzyme that converts ATP into cAMP. ACY-4 is expressed in the spermatheca, particularly in the entry neck, and is required for the ovulation of oocytes into the spermatheca. Loss of function alleles of *acy-4* is characterized by stacked oocytes, endomitotic reduplication, eggs pushed back into the gonad arm, and infertility. Additionally, we demonstrate that *acy-4* depletion impacts the actin cytoskeletal organization in the spermatheca. These results suggest ACY-4 may act downstream of GPCR signaling in the spermatheca to regulate acto-myosin contractility.

1257T **ATPase Function of SMC proteins in Chromosome-wide Gene Regulation** Bahaar Chawla, Suchi Jatia, Dillon Sloan, Gyorgyi Csankovszki Molecular, Cellular, and Developmental Biology, University of Michigan

Structural Maintenance of Chromosome (SMC) proteins function in condensin complexes, hydrolyzing ATP for energy to condense DNA for mitosis. However, their role in interphase gene regulation is not well understood because most mutations in SMC proteins are lethal. *C. elegans* present a unique opportunity to study SMC proteins through their third condensin complex, condensin I^{DC}, which has a unique SMC protein DPY-27 that works specifically in the dosage compensation complex (DCC) to regulate X-chromosome gene expression. However, the contribution of the ATPase activity by condensin I^{DC} in this chromosomal-wide gene regulation is unknown.

We aim to understand this role with ATPase deficient *dpy-27* mutant worms and evaluating the effect on X chromosome structure, gene regulation, and other DCC functions. These studies will help us understand if condensin I^{DC} is a true motor like other condensins or if it only serves as a scaffold for DCC members.

DPY-27, like other eukaryotic SMC proteins, functions in a dimer with another SMC protein, MIX-1. *In vitro* biochemical analysis of DPY-27 and MIX-1 demonstrate that DPY-27 is a true ATPase. We mutated the essential glutamate in the Walker B motif to a glutamine and demonstrated *in vitro* that it disrupts ATPase function. We generated the same mutation in *C. elegans dpy-27* through CRISPR. Using this mutant, we found that the subunits of condensin I^{DC} localize with each other but result in two populations of condensin I^{DC}; one that is strongly DNA bound and the other is transiently. Further experiments have shown that the X chromosomes in mutant nuclei are significantly decondensed and mutant DPY-27 is not found exclusively on the X chromosomes.

Taken together, our results suggest that losing the ATPase function of condensin I^{DC} causes decreased binding of the DCC to the X chromosome, resulting in improper dosage compensation and a loss of viability.

1258T **Loss of the H3K4 methyltransferase subunit *wdr-5* in *C. elegans* results in a transgenerational decrease in chemotaxis** Mackenzie S Roberson[1], Jaely Z Chavez[1], Monica Reeves[2], Karen L Schmeichel[3], David J Katz[2] [1]Biology, Oglethorpe University, [2]Emory University, [3]Oglethorpe University

In *C. elegans* we have previously showed that mutations in *wdr-5*, an essential subunit of the COMPASS complex that is required for depositing H3K4 methylation, lead to the transgenerational enrichment of the repressive mark H3K9me2. To determine whether the accumulation of H3K9me2 affects behavior, we performed chemotaxis assays on *wdr-5* mutants. We find that in comparison to wild-type (N2), *C. elegans* mutant for *wdr-5* exhibit significantly reduced chemotactic behavior towards bacteria. Consistent with this being an inherited epigenetic effect, the chemotaxis index (C.I.) in *wdr-5* worms declines by 50.2% between the F4 and F7 generations ($C.I._{F4}$=0.80 and $C.I._{F7}$= 0.40). To our knowledge, this is the first example of a transgenerational behavior phenotype potentially caused by the accumulation of histone methylation cross generations. Interestingly, after the 7th generation, *wdr-5* mutants gradually restore their chemotactic behaviors to levels comparable to early generations ($C.I._{F13}$= 0.74). The transgenerational decline in chemotactic behavior and the subsequent reversion of phenotype is phenocopied in worms that lack the H3K9me2 demethylase *jhdm-1*. Collectively, these data are consistent with the interpretation that transgenerational establishment of repressed chromatin through the accumulation of H3K9me2 can result in abnormal behavior *C. elegans*. We are currently performing RNA sequencing and analyzing H3K9me2 Chromatin immunoprecipitation (ChIP) data to test this hypothesis.

1259T **H4K20 Methylation Regulation in Dosage Compensation and Cell Cycle of *C. elegans*** Anati Alyaa Azhar, Jianhao Jiang, Györgyi Csankovszki MCDB, University of Michigan, Ann Arbor

In *C. elegans*, hermaphrodites have two X chromosomes while males have a single X chromosome, leading to unequal gene expression. Dosage compensation is a process that solves this issue by equalizing this difference in gene expression between the two sexes. In *C. elegans*, hermaphrodites (XX) downregulate their X chromosomes by half to equalize it to males (X) via the Dosage Compensation Complex (DCC) in somatic cells. The DCC consists of a 5-subunit Condensin I^{DC} complex as well as additional accessory proteins that cooperate to downregulate the gene expression of the X chromosomes. One of the accessory subunits of the DCC is DPY-21, a H4K20-specific demethylase that enriches for H4K20me1 on dosage compensated X chromosomes which is the same chromatin mark enriched on mitotic chromosomes. We aim to understand the coordination between H4K20me1 regulation in dosage compensation and the cell cycle.

In *C. elegans*, H4K20 methylation is affected by SET-1, a methyltransferase that places the first methyl mark on H4K20; SET-4, which converts H4K20me1 to di- and tri-methylation; and DPY-21, a non-condensin subunit of the DCC, which demethylates H4K20me2/3 to H4K20me1 on the X chromosomes. We show that in young embryos, where the cell cycle switches between M and S phases, DPY-21 and SET-4 play a limited role in the regulation of H4K20 methylation. However, in late embryos which have cell cycles with gap phases, the two proteins begin to affect H4K20 methylation. In dosage compensated wild-type late embryos, H4K20me1 decreases in all chromosomes in S phase, increases in all chromosomes during mitosis, and is enriched on hermaphrodite X chromosomes during G1 phase. However, H4K20me in G1 phase is disrupted in the mutants whereby H4K20me1 is diffusely distributed on all chromosomes in dpy-21 mutant and H4K20me1 is present in high levels on all chromosomes in set-4 mutant. We show a complementary trend with H4K20 di- and tri-methylation, in which H4K20me2/3 is present on all chromosomes in dpy-21 mutant while it is diminished on all chromosomes in set-4 mutant. Thus, SET-4 and DPY-21 have the greatest impact on H4K20me during G1. Our goal is to characterize the function and regulation of these two proteins by identifying their interactors and regulators.

1260T **Starvation changes the pre-rRNA accumulation in *C. elegans*** Shahriar Rahman Shovon[1], Naoki Uematsu[2], Yuki Osaki[2], Tatsushi Masui[2], Chisato Ushida[1,2] [1]Bioresources Science, Iwate University, [2]Biochemistry and Molecular Biology, Hirosaki University

The depletion of nutrients significantly impacts cellular processes across all organisms, triggering a restructuring of ribosome biogenesis. Ribophagy, a specialized process involving the selective degradation and recycling of pre-ribosomes and mature ribosomes during stress, is a pivotal response to nutrient depletion. However, the specific effects of nutrient scarcity on ribosome biogenesis remain elusive. Our investigations revealed a novel mechanism regarding the alteration in the accumulation pattern of two distinct ribosomal RNA (rRNA) precursors, namely rRNA precursor b (a precursor of 18S rRNA) and rRNA precursor $27SA_2$ (a precursor of 5.8S and 26S rRNAs), particularly under short-term starvation conditions. Interestingly, we observed a substantial decrease in the $27SA_2$ rRNA precursor, while there was a notable increase in the accumulation of b rRNA precursor. Intriguingly, the rRNA processing pathway recovered when starved animals were provided with an adequate food supply. This observation suggests a novel cellular mechanism for selectively degrading the $27SA_2$ precursor while potentially recycling nucleic acids to adapt to nutritional deprivation. Moreover, the precise cleavage site responsible

for dissociating the 5.8S rRNA precursors and 26S rRNA precursors in *C. elegans* remains unidentified. Through our northern hybridization experiments, we successfully identified the precursor of 5.8S rRNA. Subsequent primer extension experiments further confirmed the precise cleavage position at the internal transcribed spacer 2 (ITS2), which generates the precursor of 5.8S rRNA and the precursors of 26S rRNA. These findings underscore the intricate adaptations within ribosome biogenesis in response to short-term nutritional stress, shedding light on the selective degradation and potential recycling of specific rRNA precursors. Nevertheless, further investigations are imperative to fully elucidate the mechanisms governing this intricate cellular response to nutrient depletion.

1261T **Exploring Novel Intracellular Pathogen Response (IPR) Triggers in *Caenorhabditis elegans*: Analyzing the Impact of Ethanol on Intestinal Permeability and its implications for Innate Immunity in Humans** Iris Kazzi[1], Adrian Alvarado[2], Jessica Sowa[3] [1]Chemistry, West Chester University of Pennsylvania, [2]Biology, West Chester University of Pennsylvania ylvania, [3]Biology, West Chester University of Pennsylvania

The ability to develop and sustain immune responses in organisms plays an important role in their survival against pathogens and stressors. In the nematode *Caenorhabditis elegans*, the Intracellular Pathogen Response (IPR) functions as an important immune defense mechanism against a range of stressors and pathogenic threats. While viral infection, proteasome activity, and exposure to heat stress are recognized as triggers for activating the IPR in *C. elegans*, our research findings have unveiled a previously unrecognized inducer: Ethanol-induced intestinal wounding in *C. elegans*, leading to the upregulation of IPR-related genes. This discovery raises the hypothesis that intestinal wounding may represent a distinct branch within the IPR activation pathway but the factors responsible for initiating and defining this pathway and its implications for innate immunity in humans remain to be solved. Our research has identified 6% ethanol as a novel method for inducing intestinal wounding, thereby stimulating IPR activation. This discovery presents the potential for its application in high-throughput procedures, facilitating genome-wide screenings and advancing our understanding of this intricate immune response mechanism.

1262T **Targeted mutations of miRNA duplexes reveal asymmetries important for proper strand selection *in vivo*** Jeffrey C Medley[1], Sumire Kurosu[1], Ganesh Panzade[2], Sarah Coffey[1], Will Sydzyik[1], Joel Sydzyik[1], Mira Bhandari[3], Anna Zinovyeva[1] [1]Division of Biology, Kansas State University, [2]Frederick National Laboratory for Cancer Research, [3]Department of Molecular and Integrative Physiology, University of Michigan

Animal development relies on timely expression and inactivation of genes to achieve diverse cellular functions. microRNAs (miRNAs) are non-coding RNAs that play a central role in the regulation of eukaryotic gene expression, typically by repressing their target genes. miRNAs are genomically encoded as double-stranded molecules that are processed into a duplex comprising two functionally distinct strands. One dominant (guide) strand is loaded into an Argonaute (Ago) protein to form the miRNA-induced silencing complex (miRISC), while the other (passenger) strand is degraded. As miRNAs target genes based on nucleotide base-pairing, the asymmetric decision of which strand is loaded into Ago effectively determines the target repertoire of miRISC. Previous studies have suggested that 5' nucleotide identity and thermodynamic asymmetry of miRNA duplex ends is sufficient to explain which strand is preferred for Ago loading *in vitro* and can predict which strand is selected *in vivo*. However, many mature miRNAs do not have sequence features favorable for Ago loading. In addition, the actual ratio of each strand remains difficult to predict. Here, we tested different approaches for calculating duplex end stabilities and assessed how each approach predicted experimentally observed *in vivo C. elegans* miRNA strand ratios. By testing different models of thermodynamic asymmetry, we were able to closely predict the direction and relative strand ratios of most *C. elegans* miRNAs. We find that strand predictions can sometimes be improved by considering how miRNA precursors may constrain the duplex structure, rather than only considering the minimum free energy state of the duplex. To test different strand selection models, we mutated three endogenous *C. elegans* miRNAs to alter their duplex characteristics and examine how strand selection was affected. We found mutations affecting both 5' nucleotide and thermodynamic asymmetry were sufficient to reverse strand selection of each miRNA *in vivo*, although the relative contribution of each factor appeared miRNA-dependent. In part, these differences might be explained by differences in the relative stability of each miRNA strand, or inability of certain strands to stably load into Ago. Current work is aimed at refining strand selection predictions and examining the contributions of Agos and other factors towards proper strand selection. Collectively, our findings provide insights into how asymmetric miRNA strand selection is achieved *in vivo*.

1263T **Cohesin mediated loop extrusion from active enhancers form chromatin jets in *C. elegans*** Sevinc Ercan, Jun Kim New York University

In mammals, cohesin and CTCF organize the 3D genome into topologically associated domains (TADs) to regulate communication between cis-regulatory elements. However, many organisms, including S. cerevisiae, C. elegans, and A. thaliana lack CTCF. Here, we use C. elegans as a model to investigate the function of cohesin in 3D genome organization in an animal without CTCF. We use auxin-inducible degradation to acutely deplete SMC-3 or its negative regulator WAPL-1 from

somatic cells. Using Hi-C data, we identify a cohesin-dependent 3D genome feature termed chromatin jets (aka fountains), also observed in zebrafish and mammalian genomes. The jets emerge from NIPBL occupied segments, and the trajectory of the jets coincides with cohesin binding. The spreading of cohesin from jet origins depends on a fully intact cohesin complex and is extended upon WAPL-1 depletion. These results support the idea that cohesin is preferentially loaded at NIPBL occupied sites, from which cohesin loop extrudes in an effectively two-sided manner. The location of putative loading sites coincides with active enhancers and the pattern of chromatin jets correlates with transcription. We propose that in the absence of CTCF, preferential loading of cohesin at enhancers is a conserved mechanism of genome organization that regulates the interaction of gene regulatory elements in 3D.

1264T **S-adenosylmethionine synthases specify distinct H3K4me3 populations and gene expression patterns during heat stress** Amy K Walker[1], Adwait Godbole[2], Alexander Munden[2] [1]Program in Molecular Medicine, UMASS Medical School, [2]PMM, UMASS Medical School

Methylation is a widely occurring modification that requires the methyl donor S-adenosylmethionine (SAM) and acts in regulation of gene expression and other processes. SAM is synthesized from methionine, which is imported or generated through the 1-carbon cycle (1CC). Alterations in 1CC function have clear effects on lifespan and stress responses, but the wide distribution of this modification has made identification of specific mechanistic links difficult. We hypothesize that provisioning of SAM through specific synthases provides a level of regulatory specificity to methylation dependent pathways. In most animals, SAM may be synthesized by one of several SAM synthases. For example, mammals contain two SAM synthases, one of which is specific to adult liver (MAT1A). While MAT2A is ubiquitous, it may exist in multiple isoforms. The SAM synthase family in C. elegans is expanded, with 4 isoforms. Sams-1 is the most highly studied, with roles in lifespan extension, lipid storage and complex function in the stress response. Lowering SAM to similar levels by limiting *sams-4* is not sufficient to recapitulate these phenotypes, suggesting it is not the level of SAM, but how or where it is produced that provides the regulatory specificity. Tissue specific effects could explain some functional differences. However, using CRISPR tagged alleles, we find that SAMS-1 and SAMS-4 are largely co-expressed with the exception of the germline, which lacks SAMS-1.

We are leveraging the heat stress response to identify regulatory effects controlling differential effects. Reduction in these enzymes produces opposite phenotypes, distinct heat responsive gene expression programs, metabolic changes and H3K4me3 methylation patterns. We also find that SAMS-4 initiates a distinct histone methylation program in the absence of SAMS-1 that impacts survival. Our preliminary data suggest SAMS-1 and SAMS-4 have some distinctions in their local proteomes, suggesting potential for distinct methylation targets or regulatory interactions. Taken together, our results suggest that the regulatory functions of SAM depend on its enzymatic source and that provisioning of SAM may be an important regulatory step linking 1CC function to phenotypes in aging and stress.

1265T **Optimization of CUT&RUN for lowly expressed transcription factors in C. elegans' larval stages** Jada Coffey, Dagmawi Lulseged, Alexis Roudenko, Deborah M Thurtle-Schmidt Biology, Davidson College

Genome-wide chromatin profiling is a vital technique that elucidates interaction between transcription factors and DNA. These interactions are necessary for proper gene regulation. Cleavage Under Targets and Release Using Nuclease (CUT&RUN) is a recently developed chromatin profiling method that allows for profiling specific DNA-protein interactions in a short amount of time and with much less background noise. CUT&RUN uses antibody-targeted cleavage to release specific protein-DNA fragment complexes for DNA sequencing. Chromatin profiling techniques have been difficult to adapt to *C. elegans* due to the worm's tough cuticle. Two studies thus far have adapted CUT&RUN for *C. elegans*, using abundant histone epitopes or in adults. Here we optimize the CUT&RUN protocol for *C. elegans* to characterize lowly expressed transcription factors at larval stages. We optimized our worm-growing and bleaching protocol, to isolate a sufficient number of worms at the correct larval stage. *C. elegans* were permeabilized using a grinding protocol and Tapestation and Qubit analysis indicated DNA recovery. The sequencing analysis is pending. In future studies, we will adapt this CUT&RUN protocol to determine if EOR-1 is a pioneer factor for NHR-25 through profiling of NHR-25 binding in the presence and absence of *eor-1*.

1266T **Prophage proteins modulate eukaryotic long non-coding RNA and DNA to spread *Wolbachia* symbiont** Rupinder Kaur[1], Angelina McGarry[1], Dylan J Shropshire[2,3], Brittany A Leigh[2], Isabella T Ritchie[2], Seth R Bordenstein[4] [1]Biology, Pennsylvania State University, [2]Vanderbilt University, [3]Lehigh University, [4]Pennsylvania State University

The widespread distribution of endosymbiotic bacteria *Wolbachia* in arthropods and massive success in mosquito control efforts is in part due to a drive system named cytoplasmic incompatibility (CI). CI confers a paternal-effect, embryonic lethality when sperm from *Wolbachia*-bearing testes fertilize eggs from uninfected females. The rising success in deploying CI for vector control strategies necessitates an explanation of the CI mechanism. In *Drosophila melanogaster* carrying *w*Mel *Wolbachia* strain, CI is induced by two prophage-WO encoded proteins – CifA and CifB that

target sperm nuclei during development. Here we characterize the cellular and biochemical properties of the Cif proteins and show that 1) CifA is a RNase enzyme that diminishes a spermatocyte-expressing long non-coding (lnc) RNA earlier in spermatogenesis, and knockdown of the lncRNA in spermatocytes enhances CI levels, 2) CifA and CifB are both DNases that elevate DNA damage in elongating spermatids, 3) Cifs alter the sperm chromatin integrity by impairing histone and protamine nucleoproteins composition during late spermiogenesis, and finally 4) the uninfected embryo fertilized by compromised CI sperm suffers from DNA damage during nuclear divisions leading to embryonic death. We conclude that the mechanism of CI-induced embryonic death relies on a cascade of paternal chromatin integrity changes pre-established in testes during sperm development. This work unlocks a previously-unrecognized phenomenon by which prophage proteins alter central dogma features of *Drosophila* gametogenesis to fashion a worldwide symbiosis with relevance to vector control and insect evolution.

1267T **Targeting an Active Chromatin Domain to the Drosophila X-chromosome** Melissa Aldana, Angelica Aragon Vasquez, Claire Gray, Joseph Aguilera, Mukulika Ray, Erica Larschan MCB, Brown University

In male Drosophila, the Dosage Compensation Complex (DCC) is targeted to the X-chromosome via a transcription factor-Chromatin-linked Adaptor for MSL complex (CLAMP). Targeting the DCC to the X-chromosome upregulates the active genes along the single X-chromosome in males two-fold, equalizing the X-chromosome transcriptional output with that from the two autosomes. Different regions of CLAMP were excised to dissect the regions necessary for proper DCC distribution along the X-chromosome. However, CLAMP binds to all chromosomes and therefore the key question is: How does CLAMP specifically target the DCC to all chromosomes? I performed Cleavage Under Targets and Release Using Nuclease (CUT&RUN) to better understand DCC targeting the X-chromosome in CLAMP mutants. After isolating the DNA fragments post-CUT&RUN, I prepared for Next Generation Sequencing. I obtained my sequencing data, I performed analyses to investigate DCC binding with Deeptools. Looking at the conserved motifs in this region, high promiscuity suggests other transcription factors can bind at the sites where there are not as many conserved motifs. Using ReactomePA, the pathway and gene ontology enrichment clusters in clamp mutants but not wild type are significantly associated with programmed cell death suggesting that CLAMP prevents binding to genes that induce cell death.

1268T **The single-cell transcriptome and chromatin landscape analysis elucidates synaptic gene regulation during Drosophila embryonic development** Tuan Pham, Justin Currie, James Kentro, Gunjan Singh, Erica Larschan, Kate O›Connor-Giles Brown University

Coordinated gene regulation is essential for the generation and maintenance of diverse cellular states during development. The precise activation or repression of transcription is primarily controlled by transcription factors (TFs) that form gene regulatory networks (GRNs) amongst themselves and with their target genes.The Drosophila brain is an excellent model in neuroscience. Leveraging an atlas of scRNA-seq and scATAC-seq from the Drosophila embryonic development and current computational methods, we have identified specific GRNs modulating synaptic genes for 6 timepoints during nervous system development from 6h to18h. Our findings not only show well-defined regulators of synaptic genes consistent with current literature but also less-studied TFs that are excellent candidates for further experimental investigation in nervous system development. We also highlight noticeable similarities and changes over time in GRNs that might be key to understanding temporal regulation of the brain.

1269T **Impacts of Heat Shock on Transcriptional Noise Driven by Developmental Shadow Enhancers** Julia Gibbs[1], Zeba Wunderlich[2], Jillian Ness[2] [1]Biology, Boston University, [2]Boston University

The precise control of developmental gene expression drives the development of the whole organism, from specifying individual cells to patterning tissue development. Yet this occurs through inherently noisy processes, like transcription and translation, and often does so under stressful environmental conditions. Stress can increase noise in a system, as it disrupts several processes central to normal cell activity, and no species can escape heat waves, infection, or other stresses that can occur during development. Thus, several control mechanisms have evolved to control noise in developmental processes, even under stressful conditions. One of these mechanisms is shadow enhancers, sets of two or more enhancers that control the same gene and drive overlapping gene expression patterns. These enhancer sets are often not necessary for proper development under ideal conditions. However, under stressful conditions, they drive developmental stability, lowering noise in developmental gene expression and promoting formation of wild-type flies. How exactly they achieve this stability, and this lowering of noise, still needs to be explored. Previous work in the lab measured the expression dynamics of the Kruppel shadow enhancer system in early Drosophila embryos and found that the individual enhancers in the set have distinct reactions to heat stress. While the promoter-distal enhancer of the system shows the expected increase in transcriptional noise under stress, the promoter-proximal enhancer showed no significant changes in noise. There are several possible explanations for this, but central amongst them is the structure of the enhancer itself, i.e. its transcription factor binding sites and the histone marks present in vivo. To gain insight into distinct reactions of enhancers to heat stress, I performed ATAC-Seq on embryos at ideal and elevated temperatures and analyzed the resulting data using the TF footprinting method TOBIAS. This

allowed me to gather data on both chromatin accessibility changes and the changes in TF binding that occur under heat shock. Using this data, I will investigate how TF binding and histone marks affect an enhancer's response. I will use ChIP-Seq to more directly probe TF binding mechanics, or histone modifications, that affect each individual enhancer, and combine that with my ATAC-Seq data to understand each enhancer's stress reaction. From this, we will better understand how developmental genes maintain robust expression, and potentially, how we can recapitulate that robustness when developmental systems begin to fail.

1270T **Characterization of Bedwarfed in genome organization and transcription in *Drosophila*** Dagyeong Yang[1,2], Elissa P. Lei[1] [1]NIDDK/NIH, [2]University of Maryland College Park

Three-dimensional (3D) spatial organization of the interphase genome is an important factor influencing gene regulation. The interphase genome segregates into highly self-interacting topologically associated domains (TADs) that influence regulation of gene expression. The boundaries of TADs are maintained in part by DNA-protein complexes termed chromatin insulators, including the universal Centrosomal Protein 190kD (Cp190). In addition to chromatin insulators, these boundaries are often marked by active transcription and enrichment of the core promoter, motif-1. Recent studies have shown that a transcription factor that binds to motif-1, M1BP, and CP190 physically interact and are together required for motif-1 dependent gene expression and transcription near TAD boundaries.

Along with M1BP, an *in vitro* pull-down assay identified several motif-1 associated proteins, including Gfzf, Putzig, and Bdwf (Bedwarfed). Bdwf has been shown to function in *Drosophila* neuronal development. However, a functional relationship between Bdwf and motif-1 sequence remains unknown. In this study, we analyze the potential function of Bdwf in genome organization and gene regulation. Our analysis of ChIP-seq data from the ENCODE project revealed substantial overlap of Bdwf with CP190, M1BP, and BEAF-32 at TAD borders. Utilizing MEME-ChIP, we confirmed the enrichment of motif-1 at Bdwf binding sites throughout the genome. Ongoing research aims to elucidate how Bdwf contributes to motif-1 dependent gene expression using a plasmid-based luciferase reporter assay. Moreover, RNAseq analysis revealed enrichment of differentially expressed genes near TAD borders after depletion of Bdwf in Kc cells, suggesting a role for Bdwf in regulating gene expression at these sites. To further understand its role in transcription, we will perform Nascent RNAseq. Overall, our studies will reveal the function of Bdwf in *Drosophila* genome organization and transcriptional regulation.

1271T **Genome organization mediated by a MADF-BESS protein is critical for nuclear pore complex production and cell fate transition during Drosophila oogenesis** Noor M Kotb[1], Gulay Ulukaya[2], Ankita Chavan[3,4], Lydia Proskauer[5], Eric Joyce[6], Dan Hasson[2], Madhav Jagannathan[7], Prashanth Rangan[8] [1]CDRB/BMS, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA/ University of Albany, Albany,NY 12207,USA, [2]Tisch Cancer Institute Bioinformatics for Next Generation Sequencing (BiNGS) core, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA, [3]Department of Biology, Institute of Biochemistry, ETH Zürich, 8092 Zurich, [4]Department of Biology, Institute of Biochemistry, ETH Zürich, [5]Biochemistry and Molecular Biology Department, College of Natural Sciences, University of Massachusetts Amherst, [6]Department of Genetics, University of Pennsylvania, Philadelphia, PA 19104, [7]Department of Biology, ETH Zürich, 8092 Zurich, [8]Department of Cell, Developmental, and Regenerative Biology, Black Family Stem Cell Institute, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA

Genome organization can regulate gene expression and promote cell fate transitions. The differentiation of germline stem cells (GSCs) to oocytes in Drosophila melanogaster involves changes in genome organization mediated by heterochromatin and the nuclear pore complex (NPC). Heterochromatin represses germ-cell genes during differentiation and NPCs anchor these silenced genes to the nuclear periphery, maintaining silencing to allow for oocyte development. Surprisingly, we find that genome organization also contributes to NPC formation, mediated by the transcription factor Stonewall (Stwl). As GSCs differentiate, Stwl accumulates at boundaries between silenced and active gene compartments. Stwl at these boundaries plays a pivotal role in transitioning germ-cell genes into a silenced state and activating a group of oocyte genes and Nucleoporins (Nup) by regulating enhancer activity. The upregulation of these Nups during differentiation is crucial for NPC formation and further genome organization. Thus, crosstalk between genome architecture and NPCs is essential for successful cell fate transitions.

1272T **KDM5-mediated transcriptional activation of ribosomal protein genes alters translation efficiency to regulate mitochondrial metabolism in neurons** Matanel Yheskel[1], Hayden AM Hatch[2], Erika Pedrosa[3], Bethany K Terry[1], Xiang Yu[1], Laura E.R. Blok[4], Michaela Fencková[5], Simone Sidoli[6], Annette Schenck[4], Deyou Zheng[1], Herbert M Lachman[7], Julie Secombe[8] [1]Genetics, Albert Einstein College of Medicine, [2]Neuroscience, Albert Einstein College of Medicine, [3]Psychiatry and Behavioral Sciences, Albert Einstein College of Medicine, [4]Human Genetics, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, [5]Molecular Biology and Genetics, University of South Bohemia, [6]Biochemistry, Albert Einstein College of Medicine, [7]Medicine, Albert Einstein College of Medicine, [8]Albert Einstein College of Medicine

Genes encoding the KDM5 family of transcriptional regulators are disrupted in individuals with intellectual disability (ID). To understand the link between KDM5 and ID, we characterized five *Drosophila* strains harboring missense alleles analogous to those observed in patients. These alleles disrupted neuroanatomical development, cognition and other behaviors, and displayed a transcriptional signature characterized by the downregulation of many ribosomal protein genes. A similar transcriptional profile was observed in *KDM5C* knockout iPSC-induced human glutamatergic neurons, suggesting an evolutionarily conserved role for KDM5 proteins in regulating this class of genes. In *Drosophila*, reducing KDM5 changed neuronal ribosome composition, lowered the translation efficiency of mRNAs required for mitochondrial function, and altered mitochondrial metabolism. These data highlight the cellular consequences of altered KDM5-regulated transcriptional programs that could contribute to cognitive and behavioral phenotypes. Moreover, they suggest that KDM5 may be part of a broader network of proteins that influence cognition by regulating protein synthesis.

1273T **Role of different protein domains in context dependent function of transcription factors** Victoria Chen, Mukulika Ray, Jasmine Shum, Pranav Mahableshwarkar, Julia Zaborowsky, Nicolas Fawzi, Erica Larschan Brown University

Transcription factors (TFs) play an important role in regulating spatiotemporal gene expression. It remains unclear how the same TF controls multiple processes and is targeted to the right genomic location in the right cellular context. In the present study, we explore the role of different protein domains in deciding TF function. We use the GA-rich DNA binding transcription factor CLAMP (Chromatin-linked adapter for MSL proteins) as a model.

CLAMP is enriched on the Male-X chromosome and helps in recruitment of the Male-sex lethal complex (MSL complex) that increases transcription on the Male-X chromosome, a process called dosage compensation since it maintains the ratio of transcription between XX female and XY male individuals. Also, CLAMP is important for sex-specific splicing in female and male individuals from early embryonic stage. We studied the role of different regions of the CLAMP protein in regulating both of these functions.

The N-terminal 52-153 amino acid (a.a) region with a zinc finger domain in the CLAMP protein is important for binding to the MSL complex protein MSL2. Adjacent to the MSL2 binding domain is the disordered glycine-rich PrLD region (153-292 a.a), known to be important for RNA binding. Earlier studies in CRISPR-generated fly mutants have shown that deletion of the N-terminal Zinc Finger domain and Prion-like domain (PrLD) results in CLAMP-dependent splicing changes. The former mutant affected distribution of MSL complex protein MSL2. We hypothesize that different domains of CLAMP influence CLAMP interaction with specific DNA and RNA sequences, thus resulting in specific function.

In the lab, we had already expressed PrLD-deleted CLAMP proteins in the bacterial expression system with the help of the Fawzi Lab. We also used PCR-mutagenesis to generate plasmids with deletions in the Zinc Finger (ZnF) domain of the full-length and 1-300 amino acid long CLAMP. Mutant proteins using these plasmids were expressed, which were used to perform RNA and DNA gel shift assays to determine protein-nucleic acid interactions. We found that the PrLD domain of CLAMP is essential for binding to specific RNA sequences. We also identified specific RNA sequences that aid in binding to CLAMP proteins. Furthermore, full-length CLAMP has better binding efficiency than 1-300 length CLAMP.

1274T **SUMO inhibits Scm polymerization and association with developmentally-silenced target genes** Steven Z DeLuca[1,2], Tian Tan[2], David Lyons[1] [1]Microbiology and Cell Biology, Montana State University, [2]Biology, Brandeis University

During animal development, Polycomb-group (PcG) proteins associate with tissue-specific target genes to inhibit their inappropriate expression in the wrong tissues. In the correct tissue, Trithorax-group (TxG) proteins associate with target genes to somehow prevent PcG proteins from inhibiting them. There are likely multiple mechanisms through which TxG proteins inhibit PcG proteins. Here, we use the Drosophila ovary model system to identify a new TxG protein, Su(var)2-10, that is important for preventing the silencing of the expressed target gene, caudal. Furthermore, we show that Su(var)2-10 promotes the SUMOylation of the PcG protein, Scm, on three lysine residues. These SUMOylated lysines allosterically inhibit Scm from polymerizing and fully associating with Polycomb Response Elements (PREs) on target genes like caudal. Through genetic alterations to the Scm polymerization domain and SUMOylation sites, we show that polymerization correlates with PRE occupancy and target gene silencing. Together, our experiments suggest a new model where Scm is differentially SUMOylated and polymerized on target genes to regulate their expression or silencing.

1275T **Histone H3 lysine 4 is required for proper activation of Polycomb target genes** Cyril S Anyetei-Anum[1], Daniel J. McKay[2,3,4] [1]Curriculum in Genetics & Molecular Biology, University of North Carolina Chapel Hill, [2]Department of Biology, University of North Carolina Chapel Hill, [3]Department of Genetics, University of North Carolina Chapel Hill, [4]Integrative Program for Biological and Genome Sciences, University of North Carolina Chapel Hill

Polycomb Group (PcG) genes encode a highly conserved group of epigenetic regulators required for maintenance of cell

identities. They function through heritable silencing of important developmental genes such as the Hox genes. There are two major Polycomb Repressive complexes, PRC1 and PRC2, that have different roles in target gene repression. PRC2 contains the histone methyltransferase subunit E(z) in *Drosophila* that trimethylates histone H3 lysine 27 (H3K27me3). PRC1 binds this post-translational modification (PTM), and together with PRC2, forms repressive chromatin domains that extend across silenced target genes. Trithorax Group (TrxG) proteins, by contrast, are required to promote gene expression. The TrxG founding member, Trithorax, is a methyltransferase specific to histone H3 lysine 4 (H3K4) -- a PTM tightly associated with active genes. Genetic studies indicate that Trx antagonizes the function of PcG complexes, leading to current models in which the balance of Trx and PcG activity determines whether target genes are expressed or repressed. However, the mechanisms underlying this antagonism are unclear. One line of evidence suggests a contribution of H3K4 methylation in controlling the balance between the on and off state. Namely, H3K4me3 peptides inhibit the enzymatic activity of PRC2 *in vitro*. Here, we test the functional role of H3K4 in the balance between the active and repressed states *in vivo*. We employ a genetic platform to replace the endogenous replication-dependent histone genes with transgenic versions engineered to encode a non-modifiable H3.2K4 residue (H3.2K4R). We find that H3.2K4R mutants die early in development with decreased H3K4 methylation levels. Surprisingly, H3.2K4R mutants also exhibit decreased H3K27me3 levels, suggesting a defect in PcG function. However, despite lower H3K27me3 levels, H3.2K4R mutant cells do not exhibit Hox gene derepression, suggesting that H3.2K4 contributes to PcG target gene activation. To directly test whether H3.2K4 is required for activation of PcG target genes, we generated replacement flies expressing H3.2K4R,K27R double mutant histones. We find that Hox gene derepression is significantly reduced relative to levels observed in H3.2K27R single mutant cells. Collectively, our studies support a role for H3.2K4 in PcG target gene activation.

1276T **Transcriptomic analyses of Set2 and H3^{K36R} mutants reveal heterogeneous regulation of X chromosome gene expression** Harmony Salzler[1], Vasudha Vandadi[1], A. Gregory Matera[1,2,2,3,4] [1]Integrative Program for Biological and Genome Sciences, UNC Chapel Hill, [2]Genetics, UNC Chapel Hill, [3]Biology, UNC Chapel Hill, [4]Lineberger Comprehensive Cancer Center, UNC Chapel Hill

Different sex chromosome karyotypes present a challenge to balanced X chromosome gene expression in many species. In flies, dosage compensation (DC) is achieved by upregulation of male X genes by the male-specific lethal (MSL) complex, which binds high-affinity sites and spreads to surrounding genes, propagating H4 lysine 16 (H4K16) acetylation. A full understanding of MSL complex spreading has been elusive, but current models focus on the potential of male-specific lethal 3 to interact with modified histone tails, in particular Set2-dependent trimethylation of H3 lysine 36 (H3K36me3). Recent work in the DC field questions the relevance of H3K36me3 to MSL spreading, suggesting that Set2 may exert an effect on DC via another target. While intriguing, the possibility of redundancy between lysine 36 of H3.2 and H3.3 histone variants has not been sufficiently investigated, and distinctions between canonical (MSL mediated) DC and other modes of X chromosome regulation (applicable to females) have not been explored.

To address these questions, we employed genomic approaches in *H3.2^{K36R}*, *H3.3^{K36R}*, *H4^{K16R}*, and *Set2Δ* mutants. Larval brain RNA-Seq in both sexes confirms a role for Set2 in X chromosome gene regulation and reveals that many genes bound by high levels of MSL complex in males follow the same gene expression trends in females (where the MSL complex is inactive), albeit to a lesser degree. Furthermore, *k*-means clustering of expression changes uncovers surprisingly heterogeneous effects of Set2 and H3K36 on X chromosome genes. Intriguingly, we observe gene groups where residue and writer mutations push gene expression in opposite directions, suggesting that other modification states of H3K36 may be important regulators of these genes. To address redundancy between H3 variants, we performed RNA-Seq in L1 animals combining *H3.2^{K36R}* and *H3.3^{K36R}* mutations. These data suggest that H3.2K36 and H3.3K36 are largely redundant in regulation of X genes. Importantly, heterogeneous expression changes in *Set2Δ* and *H3^{K36R}* mutants contrast strongly to the ubiquitous reduction in X chromosome gene expression in *H4^{K16R}* mutants. We also observe that *Set2* mutation exerts opposite effects on many genes at this different tissue/stage, suggesting significant context dependence. Overall, these data are inconsistent with the prevailing model where Set2 and H3K36 directly recruit the MSL complex. Rather we hypothesize that Set2 via H3K36 supports DC indirectly by regulating processes involved in DC, but common to both sexes.

1277T **Defining Activities of KDM5 Essential to Development and Viability** Melissa Castiglione[1], Hayden Hatch[2], Andreas Bergmann[3,4], Hans Martin-Herz[4,5], Julie Secombe[2,6] [1]Albert Einstein College of Medicine, [2]Neuroscience, Albert Einstein College of Medicine, [3]University of Massachusetts Chan Medical School, [4]MD Anderson Cancer Center, [5]St. Jude Children's Research Hospital, [6]Genetics, Albert Einstein College of Medicine

The Lysine demethylase 5 (KDM5) family of transcriptional regulators are important for normal development, and their dysregulation is a key driver of intellectual disability and several forms of cancer. In this work, we examine essential functions of KDM5 via a novel truncation allele, *kdm5Q19. kdm5Q19* inserts a stop codon in a previously unrecognized, evolutionarily conserved, motif within an intrinsically disordered region of KDM5 at the C-terminus, removing the final 311 amino

acids. *kdm5Q19* animals do not survive to adulthood and have a slight developmental delay, a phenotype distinct from null, demethylase dead, and other mutants generated in our lab, suggesting that the region disrupted by the truncation has an essential as-yet-unknown role in normal KDM5 function in development. To further dissect the molecular activities of this region of KDM5, we generate additional alleles of *kdm5* to refine the critical region(s) of the protein and assess viability and changes to transcription.

In this work, we will (1) define essential regions within KDM5 required for viability, and to characterize their roles in development (2) define the essential molecular functions imparted by the C-terminus of KDM5. Together, these studies will refine the critical region(s) of the C-terminus of KDM5, and define the normal role of these regions in regulating transcription.

1278T **Determining essential, pioneering features of the conserved transcription factor Grainy head** Meghan M Freund[1], Tyler J Gibson[1], Andrew Q Rashoff[1], F. Javier deHaro-Arbano[2], Sarah Baloul[2], Abby J. Ruffridge[1], Peter W. Lewis[1], Sara J. Bray[2], Melissa M. Harrison[1] [1]University of Wisconsin-Madison, [2]University of Cambridge

Beginning from a single cell, organisms undergo a journey of differentiation that results in many unique cell types. Because these cells all possess the same genome, distinct cell types do not arise due to differences in genotype. Instead, regulation of gene expression drives cell-type specification. Transcription factors play an important role in this process by binding DNA to promote gene expression. Nonetheless, compacted chromatin acts as a barrier to transcription-factor binding. A specialized class of transcription factors, known as pioneer factors, overcome this barrier by binding to condensed chromatin and increasing chromatin accessibility. The mechanisms governing pioneer factor activity are not well understood. Grainy head (Grh) is an essential and highly conserved pioneer factor that drives epithelial cell fate and when mis-expressed leads to cancer. We use Grh as a model to explore the fundamental mechanisms by which pioneer factors engage the genome and shape cellular identity. A combination of biochemistry, genomics, and quantitative imaging has begun to elucidate key features of Grh. We showed that full-length Grh binds nucleosomes *in vitro* and drives accessibility when exogenously expressed in tissue culture. This pioneering activity requires DNA binding, but the DBD is not sufficient. Quantitative imaging revealed that Grh stably occupies the genome, likely an essential feature of pioneer activity, and that regions outside the DBD are required for stable occupancy. Altogether this suggests that regions within and outside the Grh DBD are instrumental in pioneering. Additionally, expression of mammalian orthologs in *Drosophila* tissue culture demonstrates that pioneering is a conserved feature of Grh. A subset of pioneer factors, including Grh, is retained on compacted mitotic chromosomes, yet the relationship between mitotic retention and pioneering function remains unclear. Residues that mediate DNA binding are necessary for mitotic retention, but regions outside the DBD are dispensable. This contrasts with the requirement of additional domains for stable-genome occupancy and pioneer-factor function. By exploring the properties of Grh using multiple, complementary assays, we provide fundamental insights into the mechanisms by which a conserved pioneer factor engages the genome to promote chromatin accessibility and drive cell fate.

1279T **Interactions Between the Histone Variant H2Av and Insulators in *Drosophila* Influence the DNA Damage Response and Lymph Gland Development** James R Simmons[1], Justin D. J. Kemp[2], Mariano Labrador[3] [1]Biochemistry and Cell and Molecular Biology, The University of Tennessee at Knoxville, [2]Biochemistry and Cell and Molecular Biology, The University of Tennesse, [3]University of Chicago Alumni

Genome architecture is regulated by chromatin insulator proteins, and misregulation of insulator function is associated with genome instability and transcriptional regulatory defects in both vertebrates and *Drosophila*. Indeed, mutations of the sole insulator protein in humans, CTCF, are carcinogenic and mutations in the *Drosophila* insulator protein *Suppressor of Hairy wing* [Su(Hw)] lead to chromosomal rearrangements. However, the mechanism that links the DNA damage response and the regulation of transcription with insulator function is not yet understood. Here we show that enrichment of Su(Hw) insulator proteins at insulator sites increases after DNA damage. Additionally, Su(Hw) is necessary for phosphorylation of the histone variant H2Av in response to both UV treatment and X-ray irradiation. Similarly, we provide evidence that Su(Hw) and H2Av work together to ensure proper development of the lymph gland in *Drosophila* larvae. We show that H2Av regulates formation of the larval lymph gland, and mutation of H2Av causes formation of large melanotic tumors that are rescued by mutation of *su(Hw)* in the *His2Av^{810}* mutant background. Double mutants of *su(Hw)$^{-}$* and *His2Av^{810}* also form supernumerary lymph gland lobes that are larger than in wild type. Our findings support a role for the Su(Hw) in the DNA damage response through the regulation of H2Av phosphorylation and suggest that Su(Hw) and H2Av also work together to ensure proper development of the lymph gland.

1280T **Altering phosphorylation of HP1a induces sterility and excites early cell death in *Drosophila melanogaster*** James C Walts[1], Nicole C Riddle[2] [1]Biology, University of Alabama at Birmingham, [2]University of Alabama at Birmingham

Authors: James C. Walts, Nicole C. Riddle

Affiliations: Department of Biology, The University of Alabama at Birmingham, Birmingham, AL

Abstract

The Heterochromatin protein 1 (HP1) family are non-histone chromosomal proteins that are key factors in the formation of heterochromatin and in transcriptional regulation. HP1 proteins are found in many eukaryotic organisms including plants, animals, and fungi. HP1a from *D. melanogaster* was the first HP1 protein discovered, and it has been intensively studies for more than three decades. HP1a can act both as a repressor and an activator of transcription. Like many other proteins, HP1a undergoes post-translational modifications such as phosphorylation. However, little is known about the functions of HP1 post-translational modifications, including phosphorylation. To advance our understanding of HP1a's post-translational modifications, we produced two HP1a mutants that either mimic or block phosphorylation. Specifically, we replaced serines (S) 88/89/91 (S88/89/91) either with glutamic acid (E) to mimic permanent phosphorylation or with alanine (A) block phosphorylation. Using these mutant strains, we investigated how phosphorylation of HP1a impacts its known functions. Western blot analysis demonstrated that the phospho-mimic HP1a protein is stable but accumulates in decreased levels compared to wildtype HP1a. A position effect variegation (PEV) assay indicated that both phospho-mimic and phospho-block HP1a alleles act as suppressors of variegation. On the organismal level, we found that homozygous phospho-mimic HP1a mutants have a significant reduction in fertility for both males and females compared to heterozygous and wildtype animals. We observed a significant decrease in ovary size for the homozygous phospho-mimic HP1a mutant females when compared to heterozygous and wildtype animals. Parallel experiments with the HP1a phospho-block mutant strain are ongoing. Overall, our results show a significant fertility decrease, possibly due to the decreased ovary size in homozygous mutants, a decrease in overall mutant protein concentration with an increase in suppression of variegation when compared to a control. These results suggest that phosphorylation of HP1a proteins at the site we modified (S88/89/91) might have specific functions in the Drosophila germline.

1281T **The effects of *draper* gene knockdown in different tissues on ovarian function in *Drosophila melanogaster*** Pamela Yang, Cameron Dixon, Kimberly McCall, Jeremy Rojas Boston University

The gene *draper (drpr)* in *Drosophila melanogaster* is critical in cell clearance through its role as a phagocytic receptor. *drpr* plays a vital role in maintaining multiple tissues by clearing dead cells, bacteria, and debris. Recent research has shown decreased fecundity and increased egg retention when the *drpr* gene is absent. While mutants show defects in ovary maintenance, it is unclear which tissues are critical in this gene expression for whole body physiology. Using a tissue-specific RNA interference approach, dissection results showed a strong egg retention phenotype when *drpr* was knocked down with two different drivers: *elavGal4* (neurons) and *esgGal4* (gut). These initial results suggest that *Drosophila* with *drpr* deficient neurons or gut precursor cells have severe egg retention. Interestingly, another neuron driver tested, *nSybGal4*, did not have the same egg retention phenotype as *elavGal4* even though they targeted the same tissue. This may be due to the expression of *elav* primarily in early embryonic stages while *nSyb* is expressed mainly in adulthood, which questions the role of *drpr* expression in developmental stages for proper ovarian function. To further investigate this hypothesis, we are currently conducting temperature sensitive Gal80 experiments to introduce conditional knockdowns of *drpr* expression at different developmental stages in order to analyze their respective phenotypes. There are 3 transitional stages: larval, pupal, and adult, in which the *drpr* gene will be knocked down. We expect different severities in adult ovarian function with the larval transition group potentially having the highest egg retention phenotype. Further study will test this hypothesis and determine the severity of phenotype corresponding with each developmental stage *drpr* knockdown.

1282T **Drosophila Amus and Bin3 methylases functionally replace mammalian MePCE for capping and the stabilization of U6 and 7SK snRNAs** qiu peng, yiqing wang, ying xiao, Yikang Rong hengyang college of medicine, university of south china

U6 and 7SK snRNAs possess a 5' cap, believed to be essential for their stability and maintained by mammalian MePCE or Drosophila Bin3 enzymes. Although both proteins are required for 7SK stability, loss of neither destabilizes U6, casting doubts on the function of capping U6. Here we show that the Drosophila Amus protein, homologous to both proteins, is essential for U6 but not 7SK stability. The loss of U6 is rescued by the expression of an Amus-MePCE hybrid protein harboring the methyltransferase domain from MePCE, highlighting the conserved function of the two proteins as the U6 capping enzyme. Our new investigations in human cells establish a dependence of both U6 and 7SK stability on MePCE, resolving a long-standing uncertainty. While uncovering a division of labor of Bin3/MePCE/Amus proteins, we discovered a "Bin3-Box" domain present only in enzymes associated with 7SK regulation. Targeted mutagenesis confirms its importance for Bin3 function, revealing a possible conserved element in 7SK but not U6 biology.

1283T **Predicting evolutionary targets and parameters of gene deletion from expression data** Andre Luiz Campelo dos Santos, Michael DeGiorgio, Raquel Assis Florida Atlantic University

Gene deletion is traditionally thought of as a nonadaptive process that removes functional redundancy from genomes, such that it generally receives less attention than duplication in evolutionary turnover studies. Yet, mounting evidence suggests that deletion may promote adaptation via the "less-is-more" evolutionary hypothesis, as it often targets genes harboring unique sequences, expression profiles, and molecular functions. Hence, predicting the relative prevalence of redundant and unique functions among genes targeted by deletion, as well as the parameters underlying their evolution, can shed light on the role of gene deletion in adaptation. Here we present CLOUDe, a suite of machine learning methods for predicting evolutionary targets of gene deletion events from expression data. Specifically, CLOUDe models expression evolution as an Ornstein-Uhlenbeck process, and employs multi-layer neural network, extreme gradient boosting, random forest, and support vector machine architectures to predict whether deleted genes are "redundant" or "unique", as well as several parameters underlying their evolution. We show that CLOUDe boasts high power and accuracy in differentiating between classes, and high accuracy and precision in estimating evolutionary parameters, with optimal performance achieved by its neural network architecture. Application of CLOUDe to empirical data from *Drosophila* suggests that deletion primarily targets genes with unique functions, with further analysis showing these functions to be enriched for protein deubiquitination. Thus, CLOUDe represents a key advance in learning about the role of gene deletion in functional evolution and adaptation.

1284T **The Drosophila histone variant H2Av associates with insulator proteins to mediate an immuno-metabolic response** Bright Amankwaa[1], Mariano Labrador[2] [1]Biochemistry, Cell, Mol. Biology, University of Tennessee, Knoxville, [2]Biochemistry, Cell, Molecular Biology, The University of Tennessee, Knoxville

Dysregulation of chromatin insulators is associated with changes in gene expression and the onset of disease conditions, including cancer. Gypsy insulators in Drosophila contain binding sites for the Suppressor of Hairy-wing [Su(Hw)] protein and *su(Hw)* mutants display elevated number of chromosome breaks in dividing neuroblasts and in the germline, indicating an important role of Su(Hw) in the DNA damage response and the maintenance of genome integrity. Our recent genetic and bioinformatic analysis suggests a strong connection between gypsy insulators and the phosphorylated histone variant H2Av (γH2Av), which is critical for DNA damage repair. H2Av is also documented to suppress the Drosophila immune deficiency (IMD) pathway as evinced by the formation of melanotic masses in third instar of *His2Av* null mutants. Melanization is a first line insect-specific innate immune response that culminates in the enrichment of melanin at injury or infection sites. This work aims to understand the immune response role of H2Av and its connection with Drosophila insulator proteins. We found that the melanotic mass phenotype in H2Av null mutants is fully rescued in *His2Av-su(Hw)* double mutants. Our analysis revealed that fat body lipid droplets surround the melanotic masses occasionally becoming internalized within the melanotic mass, suggesting that the fat body tissue itself is the target for melanization. We also noticed that lipid droplets in the *His2Av* null mutants were significantly larger, but were reduced in the background of the *su(Hw)* mutant. Interestingly mutating any of the core gypsy insulator proteins or overexpression of H2Av in the fat body led to smaller lipid droplet formation. Mechanistically, we discovered that the elevated lipid droplets are linked to H2Av phosphorylation as the amount of lipid droplets in Drosophila S2 cells increases in response to treatment with okadaic acid, a known enhancer of phosphorylation. RNA-seq analysis associated the fat body phenotype with the expression of a number of metabolic genes including the Activity-regulated cytoskeleton associated protein 1(Arc1), which is an important regulator of lipid homeostasis and proper body fat storage. We propose a mechanism whereby H2Av cooperates with the canonical Drosophila insulator proteins to modulate an immuno-metabolic response via a pathway that has not yet been characterized.

1285T **Investigating mechanisms of gene expression as a function of dosage using multiple Drosophila species** Sierra Falcone[1], Leila Rieder[2] [1]Emory University, [2]Biology, Emory University

Histone proteins are essential for organization of the genome. Misregulation of these genes can cause aberrations in cellular divisions, leading to embryonic lethality. Canonical histone proteins in most metazoans are encoded by multigene families, but it is unclear how these genes are co-regulated to carefully control histone levels. Other multigene families, such as the rRNA genes, can provide clues: rRNA genes are controlled by epigenetic "nucleolar dominance" leading to expression of a subset of genes. Understanding how similar genes are differentially regulated is critical to our understanding of the relationship between transcriptional regulation and gene dosage.

I am investigating how expression of multiple histone genes is controlled using the powerful genetic model Drosophila. I am leveraging existing tools available in *Drosophila melanogaster*, as well as the novel histone locus organization found in other Drosophila species to investigate mechanisms of histone gene expression. I will utilize a parallel approach to profile dynamic developmental histone gene expression from a single locus using RNA sequencing. I will be utilizing the natural system of *Drosophila simulans*, in which there exists natural sequence variation in histone coding regions, and a transgenic system in *Drosophila melanogaster*. I will also profile locus-specific expression of histone genes in tissues with varying histone requirements. I will be using SNV FISH to determine relative abundance of histone transcripts using *Drosophila virilis*, which carries two asymmetrical histone loci, and *D. melanogaster-D. simulans* hybrids. These experiments will elucidate critical

mechanisms in gene family regulation by leveraging transgenic tools in *D. melanogaster* and underutilized genomes of non-melanogaster species.

1286T **Insights into sequential enhancer action through study of chromatin conformation dynamics at a single locus** Minh Tam Le[1], Leslie Dunipace[1], Dave Rumph[2], Angelike Stathopoulos[1] [1]Biology and Biological Engineering, California Institute of Technology, [2]Schmidt Academy for Software Engineering, California Institute of Technology

In the *Drosophila* embryo, gene expression patterns are often controlled by multiple enhancers acting in a coordinated manner to modulate expression over time. This study proposes that chromatin plays an important role in managing the sequential action of enhancers. Previous studies have shown that the early embryonic expression of the gene *brinker (brk)* is controlled by two cis-regulatory elements that act sequentially during cellularization. At this stage, the promoter proximal element (PPE) regulates the switch between the early 5' enhancer towards the late 3' enhancer resulting in a change in *brk* gene expression from narrow to broad (Dunipace et.al, *Developmental Cell*, 2013). We hypothesized that the PPE regulates sequential enhancer action by controlling chromatin conformation dynamics. This study proposes a new method to measure local chromatin changes over time utilizing Oligo-paint DNA fluorescence in situ hybridization (FISH) and an in-house computational pipeline to analyze co-localization of three DNA segments that vary on the linear DNA strand by ~10 kB. This imaging and computational approach is able to extract 3D conformations within co-localizing triplet spots. This set of tools will facilitate our study of how sequential-action of enhancers is regulated by a query of chromatin conformations in space and time within embryos. Our preliminary results have identified a subtle change in chromatin structure over developmental time at the *brk* locus. Specifically, in wild-type embryos, our results point to an increase in chromatin compaction in fully cellularized embryos as compared to earlier stages suggesting the 3' enhancer more frequently interacts with the PPE at this later developmental stage. Future experiments include assay of other mutants that have been shown to regulate *brk* gene expression to test whether they affect chromatin conformation. To start, we will utilize our developed tool to test the hypothesis that the PPE affects chromatin conformation by using a mutant that has a 800 base pair deletion within the PPE region. By assaying this and other mutant embryos, this approach also may help to identify the protein effectors that control chromatin dynamics and impact sequential enhancer action.

1287T **Identification of a candidate *akirin* enhancer sequence** Miranda Forman-Grimm, Georgette-Vanelle Wandji, Scott J. Nowak Department of Molecular and Cellular Biology, Kennesaw State University

Akirin, a small nuclear protein with conserved function across eukaryotes, is a critical determinant in the development of functional and robust cardiac and skeletal patterning and musculature. Akirin serves as a transcription cofactor by acting as a bridge or link between transcription factors such as Twist with chromatin remodeling complexes to ensure that Twist functions appropriately during transcription. If Akirin function is impaired, the resulting muscle patterning and structure is greatly impacted. We have identified a short sequence within the first intron of *akirin* that is highly conserved among closely related *Drosophilid* species. We are evaluating this sequence for possible promoter or enhancer activity. This evaluation is being performed using a variety of *in vivo* and *in vitro* techniques, both in live *Drosophila* embryos, as well as in cultured S2 cells. We have determined that a likely candidate enhancer sequence does indeed occur within this conserved element and are investigating a number of candidates that regulate this particular DNA sequence for *akirin* expression.

1288T **Investigating mechanisms of *D. melanogaster* histone locus body initiation and maintenance.** Nicole Roos[1], Greg Kimmerer[2], Leila Rieder[2] [1]Biology, Emory University, [2]Emory University

Histone proteins are essential for compaction and regulation of the eukaryotic genome. Dysregulation of histone gene expression leads to aberrant development and lethality. In animals, genes encoding the histone proteins are commonly clustered at loci. The histone locus body (HLB) is a collection of factors that localize to histone loci and regulate histone gene expression. By studying initiation and maintenance of the HLB, we gain insight into how unique genes are targeted by specialized transcription factors for specialized regulation. We are employing the powerful model system *Drosophila melanogaster* in which we leverage histone transgenes that recruit HLB factors, allowing us to manipulate *cis* regulatory elements and determine the effects on HLB formation and histone expression. In flies, the HLB is initiated during early embryogenesis. The HLB is then maintained at the single locus in mature tissues and throughout cell divisions. To test whether the cis elements that are critical for HLB initiation are also important for maintenance, we employ a transgenic system where we will detect HLB maintenance using a combined DNA FISH and immunofluorescence protocol. To test whether HLB initiation can occur in non-embryonic cells, we will combine transgenes and mitotic recombination in wing discs. Overall, studying HLB initiation and maintenance allows us to illustrate how and when histone proteins are regulated and in what contexts factors target these crucial genes for regulation.

1289T **Transcription factor localization to the *D. melanogaster* histone genes** Connor Smith[1], Thomas O'Haren[2], Leila

Rieder[3] [1]Emory, [2]Emory Genetics and Molecular Biology, [3]Emorty

Eukaryotic cells need to fit a large amount of DNA into a very small space. Histones are important proteins that condense DNA in the nucleus, influencing gene expression. The histone genes themselves are rigorously controlled; even small changes in histone biogenesis may lead to global defects in pre-mRNA splicing, temporal errors in cell division, whole genome duplications, genomic instability, and embryonic lethality. In metazoan genomes, the histone genes are typically repetitive and clustered and attract a myriad of transcription factors. These TFs, along with histone mRNA processing factors, collectively form the histone locus body (HLB). HLB TFs are largely discovered by chance, and the inventory of known factors is not comprehensive. This leaves current knowledge of the HLB limited – both compositionally and systematically. A complete list of all HLB factors is required for better understanding of the mechanisms of histone gene regulation.

Through expansion of a bioinformatic screening mining publicly available ChIP-seq data, we discovered several exciting candidates that show localization to the histone gene array. To confirm candidate localization *in vivo*, we will perform polytene chromosome immunostaining. Additionally, we will drive depletion of candidate through RNA interference using available transgenic fly lines to determine if candidate removal results in a change of histone transcript levels.

To extend our screening efforts, we will also be performing a Yeast-2-Hybrid on a protein that solely targets the histone array. Multi-sex comb (Mxc) is an HLB scaffolding protein that is conserved from humans to Drosophila and only targets the histone locus. Due to this specific localization, we hypothesize that examination of Mxc interactors will identify novel HLB TFs. This method uniquely provides us with a nonrandom, unbiased method of discovering transcription factors that localize to the histone locus These experiments in tandem will expand our understanding of how factors that compose the HLB interact and orchestrate histone production.

1290T **Functional clusters of the *even-skipped* stripe 2 enhancer in Drosophilidae and Sepsidae** Alan U Sabino[1], Ah-Ram Kim[2,3,4,5], Pengyao Jiang[2,6], Chan-Koo Kang[5], Michael Z Ludwig[2], David H Sharp[7], Alexandre F Ramos[8], John Reinitz[2,9,10] [1]Departamento de Radiologia e Oncologia, Universidade de Sao Paulo, [2]Department of Ecology and Evolution, University of Chicago, [3]Department of Biochemistry and Cell Biology, Stony Brook University, [4]School of Life Science, Handong Global University, [5]School of Creative Convergence Education, Handong Global University, [6]Department of Evolutionary Biology, Arizona State University, [7]Los Alamos National Laboratory, [8]Escola de Artes, Ciencias e Humanidades, Universidade de Sao Paulo, [9]Department of Statistics, University of Chicago, [10]Department of Molecular Genetics and Cell Biology, University of Chicago

Metazoan genes contain large segments of regulatory DNA which is divided into functional subunits known as enhancers. Exactly how the DNA sequence in open regions of chromatin encodes a pattern of expression remains an unsolved problem, particularly in the case of ”billboard” enhancers, in which the spacing and number of binding sites may vary. In this study, we report progress in elucidating these rules by the analysis of a collection of enhancers from a variety of dipteran species. We sought to understand how reporters driven by enhancers from the Drosophilid species *D. yakuba* and *D. pseudoobscura* and the Sepsid species *C. cynipsea* and *T. putris* drive *eve* stripe 2 expression at the native position when placed in *D. melanogaster* embryos, despite significant sequence changes in the two Drosophilid species and even larger ones in the two Sepsid species. Using an *in silico* model informed by genetic experiments, we show how these phenomena can be understood in terms of the molecular interactions that control stripe 2 expression. We find that stripe 2 is driven by Hb bound at two sites, each under the influence of clusters of neighboring bound coactivators and repressors. We further show how the role of Bcd as a coactivator in conjunction with a “shadow” Hb binding site gave rise to the classic picture that Bcd, rather than Hb, is the main activator of stripe 2. The robustness of this result and other results shown is supported by a new computational algorithm for analyzing large ensembles of models. In the Drosophilids, some of these interactions among bound transcription factors are conserved across species, while others are lost and replaced by new compensatory interactions which result in the same output. Certain important features of the clusters appear in both Drosophilidae and Sepsidae, but Bcd is partially replaced by Cad as a coactivator in the Sepsidae. We present experimental results confirming this finding. These clusters are an essential feature of the *cis*-regulatory code for transcriptional control. We further report on the extension of this method of analysis to a wider class of enhancers and dipteran species. The functioning of these clusters involves the whole group of binding sites and is insensitive to small changes in the spacing, number, or affinity of individual sites.

1291T **Regulation of Oogenesis by JNK Signaling** Sakhee Thakkar, Evelyn Tello, Jennifer Mierisch Loyola University Chicago

Oogenesis is the process by which female gametes are formed, and begins in the germarium where germline and somatic stem cells divide to support the formation of new egg chambers. Studying regulators of oogenesis is important for understanding how genes that are mutated can lead to infertility. We are interested in exploring further the role of the Jun N-terminal kinase (JNK) Signaling pathway and related proteins in oogenesis. A combination of RNA interference (RNAi) and overexpression was

used to manipulate expression of the JNK family proteins in somatic follicle cells to examine the effect of altered JNK signaling on eggs. While overexpression of activated Hemipterous, a JNKK, severely disrupted egg production, and RNAi of basket, which encodes JNK, and jun-related antigen (jra), and raw resulted in milder defects in egg shape. We are testing if these misshapen eggs are viable and able to produce offspring via hatching assays.

We are further exploring the function of these genes in oogenesis by manipulating gene expression followed by immunohistochemistry to understand how altered JNK signaling leads to defects in oogenesis in Drosophila. We expect these findings can be applied more broadly to how JNK signaling regulates oogenesis across Drosophila species.

1292T **Functional Characterization of ZAD Gene Family in Drosophila melanogaster.** Riley T Reed[1], Jack D Jurmu[2], Andrew M Arsham[1] [1]Biology, Bemidji State University, [2]University of Utah

Many vital eukaryotic developmental processes hinge on the formation and regulation of heterochromatin. Broadly, heterochromatin is gene poor and a tightly compressed structure of chromatin which restricts the transcription of local genes. While much genomic heterochromatin (for example centromeres and telomeres) is constitutive, it can also be induced as a genomic defense against invasive DNA, and facultative heterochromatin regulates developmental gene regulation. Recently, genes in the ZAD family have been identified as key regulators of heterochromatin in Drosophila melanogaster, however many are uncharacterized. Here we identify heterochromatin regulatory functions for currently uncharacterized ZAD genes by measuring the effect of eye-specific RNAi knockdown on Position Effect Variegation (PEV), a proxy for heterochromatin-mediated reporter gene silencing. We measured the effect of ZAD gene knockdown on reporter gene expression and compared the impact of knockdown on three distinct heterochromatin types: the classic wm4 mutant in which PEV is mediated by spreading of pericentric heterochromatin on the X chromosome; a line in which a white reporter is inserted in the largely heterochromatic 4th (or dot) chromosome; and a line in which heterochromatin silencing has been triggered by the presence of a 10 kb tandem array of repeats from the e. coli lac operon. Our data define heterochromatin regulatory function for uncharacterized ZAD genes and suggest that these functions may be further categorized by the specific type of heterochromatin with which they interact.

1293T **Repetitive DNA triggers *cis* and *trans* gene inactivation in *Drosophila*** Han Rhee, Andrew M Arsham Biology, Bemidji State University

Heterochromatin is a key genomic defense against transposons. In *Drosophila,* insertion of repetitive DNA can trigger the conversion of euchromatin to heterochromatin, stochastically silencing nearby reporters by recruiting HP1 and resulting in variegated gene expression. While this phenomenon is typically studied in *cis,* examples of *trans*-inactivation, in which a silenced allele can epigenetically inactivate an expressed allele on a paired homologous chromosome, have also been described. In the context of *Drosophila* eye color reporter genes, this produces the counterintuitive effect of a normally recessive biosynthetic phenotype (loss of pigmentation leading to white eyes) becoming epigenetically dominant. The mechanisms and regulatory implications of *trans*-inactivation remain poorly understood. Here, we document a new experimental system for studying *trans*-inactivation at multiple euchromatic chromosomal locations using transgenic reporter alleles that have been silenced in *cis* by a 256-copy array of the *e. coli* lac operator (lacO) sequence. Surprisingly, we found that the epigenetically silenced allele can transmit that silenced state to a non-silenced allele at the same location on the homologous chromosome. Pigmentation levels in *trans*-inactivated flies is intermediate between the silenced and non-silenced alleles suggesting a dynamic balance between the biochemically dominant pigment biosynthesis gene and the epigenetically dominant silenced state. Identical silenced insertions at other genomic locations are being tested to investigate distance-dependence and the molecular mechanisms of this poorly understood phenomenon.

1294T **Topoisomerase 3B-TDRD3 Complex Regulates Metabolism and Development in *Drosophila melanogaster*** Anantha Korrapati, Tianyi Zhang, Weidong Wang National Institute on Aging

Topoisomerases are required during transcription to release DNA topological stresses, and Topoisomerase 3β (Top3B) is the only dual-activity enzyme that can change the topology of both DNA and RNA. Top3B forms a stable complex with Tudor domain containing protein 3 (TDRD3). Top3b/TDRD3 complexes are mainly localized in the cytoplasm and integrated into stress granules under oxidative stress conditions. Mutations in Top3B have been associated with cognitive impairments and developmental problems in humans. However, Top3b-KO flies and mice survive to the adult stage without obvious developmental defects. To understand Top3B-TDRD3's physiological role in development and metabolism, we performed gain-of-function analysis with *Drosophila melanogaster* larvae. We observed that larvae with moderate overexpression (OE) of Top3b and TDRD3 survive to the adult stage while those with high-level OE die at the pupal stage. To investigate the impacted gene pathways, we utilized RNA-seq to analyze the transcriptome of the flies with different levels of OE. Compared with the negative control, the OE flies have up-regulation of genes involved in glycolic-related metabolism and transport as well as down-regulation of genes involved in developmental, nervous system, and immune functions. We will further study the

OE-affecting tissues by analyzing tissue enrichment of the up- and down-regulated genes via RNA-seq. With these results, we will compare the transcriptomes of WT, Top3B-KO, and TDRD3-KO larvae to identify Top3b/TDRD3 targets. Meanwhile, we are doing RNA-seq with Top3b-KI (dead enzyme) and Top3b-KO mouse kidneys under normal and starved conditions to evaluate the effect of Top3B on metabolism. Our preliminary results show that several pathways and genes related to metabolism display altered expression in kidneys of Top3b mutant animals under starvation conditions. Overall, this project will elucidate the role of the Top3B-TDRD3 complex in metabolism and development and its relevance to aging.

1295T **Investigating the role of Hippo signaling in *Drosophila melanogaster* cuticle pigmentation and dopamine metabolism** Shelley B Gibson[1,2], Samantha L Deal[2,3], Shinya Yamamoto[3,4] [1]Molecular and Human Genetics, Baylor College of Medicine, [2]Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, [3]Program in Developmental Biology, Baylor College of Medicine, [4]Neuroscience, Baylor College of Medicine

Many biological processes are highly conserved between humans and *Drosophila melanogaster*, two of which are the dopamine (DA) synthesis pathway and the Hippo signaling pathway. Both pathways are implicated in and cause a wide range of diseases or disorders. Understanding the mechanisms by which DA synthesis is regulated is necessary to develop novel treatments for those affected by dysregulation of DA signaling pathways, including Parkinson's disease, schizophrenia, and mood disorders. Although the downstream signaling cascades of DA signaling in postsynaptic neurons has been characterized well, relatively few genes and proteins are known to regulate DA levels in DArgic neurons. The two enzymes that mediate DA synthesis, Tyrosine hydroxylase (TH) and Dopa decarboxylase (Ddc), are conserved between *Drosophila* and humans. In addition to its role in the nervous system, DA is used as a precursor to melanin in *Drosophila* cuticle pigmentation. We identified four kinases of the core Hippo signaling pathway, *hippo*, *salvador*, *mats* and *warts*, as well as the effector *yorkie* in the same process, thus implicating all five key genes of the canonical Hippo signaling pathway as novel regulators of pigmentation and DA levels. This pigmentation phenotype observed with *warts* knockdown (KD) was rescued with the human homolog, *LATS1*, meaning that the cuticle could be used as a screening tool to identify human disease causative variants in many different Hippo signaling genes. Additionally, KD of *warts* in DArgic cells leads to increases of DA in the fly head but not the brain, suggesting our methods are capturing cuticle only changes of DA levels due to inhibition of Hippo signaling. Because conditional KD of *warts* and overexpression of *yorkie* in the adult stage led to no change in DA levels, inhibition of Hippo signaling may alter dopamine levels during development, when TH and Ddc have highest levels of expression before cuticle melanization is established. Based on the data obtained so far, I hypothesize that the Hippo signaling pathway regulates melanin levels through key enzymes involved in DA synthesis, such as TH and Ddc and the fly cuticle may also be used as a screening tool for disease causing Hippo signaling variants. These studies will expand our knowledge of Hippo signaling targets in *Drosophila* cuticle pigmentation though dopamine regulation, and whether this link is conserved in mammalian DArgic cells, including human.

1296T **A model system to study Kabuki syndrome utilizing KMT2D histone H3 lysine 4 methylase proteomics during cranial neural crest osteoblast differentiation** Sara Vardabasso, Karl B. Shpargel Genetics, University of North Carolina at Chapel Hill

Kabuki syndrome is a human disorder that presents with characteristic craniofacial phenotypes including facial hypoplasia, a depressed nasal tip, ocular abnormalities, and cleft palate. Kabuki syndrome results from mutations in KMT2D and KDM6A enzymes that regulate histone methylation. KMT2D is a histone H3 lysine 4 methylase involved in enhancer activation. We have previously modeled facial dysmorphism of Kabuki syndrome in the mouse utilizing neural crest specific deletion of KMT2D. Neural crest cell (NCC) specific deletion of KMT2D results in deficiencies in osteoblast differentiation that lead to alterations in the formation of anterior facial bones. We have now developed KMT2D mutations in neural crest cell culture to identify functional mechanisms of histone methylation regulates osteoblast differentiation. KMT2D mutant neural crest cells exhibit strong reductions in H3K4 mono and di-methylation. When placed in osteogenic media, the KMT2D mutant stem cells are deficient in differentiating to osteoblast lineages. To further understand KMT2D mechanisms, we propose to use a knock in system for proximity biotinylation to identify associated KMT2D co-factors during osteoblast differentiation. We have inserted the APEX peroxidase on to the endogenous KMT2D carboxy-terminus. Through oxidation of phenol derivatives, APEX will catalyze the formation of reactive unstable radicals, which have a high affinity for electron-rich amino acids. This will result in proximal protein labeling with biotinylation. Proximity-dependent biotinylation followed by streptavidin capture and mass spectrometry allows for isolation and identification of protein complexes interacting with KMT2D in differentiating neural crest cells. We conclude that KMT2D function is required for H3K4 methylation, NCC osteoblast differentiation, and facial bone formation. These collective proteomics experiments will lead to a better understanding KMT2D cooperation with chromatin and transcription factor complexes during osteoblast differentiation.

1297T **Determining the cause of hemimethylation at secondary DMRs associated with imprinted genes** Tamara L. Davis[1], Jordan Ellis-Pugh[2], Jacqueline Saulnier[2], Jaclyn Lo[2], Courtney Link[2], Sophia Gibson[2], Isabel Oalican[1], Julia Kesack[1], Naideline Raymond[2] [1]Biology, Bryn Mawr College, [2]Bryn Mawr College

The monoallelic expression of imprinted genes is regulated by parent of origin-specific differential DNA methylation. Imprinting control regions, or primary DMRs, regulate epigenetic profiles and expression patterns across imprinting clusters. In contrast, differential methylation at secondary DMRs influences the expression of individual imprinted genes. Unlike primary DMRs, secondary DMRs display considerable variability in their DNA methylation patterns and have high levels of hemimethylation. We hypothesize that the high level of hemimethylation is the result of 5-hydroxymethylcytosine enrichment at these loci. We tested this hypothesis by subjecting mouse genomic DNA to parallel bisulfite and oxidative bisulfite mutagenesis reactions. Loci associated with imprinted and non-imprinted genes were amplified from the mutagenized DNA and subjected to NextGeneration amplicon sequencing. This approach allowed us to determine the amount of 5hmC at each locus through a subtractive method as the bisulfite reaction identifies 5-methylcytosine and 5-hydroxymethylcytosine while the oxidative bisulfite reaction only identifies 5-methylcytosine. Our preliminary results illustrate low levels of 5-hmC at primary DMRs and non-imprinted loci. Secondary DMRs show less consistent results, but generally indicate that there may be 5-hmC enrichment at paternally methylated secondary DMRs. Additional studies are underway to better understand the distribution of 5-hmC at differentially methylated sequences associated with imprinted genes.

1298T **Molecular basis of seasonal adaptation in mammals** liang Ren[1,2], Junfeng Chen[1], Kousuke Okimura[2,3], Yang Chen[3], Fukawa Kai[1,2], Sumiyama Kenta[2,4], Takashi Yoshimura[1,2] [1]Institute of Transformative Bio-Molecules (WPI-ITbM), Nagoya University, [2]Graduate School of Bioagricultural Sciences, Nagoya University, Japan, [3]Institute of Transformative Bio-Molecules (WPI-ITbM), Nagoya University, Japan, [4]Laboratory of Mouse Genetic Engineering, RIKEN Center for Biosystems Dynamics Research (BDR), Japan

Rhythms of life on earth are shaped by the seasons. Accordingly, various physiological functions such as hormonal secretion, metabolism, growth, immune function, and reproduction show profound seasonal changes in animals including humans. Morbidity in humans due to cardiovascular disease, influenza, and psychiatric diseases is also seasonally regulated and peaks in winter. However, their underlying molecular bases remain unknown. Our transcriptome analysis in rhesus macaques (*Macaca mulatta*) suggested the involvement of GA binding protein (GABP) in the regulation of seasonally oscillating genes. In this study, we examined the siRNA knockdown in macaque fibroblasts and revealed the involvement of GABP in the regulation of seasonally oscillating genes. To test the *in vivo* role of GABP in the seasonal adaptation, we aimed to generate GABP mutant mice by CRISPR/Cas9 method. Most of the commonly used laboratory mouse strains genetically lack melatonin that is believed to be important for seasonality. However, both melatonin-proficient CBA/N mice and melatonin-deficient C57BL/6N mice showed clear seasonality. For instance, exposure to summer- and winter-mimicking condition induced significant change in organ weight in multiple tissues under winter-mimicking condition. Histological analyses demonstrated differences in cell division and cell size between summer and winter conditions. Based on these results, we next examined organ weight in *Gabpb1* mutant mice exposed to summer- and winter-mimicking condition. As a result, *Gabpb1* mutant mice showed impaired seasonal responses, reflecting in the reduction in seasonal differences in tissue weight, cell division and cell size. These results suggest possible involvement of GABP in the seasonal adaptation in mammals.

1299T **Elucidating the mysterious function of noncanonical DNA methylation in the brain** Mandy Eckhardt, Tiffany Chin, Eric Sun UT Southwestern Medical Center

DNA methylation is an evolutionarily ancient chemical modification of DNA bases essential for development, and it typically occurs at cytosine-guanine dinucleotide sequences (mCG) in mammals. More recently, other forms of DNA methylation, most notably at cytosine-adenine sites (mCA), have been observed in specific cell types. Interestingly, mCA is most abundant in neurons where mCA levels exceed that of mCG, and this methylation pattern has not been observed in any other cell type. Further, DNA methylation is inherently mutagenic, yet it is evolutionarily conserved in most organisms, thus highlighting the fundamental and critical role of DNA methylation in biological systems. Despite its abundance in the brain, only a few proteins have been identified in the mCA pathway. DNA methyltransferase 3A (DNMT3A) facilitates all mCA deposition in the brain, but only one mCA-binding protein is known: methyl-CpG binding protein 2 (MECP2). Very little else is known about the mCA pathway, and mCA function remains unknown. However, the presence of neurodevelopmental disorders caused by mutations in *DNMT3A* or *MECP2*, including autism spectrum disorder, overgrowth syndromes, Rett syndrome, and *MECP2* duplication syndrome, underscore the importance of investigating mCA. One way to elucidate the mCA pathway is to determine proteins that preferentially interact with mCA. To do so, we utilized a proteomic screen to identify mCA-binding proteins. Consistent with current knowledge, MECP2 emerged as the most abundant protein found in the mCA pull-downs. With this screen, we identified a novel putative mCA-binding protein. This protein is not well-studied, as its function, structure, and role in the brain are unknown. Publicly available data indicates expression of this putative mCA-binding protein correlates with mCA occupancy, as it is only expressed in the brain, and is expressed primarily in neurons. Further, like mCA, this protein is conserved throughout vertebrates, suggesting both are important for vertebrate brain function and/or development. Current efforts seek to characterize the relationship between mCA and this candidate mCA-interacting protein by determining its DNA binding pattern in vivo in the context of mCA using Cleavage Under Targets and Release Using Nuclease (CUT&RUN), identifying

interacting proteins via co-immunoprecipitation, and characterizing molecular and behavioral phenotypes in a knockout mouse line.

1300T **Exploring the systems genetics of Age-related Macular Degeneration in Diversity Outbred mice** Abdulfatai Tijjani[1], Selcan Aydin[2], Gayle Collin[2], Juergen Naggert[2], Steven Munger[1] [1]Lab - Steven Munger, The Jackson Laboratory, [2]The Jackson Laboratory

Age-related Macular Degeneration (AMD) is one of the leading causes of irreversible blindness among the aging population and requires urgent therapeutic intervention. Genome-wide association studies in humans have implicated numerous genetic variants, however it's unclear how these primarily non-coding variants influence disease susceptibility. Mapping expression quantitative trait loci (eQTLs) in relevant disease tissues in genetically diverse mice enables us to link genetic variants to their proximal effects on gene expression and distal effects on disease outcomes, and in the process can help identify novel gene candidates, biomarkers associated with disease susceptibility, and potential drug targets. Here, we characterized and compared the retinal pigment epithelium (RPE) and retina transcriptomes of 190 12-week-old Diversity Outbred (DO) mice raised on a standard chow or Western diet. We quantified the expression of 15,000 transcripts and mapped eQTLs in each tissue. Interestingly, we identified two significant eQTL hotspots on Chromosomes 2 and 12 specifically affecting the RPE of DO mice fed the Western diet. Many hotspot target genes are involved in ocular development and neurological processes, potentially suggesting a genetic link between AMD and neurodegeneration. Despite these expression differences, it should be noted that these young mice displayed no overt AMD physiology, suggesting that AMD-associated effects on the RPE transcriptome can be observed long before onset of the disease. Future studies will seek to identify the causal genes underlying the eQTL hotspots and to extend our analysis to predict combinations of DO founder strain alleles that better model the full spectrum of human AMD phenotypes

1301T **Specific genes regulated by histone deacetylase Hst1 contribute to *Candida glabrata* survival under stress** Bowen Liu[1], Laura Rusche[2] [1]University at Buffalo, SUNY, [2]State University of New York at Buffalo

The yeast *Candida glabrata* is the second most common cause of candidiasis in North America and Europe. During infection, this opportunistic fungal pathogen encounters stresses such as low NAD+ availability and anti-fungal azoles. Genes that allow *C. glabrata* to respond to these stresses are repressed by the SUM1 complex, including the gene encoding NAD+ precursor transporters, *TNA1*, and the gene controlling drug resistance, *PDR1*. SUM1 complex contains a histone deacetylase Hst1 and a transcription factor Sum1. Many targets of SUM1 complex are related to stress response. However, it remains unknown the full list of genes regulated by SUM1 complex and whether they affect each other.

To find out genes physically associated with SUM1 complex, we are conducting ChIP-exo with *HST1-V5* and *SUM1-V5* strains. We completed pilot ChIP-qPCR assays on *TNA1* and *PDR1* promoters. Eventually, we will utilize RNA-seq to identify genes changing expression levels in the absence of *HST1* or *SUM1*. To do so, we made *HST1*-N293A and *sum1*Δ strains and conducted pilot RT-qPCR assays to check expression level of *TNA1* and *PDR1*.

1302T **Genes affected by NaCl during root development in *Arabidopsis thaliana*** Leonard Pysh, Davin Stevenson Biology, Roanoke College

Sodium chloride (NaCl) in soil has negative impacts on plant growth, reducing crop yields. Although soil salination occurs naturally, it has increased substantively due to modern agricultural practices. An improved understanding of the basis for the negative impacts of NaCl on plant growth is important to developing rational strategies to address and ameliorate these effects. While many investigators have studied the effects of NaCl on plant growth, relatively few have focused on roots, and most of the studies of NaCl responses in roots have been performed in the model plant *Arabidopsis thaliana* using seedlings that have been germinated and grown in the light. Light is known to affect root development, and initial analyses indicate that root responses to NaCl are affected by light. To understand better the specific effects of NaCl on root development, we have begun to identify a set of genes that are either up- or down-regulated in roots when grown on media containing elevated levels of NaCl. The longer-term goal is to use the regulatory regions of these genes to develop transcriptional reporter lines that will provide insights into the specific cellular targets of NaCl in plant roots.

1303T **The effects of mutations on gene expression and alternative splicing** Marelize Snyman[1,2], Sen Xu[2,3] [1]Dermatology, UT Southwestern Medical Center, [2]Biology, University of Texas at Arlington, [3]University of Missouri

Exploring the intricate connection between mutations and their genomic and phenotypic consequences has long been a fundamental pursuit within evolutionary biology. However, only a few studies have investigated the effects of mutations on gene expression and alternative splicing on the genome-wide scale. In this study we therefore aim to bridge this critical knowledge gap by leveraging comprehensive data from whole-genome sequencing and RNA sequencing across 16 obligately

parthenogenetic Daphnia mutant lines to investigate the impact of ethyl methanesulfonate-induced mutations on gene expression and alternative splicing. Through rigorous analysis of mutations, changes in expression, and alternative splicing patterns, our findings reveal that trans-effects overwhelmingly account for the variation in gene expression and alternative splicing between wild-type and mutant lines. In contrast, cis mutations exert a limited influence on gene expression and don't consistently lead to alterations in gene expression. Additionally, we highlight a significant correlation between differentially expressed genes and mutations occurring within exons, underscoring the pivotal role of exonic mutations in driving changes in gene expression.

1304T **Directionality of transcriptional regulatory elements reveals architectural, evolutionary and functional dynamics** You Chen, Sagar R Shah, Alden Leung, John T. Lis, Andrew Clark, Haiyuan Yu Cornell University

Divergent transcription has been demonstrated as a critical mark of active transcriptional regulatory elements (TREs). However, in addition to divergent elements (each produced divergent transcripts seen as a pair of peaks on opposite strands and within 300 bp), a considerable number of unidirectional elements (only producing transcripts from one strand) have been detected from PRO-cap data and might also function as TREs. These unidirectional elements are largely overlooked and their identity and function remain elusive.

A total of ~40,000 TREs were identified from K562 PRO-cap data and divided into proximal (within 500 bp, putative promoters) and distal (outside 500 bp, putative enhancers) categories based on their distances to transcription start sites (TSSs) of known genes. Systematic comparison of epigenomic features and transcription factor binding profiles revealed distinct architecture models for divergent and unidirectional elements. Detailed inspection of sequence content confirmed that unidirectional TREs are a true biological entity, not simply a result of experimental artifacts, low sequencing depth or poor mappability. Furthermore, we found that both divergent and unidirectional TREs are significantly older and subject to stronger selective constraints than the random genomic background, indicating that both classes of TREs may have been maintained due to their functions. In the distal category, unidirectional elements tend to be younger, with fewer evolutionary constraints compared with their divergent counterparts, which suggests that they arose more recently in evolution and represent a distinct group of functional units. Consistent with this, we found that unidirectional elements were less likely to have target genes predicted by the ABC model and had higher cell-type specificity. PRO-cap data of CD4+ T cells from human, rhesus macaque and baboon also revealed dynamic changes in directionality across species.

Altogether, the elucidation of TRE transcriptional directionality will help build a finer architecture model and enable a better understanding of evolutionary and functional dynamics of TREs.

1305T **Investigating the genomic, transcriptomic, and metabolic changes in response to DNA replication stress in the telomeres of *Saccharomyces cerevisiae*** Taizina Momtareen West Virginia University

Telomere shortening is associated with aging of healthy cells and telomere elongation is a hallmark of cancer cells. About 10-15% of cancer cells use a type of DNA recombination called Alternative lengthening of telomeres (ALT) to extend their telomeres instead of using telomerase. Similarly, telomerase-mutants of yeast (*S. cerevisiae)* proliferate using DNA recombination, whereby they undergo aging to reach replicative senescence, but few can resume cell division after that, becoming post-senescence survivors. It is unclear what occurs at a molecular level that enables these cells to revive themselves from senescence and resume proliferation. In general, as cells age, they lose mitochondrial function and accumulate damaged lipids, proteins, and DNA. One hypothesis of aging is that it is triggered by this accumulated damage. Since the telomerase-mutants are essentially reversing aging to become survivors, it can be hypothesized that their transcriptional and metabolic profiles go through major changes to enable the cells to divide again, despite the wear and tear of aging. For example, research in survivors has shown increased transcription of energy production genes, indicating a higher demand for energy to sustain the cells. However, how this variation in gene expression causes the mitochondria to generate more energy and help the telomerase-mutants to become survivors is unknown. The goal of this research is to elucidate such variations occurring in telomerase-mutants that could potentially cause them to turn into survivor cells. My research seeks to determine this by 1) evaluating and interpreting the changes in physiology and energy production processes of cells lacking telomerase, and (2) determining the transcriptional response to telomerase deletion, senescence, and telomerase-independent telomere lengthening. The data generated from this work will result in a broader view of the telomerase mutants and enable us to draw parallels with aging and ALT cancer cells.

1306T **New insights into the regulation of gene expression by the SAGA/NuA4 co-activator complexes in *Candida albicans*** Gabriela MN Librais[1], Samuel Stack-Couture[1], Yuwei Jiang[1], Iqra Razzaq[2], Matthew D Berg[3], Julie Genereaux[1], Christopher J Brandl[4], Rebecca S Shapiro[2], Patrick Lajoie[1] [1]Anatomy and Cell Biology, The University of Western Ontario, [2]University of Guelph, [3]University of Washington, [4]Biochemistry, The University of Western Ontario

Fungal infections and the emergence of drug-resistant strains are a growing worldwide threat to human health. Therefore, identifying new targets to increase susceptibility of fungal pathogens to current available therapies is crucial in developing effective treatment against fungal infections. Tra1 is an essential component of both the SAGA-and NuA4 transcription acetyltransferase complexes that acetylate histones and non-histone proteins to regulate gene expression in response to various stresses, including antifungal drug treatment. As a PIKK family member, Tra1 is characterized by a C-terminal phosphoinositide 3-kinase (PI3K) domain. Like other PIKK family members such as TOR, Tra1 should therefore be druggable. We previously identified specific residues within the putative ATP-binding cleft of the *S. cerevisiae* Tra1 PI3K domain that regulate assembly and function of both SAGA and NuA4 (**Berg *et al*., 2018, G3**). The resulting mutant termed tra1Q3 displays increased susceptibility to multiple stressors, including multiple antifungal compounds such as caspofungin and fluconazole. An equivalent mutant generated using CRISPR-Cas9 genome editing in the pathological yeast *C. albicans* displays unsuspected phenotypes. While , tra1Q3 cells show reduces virulence and increased sensitivity to caspofungin (**Razzaq *et al.* , 2021, Genetics**), it displays decreased susceptibility to azoles, suggesting a rewiring of Tra1 functions across yeast species (**Librais *et al.* , 2023 G3**). Moreover, inositol auxotrophy, one the phenotypes typically associated with SAGA mutants in budding yeast, is not recapitulated in C. albicans, further highlighting functional differences between the two yeast species. Thus, we are investigating how the assembly, composition and functions of the SAGA/NuA4 complexes regulate global protein acetylation to control *C. albicans* virulence and drug resistance. Supported by CIHR.

1307T **Unveiling a Novel Role for a Transcription Factor in Yeast RNA Splicing** Siddhant Kalra, Joseph David Coolon Biology, Wesleyan University

RNA Splicing is a fundamental cellular process in eukaryotic organisms, characterized by a multitude of intricately regulated molecular processes governed by the spliceosome protein complex. This complex orchestrates the precise excision of intron sequences from a pre-messenger RNA (pre-mRNA) molecule. Alternative splicing of pre-mRNAs can enable the production of multiple RNA isoforms from a single gene allowing cells the capability to finely regulate not only which isoforms are transcribed and further translated into proteins but also the quantity of those proteins dramatically increasing the potential protein products of the genome.

In the budding yeast Saccharomyces cerevisiae, only a small number of genes (~3%) require splicing and typically only contain 1 intron. As a result, prior work on alternative splicing of these genes has been limited. While only a few genes have introns, those that do are highly transcribed and therefore give rise to 1/3rd of all pre-mRNA transcripts in the cell. By performing RNA sequencing analysis, we elucidate a novel role of an essential transcription factor (TF) in the splicing process in yeast. Our findings demonstrate that varying expression levels of this TF can influence the splicing of multiple genes producing isoforms with different degrees of intron retention, alternate 3’ splicing, alternate 5’ splicing, and exon skipping challenging our perceptions of the importance of alternative splicing in yeast.

1308T **Understanding the function of the C-terminus of Mms21 in genome stability** Cheung Li, Nkechinye Baadi, Yee Mon Thu Biology, Colby College

MMS21 and its human homolog NSMCE2 have various functions in DNA damage repair and response pathways, which play a vital role in defense against genetic diseases and disorders. Mechanistically, Mms21 functions as an E3 SUMO (small-ubiquitin like modifier) ligase which conjugates SUMO peptides to target proteins with the help of E1 and E2 SUMO ligases. We generated mms21Δ22 mutant in S. cerevisiae, a mutant in which the C-terminus is absent, to approximately mimic the human mutation found in a rare genetic disorder. We observed that a mutant of RAD5 (key regulator of the damage tolerance pathway) and the mms21Δ22 mutant exhibit a negative genetic interaction in the presence of methyl methanesulfonate (MMS), a DNA alkylating agent. This data suggests that Rad5 and the pathway regulated by the C-terminus of Mms21 operate in parallel to counteract MMS-induced DNA damage. Rad5 can function as an E3 ubiquitin ligase to initiate the template switching pathway. In addition, the helicase activity of Rad5 modulates fork regression when the replication fork encounters impediments. To further understand this intricate and essential network of DNA damage response and repair pathways, we will determine if the mms21Δ22 mutant genetically interacts with the rad5 helicase mutant or the rad5 E3 ubiquitin ligase mutant. In addition, we are performing an experiment to understand if the human MMS21 gene, NSMCE2, can functionally rescue the lack of yeast MMS21 gene using the plasmid shuffling assay. In this assay, wild type cells are first transformed with MMS21 on a high copy plasmid. This allows us to knock out the endogenous MMS21, which is essential for cellular survival. Cells with the episomal copy of MMS21 are then transformed with the plasmid carrying NSMCE2. Resulting cells with episomal copies of MMS21 and NSMCE2 will then be grown in the presence of a toxicant (5-FOA) that would force cells to lose the plasmid containing MMS21, while retaining the plasmid with NSMCE2. Growing mms21Δ cells with the episomal copy of MMS21 in 5-FOA led to lethality, confirming the feasibility of the approach. We are currently generating all appropriate strains to determine if the human copy can functionally complement the yeast gene. If such a system is successful, we will characterize cellular and molecular significance of additional NSMCE2 mutations associated with human genetic conditions

using this approach.

1309T **Transvection at MAL6 in yeast** Man Chang[1], Richard Needleman[2,2] [1]Lumicell, [2]retired

Homology-dependent gene expression, or transvection, is a poorly understood mechanism of gene expression. Studied most intensively in *Drosophila*, **we report here the first example of a natural yeast genetic system that exhibits both intra- and inter- chromosomal interactions that satisfies the definition of transvection.** First, specific deletions or deletion/insertions in *trans* silence an otherwise competent *MAL6* locus; second, deletions at *MAL6* on chr. VIII can affect expression of ectopic *MAL6* sequences on chr. V.

Notation: D*MAL63* refers to a large deletion of *MAL63* and replacement by *LEU2*(*mal63*). Δ*MAL61* refers to a large deletion of *MAL61* and replacement by *URA3*(*mal61*).

Position Effect at *MAL6*: The *MAL6* locus is telomeric complex with three active genes: *MAL63.* encoding a positive regulator, *MAL61,* encoding the maltose permease, and *MAL12* encoding maltase. The *MAL* genes are universally described as dominant: a MAL^+ x mal^- diploid is said to always be MAL^+. **However, this is not the case. The diploid *MAL63* Δ*MAL61/* D*MAL63 MAL61*, is completely maltose negative despite having a complete complement of *MAL* genes.** While this diploid is mal-, a diploid is also maltose negative when both deletions are in *trans (i.e. MAL63 MAL61*/**Δ***MAL63* **Δ***MAL61)*. The diploid *MAL6*/**Δ***MAL6,* where **Δ***MAL6* is the deletion of *MAL63 MAL61 MAL62* and their replacement by *LEU2*, is also negative, but the mitotic recombinants *MAL6*/*MAL6* are positive. Complementation occurs in both haploids and diploids between specific *MAL* genes integrated on chr. VII, but fails when they are present on chr. VIII**.**

Stated without proof: Non-complementation is not negative complementation due to subunit mixing, nor is it due to promoter interference or haploinsufficiency. Telomeric repression does not play a role in silencing. Transcription of *MAL63* in the mal- diploid *MAL63* Δ*MAL61*/D*MAL63 MAL61* is unaffected, but *MAL61* mRNA transcripts are undetectable.

Progress will require chromosomal association studies. Our observations do not reveal a clear mechanism-nor can purely genetic studies do so. Our hope is that the genetically simple *MAL6* system will here prove valuable. In respect to modelling the current situation, as Wittgenstein said, " Where one cannot speak, one must remain silent".

1310T **Why do transcription factors work together** Lindsey Snyder[1], Emily O'Brien[1], Jia Zhao[2], Thomas Cassier[1], Nicholas Schnicker[1], Bin He[1] [1]University of Iowa, [2]Massachusetts Institute of Technology

A prevalent feature in eukaryotic transcription is combinatorial regulation, or the requirement of two or more transcription factors (TFs) to co-activate a gene. This allows multiple upstream signals to be integrated and provides a way to tune specificity by requiring a defined motif configuration for activation to occur. A basic question, however, remains elusive: why do TFs need other TFs to function? And how does combinatorial regulation evolve? We take advantage of the natural variation in coTF dependence in the Phosphate Starvation (PHO) response system in two yeast species to study its genetic and biophysical basis. In S. cerevisiae, the main TF, Pho4 (ScPho4) relies on the coTF Pho2, whereas in C. glabrata, Pho4 (CgPho4) is largely independent of Pho2 and as a result activates 2-3 times more genes. We systematically tested >50 chimeras of ScPho4 and CgPho4 using a sensitive flow cytometry assay with a dual fluorescence reporter and identified the DNA binding domain (DBD), the putative Pho2-interaction domain, and a portion of the transactivation domain as collectively contributing to Pho2 dependence. We show that the CgPho4DBD binds ~4 times tighter than ScPho4DBD to the consensus motif in vitro with faster kinetics. A protein binding microarray revealed no difference in their binding specificity. CgPho4's transactivation domain has a higher activation potential than ScPho4 when assayed as a Gal4DBD fusion. We also show that CgPho4 is more capable of binding nucleosome-occluded DNA in vivo compared with ScPho4. Lastly, the two Pho4 orthologs differed significantly in their ability to interact and thus collaborate with Pho2. Our findings thus provide a detailed molecular picture of how co-TF dependence is mediated and how mutations in functional domains of the TF can lead to changes in codependency, which results in significant consequences in the regulatory output.

1311T **Reprogramming stress responses in yeast via mutation of mediator subunit Med8** Grace Kornegay, Kelsey P Brooks, William D Park Biochemistry & Biophysics, Texas A&M University

The Mediator complex plays key roles in gene expression in all eukaryotes and serves as a "central integrator" of genetic information. To serve this role, the Mediator must coordinate the expression of thousands of genes to support robust growth in a wide range of environmental conditions and coordinate appropriate responses to many different types of stress. However, the Mediator must also be able to evolve to meet the needs of diverse organisms. To determine whether we could change the way that the mediator integrates genetic information, we made a series of 17 mutants in which nine amino acid regions of Med8 were replaced with an unrelated sequence. Together, these cover $Med8_{20\text{-}173}$ and include all the regions of Med8 visible

in structure 5OQM of the Mediator complex from *S. cerevisiae,* with the exception of the Med18/20 tether region ($Med8_{190-223}$). When transformed into the standard yeast strain BY4742 by plasmid shuffling, all these mutants had only modest effects on the growth rate in rich media (YPD) at 30°C. However, four of the mutants strongly inhibited growth on YPD containing 6% ethanol. Two of these mutants were also sensitive to 1 M NaCl. Importantly, these mutants showed differential sensitivities to 6% ethanol, 1 M NaCl, as well as to heat stress (37°C). Additional mutants also differentially alter ethanol and methanol tolerance. Thus, these findings suggest that Mediator can be "re-programmed' through mutation to alter the expression of genes or gene sets in response to specific stimuli.

1312T **Identification of Enhancers Pertinent to Eye Development** Dwon A Jordana[1], Nathan Clark[2], Jason Presnell[3] [1]Biological Science, University of Pittsburgh, [2]Biological Sciences, University of Pittsburgh, [3]Human Genetics, University of Utah

Identifying conserved enhancers that function during ocular development is important, because it will signify regions sensitive to perturbations and possibly responsible for abnormal development. Discovering enhancers which regulate vital ocular genes helps to gain an understanding into the penetrance and severity of disease.

Regulatory regions pertinent to eye development will be detected by the presence of an amplified H3K27ac signature which is typically observed by enhancers. These regulatory regions will be located within a megabase window of ocular developmental genes such as Rx3 and Otx2b. I will use conservation within Teleosts in one dataset, but also deeper conservation across vertebrates to prioritize regions based on constraint to maintain these enhancers through time. Criteria for candidate regions are as followed: proximity to recognized genes, active enhancer histone marks (H3K27ac), open chromatin peaks in the optic vesicle at relevant time points, and absence of repressive histone modifications.

Beyond the study of sequence and genomic marks, I will establish necessity through Crispr Cas9 mediated deletions of the regions to determine how vital these regions are to development. In addition, I will test sufficiency by placing regions in an expression vector to determine if these putative enhancers alone are capable to drive expression of GFP in zebrafish. These experiments will demonstrate the value of these regions in regulating gene expression and possible relevance to disease.

I hypothesize that conservation across Teleosts will predict valuable regions with regulatory properties, and I will see greater functional impact for those regions that are conserved across all vertebrates.

1313T **The contributions of DNA accessibility and transcription factor occupancy to enhancer activity during cellular differentiation** Trevor E Long, Tapas Bhattacharyya, Madison Naylor, Andrea Repele, Shawn Krueger, Sunil Nooti Biology, University of North Dakota

During gene regulation, DNA accessibility is thought to limit the availability of transcription factor (TF) binding sites, while TFs can increase DNA accessibility to recruit additional factors that upregulate gene expression. Given this interplay, the causative regulatory events in the modulation of gene expression remain unknown for the vast majority of genes. We utilized deeply sequenced ATAC-Seq data and site-specific knock-in reporter genes to investigate the relationship between the binding-site resolution dynamics of DNA accessibility and the expression dynamics of the enhancers of *Cebpa* during macrophage-neutrophil differentiation. We found that, while the enhancers upregulate reporter expression during the earliest stages of differentiation, there is little corresponding increase in their total accessibility. Conversely, total accessibility peaks during the last stages of differentiation without any increase in enhancer activity. The accessibility of positions neighboring C/EBP-family TF binding sites, which indicates TF occupancy, does increase significantly during early differentiation, showing that the early upregulation of enhancer activity is driven by TF binding. Our results imply that a generalized increase in DNA accessibility is not sufficient, and binding by enhancer-specific TFs is necessary, for the upregulation of gene expression. Additionally, we show that high-coverage ATAC-Seq combined with time-series expression data can infer the sequence of regulatory events at binding-site resolution.

1314F **Genetic analysis of *lon-1, lon-2* and *sma-9*, three genes in the bone morphogenetic protein (BMP) signaling pathway in *C. elegans*** Sergio D Moreira-Antepara, Maria Victoria Serrano, Kelly (Jun) Liu Molecular Biology and Genetics, Cornell

Bone Morphogenetic Proteins (BMPs) are members of the TGFβ superfamily of signaling proteins and play critical roles in development and homeostasis across metazoans. Core BMP pathway components, including the ligand, the type I and type II receptors, and the cytoplasmic Smad proteins, are conserved in *C. elegans*. Null mutations in each of these core components result in a small body size phenotype. We are using double mutant analysis to determine the relationship between three additional BMP pathway components, LON-1, LON-2, and SMA-9. LON-1 is a secreted protein in the CAP superfamily, while LON-2 is a membrane anchored proteoglycan. SMA-9 is a zinc finger transcription factor that participates in the regulation of some BMP target genes. While mutations in either *lon-1* or *lon-2* result in a long body size phenotype, mutations in *sma-9* cause a small body size phenotype. Using existing null mutant alleles for *lon-2* and *sma-9*, as well as a null allele we

generated for *lon-1*, we measured the body lengths of different mutant worms at the same developmental stage (larval stage 4 or L4). We found that *lon-1(0); sma-9(0)* double mutants are as long as *lon-1(0)* single mutant worms, and that *lon-2(0) sma-9(0)* double mutants are as short as *sma-9(0)* single mutant worms. However, *lon-1(0); lon-2(0)* double mutants are longer than either single mutant. These results suggest that LON-2, SMA-9 and LON-1 do not function in a simple linear pathway. We are currently conducting additional experiments to further delineate the relationship between LON-1, LON-2 and SMA-9 in the BMP pathway and in body size regulation.

1315F **A Forward Genetic Screen in *Caenorhabditis elegans* Identifies Factors Regulating Transcriptional adaptation-like Ectopic Expression** Kuan-Lun Hsu, Vahan Serobyan, Didier Stainier Department of Developmental Genetics, Max Plank Institute for Heart and Lung Research

Transcriptional adaptation (TA) is a newly identified cellular response whereby an mRNA destabilizing lesion in one gene (mutant gene) causes transcriptional changes in other gene(s) (adapting gene(s)). In a previous study in *Caenorhabditis elegans*, we reported that an *act-3* (adapting gene) fluorescent reporter is expressed in the pharynx of wild-type worms, whereas in *act-5* (mutant gene) mutants the same reporter becomes ectopically expressed in the intestine. This observation indicates that TA can also lead to ectopic expression of the adapting gene, i.e. where the mutant gene is being expressed and its mRNA degraded. To identify the genetic basis and molecular mechanisms controlling the process whereby mutant mRNA cell-autonomously triggers TA, we performed a forward genetic screen. We identified several mutants exhibiting ectopic *act-3* reporter expression in the uterus, spermatheca, intestine, as well as body wall muscles. This diversity of expression patterns in the different mutants identified in our screen suggests that multiple genes regulate the expression pattern of this *act-3* reporter, and that the expression potential of this reporter, and potentially the *act-3* gene itself is not limited to a particular cell type. We are currently mapping these mutations to identify the loci involved in regulating the expression pattern of the *act-3* reporter. Mutants exhibiting transcriptional adaptation-like phenotypes will help in revealing the mechanisms underlying transcription adaptation.

1316F **The post-transcriptional regulation mechanism and functional importance of a key maternal mRNA, *glp-1*** Peren Coskun Biochemistry and Molecular Biotechnology, UMass Chan Medical School

Translational control of maternal mRNAs is a major form of gene regulation during germline development and embryogenesis. *C. elegans* Notch homolog *glp-1* is necessary for germ cell proliferation, and embryonic fate determination. The RNA binding proteins POS-1 and GLD-1 directly regulate the translation of GLP-1 protein by binding to specific elements within the *glp-1* 3' UTR. When POS-1 or GLD-1 binding is disrupted by mutation of their respective elements, the expression pattern of a *glp-1* 3' UTR reporter changes in both the germline and in embryos. The mechanism by which POS-1 and GLD-1 mediate translation repression is not well understood.

In this study, we show that wild-type *glp-1* transgenic reporter embryos have a shorter average polyA tails than transgenic reporters with mutated GLD-1 or POS-1 binding motifs. Mutation of these sites does not affect polyA site selection or the distribution of 3'UTR isoforms. We studied the effect of cytoplasmic polymerases, deadenylases and translation initiation factors on our transgenic reporters. Our results show that two cytoplasmic polyA polymerases, GLD-2 and GLD-4, have strikingly different effects on the expression of reporter transgenes harboring GLD-1 or POS-1 binding motif mutations. By contrast, none of the deadenylases affect the transgenic reporter expression. We also observed strong derepression of all reporters upon reduction of the translation initiation factor *ife-3*. The results reveal that POS-1 and GLD-1 exert their repressive effects in different ways through cytoplasmic polyA polymerase activity, while IFE-3 mediated translation repression is independent of both POS-1 and GLD-1. Lastly, we have examined the biological significance of *glp-1* 3'UTR to the worm reproduction by using CRISPR/Cas9 mutagenesis to generate *glp-1* 3'UTR mutations in the endogenous locus. Characterization of a 71 base pair mutation that deletes the GLD-1 and POS-1 binding sites in the *glp-1* 3'UTR reveals a 2-fold reduction in the number of embryos produced and a 4-fold reduction in the hatch rate. Imaging results show that the mutant embryos have patterning defects. Together, our results show that the *glp-1* 3'UTR contributes to reproductive health but is not essential to fertility.

1317F **RNAi-mediated regulation of *alg-3* and *alg-4* coordinates the spermatogenesis developmental program in *C. elegans*** Cara McCormick, Trilotma Sen, Alicia K. Rogers Department of Biology, University of Texas Arlington

Coordination of gene regulatory networks is necessary for proper execution of cellular programs throughout development. In *C. elegans*, spermatogenesis and oogenesis occur during different life stages (L4 and adult, respectively) within the hermaphroditic germline tissue. Yet, it remains unclear how these developmental programs are robustly executed, particularly during stressful conditions. Here we show evolutionarily conserved RNA interference (RNAi) pathways act to restrict expression of spermatogenesis genes to the L4 stage. We performed differential expression analysis of mRNA-seq and small

RNA-seq libraries from L4 and adult-stage wild-type and *mut-16* mutants, which lack a critical RNAi pathway protein, grown at permissive (20ºC) and elevated temperature (25ºC). Our analyses revealed spermatogenesis-enriched gene expression is developmentally mis-regulated in a small RNA-dependent manner at elevated temperature. Our findings indicate a novel RNAi-mediated regulatory cascade is essential for properly coordinating the spermatogenesis developmental program, particularly during heat stress. This is achieved through RNAi-mediated genetic switches that regulate the expression of the Argonautes, ALG-3 and ALG-4, to control ALG-3/4 pathway function. Disruption of this cascade results in severe spermiogenesis defects that underly sterility. This work provides key insights into the different molecular mechanisms RNAi pathways employ to maintain both oocytes and sperm cells' reproductive potential, and further highlights the complexities and importance of RNAi-mediated gene regulation in development.

1318F **Investigating how heterochromatin impacts aging and larval development in *C. elegans*** Arthur Colunga, Allison Sciarratta, Deepshikha Ananthaswamy, Teresa W Lee Biological Sciences, University of Massachusetts Lowell

Within the nucleus, genomes are organized and regulated by the modifications added to histone proteins. For example, di-methylation of histone H3 at its ninth lysine (H3K9me2) is a repressive modification associated with heterochromatin in *C. elegans*. Genomic levels of heterochromatin are regulated in part by two chromatin modifiers: JHDM-1 is a putative demethylase for H3K9me, while SET-32 is a methyltransferase for the newly discovered heterochromatin factor H3K23me. We have found that *jhdm-1* mutants experience a gradual increase in lifespan over many generations, and long-lived *jhdm-1* mutants have accumulated higher levels of H3K9me2. Others have shown that *set-32 (ok1457)* mutants are also long-lived, and have elevated levels of H3K9me3. Here, we explore whether the heterochromatin modifiers SET-32 and JHDM-1 may genetically interact. We find that *set-32; jhdm-1* double mutants experience a synergistic delay in larval development, with some individuals only reaching adulthood after ten days. We are currently using immunofluorescence to examine germline levels of heterochromatin factors, and assessing the epistatic interaction on lifespan. Taken together, these data will shed light on how heritable levels of heterochromatin can affect development and aging.

1319F **Mapping regulatory element evolution in nematodes** Thomas D King, Michael S Werner School of Biological Sciences, University of Utah

Enhancers and promoters appear to play different roles: promoters strongly activate transcription near the beginnings of genes, and enhancers impart spatial and temporal specificity to gene expression. However, both regulatory elements share important structural features, and both elements induce bidirectional transcription in many taxa, including nematodes. These similarities suggest that enhancers and promoters share a common evolutionary origin -- and that promoters could be reprogrammed into enhancers, or vice versa, over evolutionary time.

Our goal is to identify instances of these transitions, and identify and test the mechanisms by which they occur. We are mapping enhancers and promoters in several nematode taxa: *C. elegans* strain N2, *C. elegans* strain CB4856, *C. briggsae*, *C. tropicalis*, and *P. pacificus*. I have conducted internally calibrated ChIP (Ice-ChIP) to quantitatively map histone modifications characteristic of enhancers and promoters (H3K4me1, H3K4me3, and H3K27ac) in these taxa. I am also conducting capped small RNA sequencing in the same taxa to locate enhancers and promoters based on their characteristic bidirectional transcription patterns. Together, these datasets will provide a high-confidence annotation of enhancers and promoters across nematode taxa representing several different degrees of evolutionary divergence. I will identify examples where syntenic regulatory elements appear to have been reprogrammed, and look for correlations between these events and changes in histone modifications, DNA sequence changes, changes in expression patterns, and birth and death of nearby genes. I hope to gain insight into the mechanisms of regulatory element reprogramming, and I also hope to offer my regulatory element annotations as a resource for other researchers interested in the control and evolution of gene expression.

1320F **A new noncanonical biogenesis pathway generates a germline enriched miRNA family in C*. elegans*** Rima Sakhawala[1,2], Dustin Haskell[3], Anna Zinovyeva[3], Katherine McJunkin[4] [1]Laboratory of Cellular and Developmental Biology, National Institute of Diabetes and Digestive and Kidney Diseases, [2]Johns Hopkins University, [3]Kansas State University, [4]National Institute of Diabetes and Digestive and Kidney Diseases

MicroRNAs (miRNAs) are short RNAs that post-transcriptionally regulate gene expression and play critical roles in development and differentiation. Despite their crucial biological importance, the biogenesis pathways that generate miRNAs are not completely understood. In canonical miRNA biogenesis, primary miRNAs are transcribed from intergenic loci or intronic regions by RNA polymerase II. These transcripts are then processed by the Microprocessor, an enzyme complex that consists of Drosha and RNA-binding protein DGCR8 (known as PASH-1 in *C. elegans*). Subsequent processing by Dicer produces the miRNA that is loaded into Argonaute to repress target mRNAs. However, rare noncanonical pathways also bypass the requirement for the Microprocessor and/or Dicer. Using a temperature-sensitive allele of *pash-1* in *C. elegans*, we discovered a unique family

of PASH-1-independent miRNAs, the *mir-1829* family. The *mir-1829* family resides in unusually long introns of three host genes that have no apparent overlapping functions. From 5' RACE data, we determined that the *mir-1829* family is derived from independent transcripts with a semiconserved TSS. We posited that these miRNAs are transcribed by RNA Polymerase III (RNAPIII) based on published RNAPIII ChIP-sequencing and conserved RNAPIII promoter elements. In support of this, CRISPR-mediated mutation of these elements abrogated *mir-1829b* expression. Furthermore, we have reintegrated a minimal transcriptional unit containing these putative RNAPIII promoter elements at an intergenic locus and observed expression of *mir-1829b* at similar levels to that of the endogenous locus. Downstream of transcription, although *mir-1829* family biogenesis bypasses Microprocessor, we have determined that it is Dicer-dependent by Northern blot and small RNA-sequencing. Thus, we have delineated a novel biogenesis pathway involving RNAPIII and Dicer, but not Microprocessor. Future work will examine the biology of these miRNAs. While our quadruple knockout of the miRNA family does not have an overt impact on viability or reproduction, we and others have demonstrated that it is enriched in a germline-specific Argonaute protein and may play a role in the robustness of the mitosis to meiosis transition in germ cell development.

1321F **Investigating HPV-E7 protein mediated disruption of the DREAM transcriptional repressor complex** Emily Washeleski[1], Ryleigh Parsons[2], Paul D Goetsch[2] [1]Michigan Technological University, [2]Biological Sciences, Michigan Technological University

E7, a small protein encoded by the Human Papilloma virus (HPV), plays a large role in the oncogenic progression of infected cells. Approximately 4.5% of new cancer cases worldwide develop from HPV infections. Although there is an available vaccine for the most common oncogenic HPVs, there remains no treatment to prevent oncogenesis if a patient does get infected. Oncogenic HPV-E7 proteins cause cancer via disrupting the transcriptional regulation of the cell cycle by inhibiting the function of the 3 mammalian pocket proteins, the Retinoblastoma protein (pRb), p107, and p130. Since HPV-E7 interacts with the pocket proteins through their "LxCxE" binding cleft, the viral oncoprotein impairs p107 and p130 from forming the DREAM transcriptional repressor complex as well as impairs pRb's tumor suppressor activity as a major checkpoint inhibitor of early cell cycle progression. The goal of this project is to better understand how the HPV-E7 oncoprotein disrupts DREAM complex function by establishing HPV-E7 transgenic lines in *Caenorhabditis elegans* using CRISPR/Cas9 mediated genome editing. Because the DREAM complex subunits are highly conserved, the sole *C. elegans* pocket protein homolog lin-35 is a likely candidate for binding by HPV-E7 proteins. Most HPV-E7 proteins, including all cancer associated strains, share a conserved LxCxE binding motif. This E7 motif is identical to the interaction motif required for LIN-52, another DREAM subunit, to bind to LIN-35 and form the *C. elegans* DREAM complex. I hypothesize that HPV-E7 proteins containing the LxCxE motif will compete against LIN-52 for association with the LIN-35 pocket protein, inhibiting DREAM complex formation and function. In contrast, I expect that HPV-E7 proteins lacking the motif will not disrupt DREAM formation. In *C. elegans*, loss of DREAM complex activity is readily observed via high penetrance of a synthetic multivulval (SynMuv) phenotype when combined with SynMuv A class gene mutants. I will use SynMuv phenotype analyses, along with co-immunoprecipitation, chromatin immunoprecipitation, and RNA-seq analyses, to determine the level by which transgenic HPV-E7 protein expression affects *C. elegans* DREAM function. Additionally, I will test if chemical antagonists to E7 LxCxE association will restore DREAM function in strains that generate a Muv phenotype. Overall, my goal is to establish a novel platform in *C. elegans* to study HPV-E7 protein specific associations *in vivo*.

1322F ***SPR-5; MET-2 maternal reprogramming cooperates with the Dream and MEC Complexes to regulate developmental cell fates*** Brandon S Carpenter[1], Jazmin S Dozier[1], Sandra S Nguyen[1], David Katz[2] [1]Kennesaw State University, [2]Emory University

At fertilization, histone methylation must undergo maternal reprogramming to reset the epigenetic landscape in the new zygote. During maternal reprogramming of histone methylation in the nematode, *C. elegans*, H3K4me is removed by the H3K4 demethylase, SPR-5, and H3K9me is subsequently added by the histone methyltransferase, MET-2. Recently, it was demonstrated that SPR-5; MET-2 maternal reprogramming antagonizes the H3K36 methyltransferase, MES-4, which maintains a transcriptional memory of a subset of germline genes between generations. Maternal loss of SPR-5 and MET-2 results in ectopic expression of MES-4 germline genes in somatic tissues and a severe developmental delay. Data from the Petrella and Ahringer Labs demonstrates that members of the DREAM Complex, a transcriptional repressor complex that regulates cell cycle, also represses germline genes in somatic tissues through H3K9me2 promoter marking. Furthermore, preliminary data from our lab shows that the histone deacetylation, MEC Complex, is also required to prevent a soma-to-germline transition. These data suggest that the DREAM Complex, MEC Complex, and SPR-5; MET-2 maternal reprogramming may work together to prevent ectopic expression of germline genes in somatic tissues and developmental delay. To test this hypothesis, we knocked down Dream Complex and MEC complex members in *spr-5; met-2* mutants using RNAi and found that knocking down either complex exacerbates the severe developmental delay that we normally observe in *spr-5; met-2* mutants leading to a complete L1 larval arrest. Using RNA-seq, we further demonstrate that knocking down Dream Complex and MEC complex members exacerbates the ectopic expression of MES-4 germline genes in *spr-5; met-2* mutant somas. Our findings provide mechanistic insight into how evolutionary conserved transcriptional repressor complexes and reprogramming of histone methylation

synergize to ensure proper germline versus somatic cell fates during development.

1323F **Inactivation of SPR-2, a histone acetyltransferase inhibitor, results in transgenerational germline mortality phenotype in *C. elegans*** Thalia Boston[1], Monica Reeves[2], Mackenzie S Roberson[1], Scott Roques[3], Karen L Schmeichel[1], David J Katz[2] [1]Biology, Oglethorpe University, [2]Cell Biology, Emory University, [3]Biological Sciences, University of Massachusetts

Work in *C. elegans by* Wen et al., showed that mutations in either *spr-5*, encoding an H3K4me2 demethylase, or *spr-2*, encoding a histone acetyltransferase inhibitor (INHAT), suppress the egg-laying defect of *sel-12* mutants by causing the normally germline-restricted paralog of *sel-12, hop-1,* to be expressed in the soma. Previously, we found that *spr-5* mutants in *C. elegans* exhibit transgenerational germline mortality, where the brood size of the population steadily declines across generations. In these animals, transcriptionally activating H3K4me2 marks accumulate in germline genes leading to the aberrant expression of these genes in the soma over time. Like H3K4me2, histone acetylation is associated with transcriptionally active chromatin. Therefore, by inhibiting the accumulation of histone acetylation in the germline, SPR-2 may also function to prevent germline genes from being inappropriately activated in the soma of the subsequent generation. To determine whether *spr-2* mutants exhibit a germline mortality phenotype, we examined the brood size of homozygous mutant animals harboring one of two *spr-2* mutant alleles: *spr-2(ar211)*, with a nonsense mutation in *spr-2*'s third exon, and *spr-2(ar199),* with a deletion in the gene's promoter. Over 16 generations, *spr-2(ar211*) point mutant worms yielded brood counts that were comparable to those seen in wild-type N2 worms (average brood count was 278.3, $p>0.05$). However, promoter-deleted *spr-2(ar199)* mutants displayed a statistically significant reduction in brood size starting at F7 (average brood count was 49% of N2, $p < 0.05$). By generation F13, populations were severely infertile exhibiting brood counts that were 10% of N2 ($p<0.05$). The germline mortality of *spr-2(ar199)* animals raises the possibility that histone acetylation may be accumulating transgenerationally, resulting in the expression of germline genes in the soma. We are currently performing experiments to test this possibility. As far as we know, there is no previous evidence that histone acetylation can function as a transgenerational transcriptional memory.

1324F **Guiding mRNA to nuclear periphery: Lessons from imb-2 in C elegans** Ambika Basu, Lindsay Winkenbach, Dylan Parker, Erin Nishimura Biochemistry and Moelcular Biology, Colorado State University

The *Caenorhabditis elegans* maternally inherited mRNA transcript *imb*-2(Importin beta-2) concentrates at the nuclear periphery along with its encoded protein. To understand signals that guide the *imb-2* transcript to the nuclear periphery, we assessed whether its mRNA sequence or peptide sequence direct localization. To test the sufficiency of the 3'UTR of *imb-2* in driving localization, the 3'UTR was appended to a naive reporter. The reporter could not make it to its desired location, hence we concluded that 3'UTR was not sufficient. Experiments with translation-inhibitors cycloheximide and puromycin revealed that ongoing translation elongation is not necessary. Instead, an intact ribosome nascent chain complex is required for *imb-2* localization. This suggests that peptide sequences in the nascent IMB-2 protein direct nuclear localization of the nascent chain, the ribosome, and the associated *imb-2* mRNA. We went on to ask if the mRNA coding sequence or amino acid sequence is necessary for mRNA localization. For this, we re-coded the mRNA coding sequence while preserving a synonymous IMB-2 protein sequence intact by virtue of redundant codon usage. We observed that the re-coded mRNA led to loss of mRNA and protein localization and also caused mRNA instability. This brought us to the conclusion that the peptide sequence alone does not recapitulate the wild-type mRNA behavior. Taken together, *imb-2* nuclear periphery localization depends on a combination of mRNA and amino acid encoded information to ensure mRNA stability, translational complex formation, and transport.

1325F **Histone methylation readers *cec-3* and *cec-6* regulate germ granule integrity and small RNA pathways** Tammy L Lee, Chengyin Li, Phoebe AW Bhagoutie, Arneet L Saltzman University of Toronto

Small RNA and chromatin regulation pathways cooperate to safeguard germline immortality and the inheritance of genetic information. Importantly, many factors involved in small RNA-mediated gene regulation reside in evolutionarily conserved perinuclear germ granules. We previously found that two *C. elegans* chromodomain proteins, *C. elegans* Chromodomain (CEC)-3 and CEC-6 recognize heterochromatin-associated histone H3K9 and H3K27 methylation *in vitro*. *cec-3; cec-6* mutant animals show a progressive sterility or 'mortal germline' phenotype, but the underlying cause of this fertility defect is unknown. Live imaging analysis of GFP-tagged germ granule components PGL-1 and DEPS-1 reveals that germ granule formation is disrupted in *cec-3; cec-6* mutant adult germlines. Furthermore, progressive loss of germ granule integrity was accompanied by defects in meiotic prophase progression as *cec-3; cec-6* lines approach sterility. Our small RNA-seq analysis also shows that late generation *cec-3;cec-6* mutants have increased antisense small RNAs targeting a germline reporter that remained silenced for extended generations, and differentially regulated WAGO-class small RNAs. Our transcriptome analysis suggests that a subset of repetitive elements, transposons, germ granule components, and endogenous siRNA targets are mis-regulated in *cec-3; cec-6* mutants. While *cec-3; cec-6* mutants have similar germ granule and mortal germline phenotypes to the piRNA Argonaute

mutant *prg-1,* our analyses using a germline piRNA sensor suggest that *cec-3* and *cec-6* are not required for piRNA-mediated silencing. We are currently investigating how *cec-3* and *cec-6* impact the small RNA repertoire and transcriptome over generations. Together, our results suggest a role for these heterochromatin reader proteins in the small RNA and chromatin silencing pathways that maintain germ cell fate and genome integrity.

1326F **Control of spermatogenesis developmental program via RNAi-mediated regulation of ALG-3/4 small RNA pathway in *C. elegans*** Trilotma Sen, Cara McCormick, Alicia K Rogers Biology, The University of Texas at Arlington

Gene regulation is necessary for maintaining coordination of molecular mechanisms during development to ensure proper fertility. Precise activation and silencing of genes within totipotent germ cells is crucial for gametogenesis. In *C. elegans,* RNA interference (RNAi) pathways restrict spermatogenesis during the L4 stage and permit the expression of oogenesis genes in the adult stage. Yet, it remains unclear how these developmental programs are robustly executed, particularly during stressful conditions. We leveraged *mut-16* mutants, which exhibit sperm-based infertility at elevated temperature (25ºC), to examine how RNAi pathways protect sperm reproductive potential during stress. We found that sperm genes were developmentally mis-coordinated in heat-stressed *mut-16* mutant hermaphrodites. Bioinformatic analyses revealed the mis-regulated genes largely overlapped with ALG-3/4 pathway targets indicating that small RNA mediated regulation from the *mutator* complex is essential throughout development, despite ALG-3/4 pathway being independent of the *mutator* complex for amplification of its downstream 22G-RNAs. Further analysis revealed developmental mis-regulation of *alg-3* and *alg-4* gene expression in heat-stressed *mut-16* mutants, correlating with changes in 22G-RNA and 26G-RNA levels at the *alg-3* and *alg-4* genomic loci. These discoveries suggest that small RNA pathways play a role in activating and deactivating the ALG-3/4 pathway at the proper developmental stages.

1327F **Genome-wide studies of natural variation reveal putative members of the Gap Gene Regulatory Network** Lossie (Elle) Rooney[1], Gregory T. Reeves[2] [1]Biological Sciences (Genetics), North Carolina State University, [2]Texas A&M University

Axial patterning conveys positional information throughout the body of an organism during embryogenesis through a cascade of gene expression controlled by a gene regulatory network (GRN). GRNs contain multiple agents, including transcription factors and genomic sequences, that interact to determine complex traits. Determination of these traits may be impacted by perturbation of part of the network unless network architecture effectively adapts to maintain a robust phenotype. Across a population, natural genetic variation is one such perturbation. Here, we use the natural variation found in the *Drosophila melanogaster* Genetic Reference Panel (DGRP) to examine the Gap GRN that patterns the anterior-posterior (AP) axis of the early (1-3 h old) *Drosophila* embryo. AP axis specification is a well-studied phenomenon of early embryogenesis for which many genes, regulatory sequences, and transcription factors have been identified, though the knowledge of its functioning remains incomplete. The DGRP is a panel developed for association mapping while maintaining the natural variation of the original population and showing between-line variability for many phenotypes. Our lab has previously shown differences in spatial expression patterns of known Gap GRN genes using a small subset of DGRP lines. We expand on these findings with additional lines of the DGRP, using RNAseq as well as confocal microscopy, and discuss targets for further study.

1328F **Determining Jagunal as a Regulator in the Development of the Drosophila larval brain** Stephanie Uzordinma Awuzie[1], Judy Abuel[2], Maria Mendoza[1], Todd Nystul[3], Blake Riggs[2] [1]San Francisco State University, [2]Cell and Molecular Biology, San Francisco State University, [3]Anatomy, University of California, San Francisco

Asymmetric cell division is a highly conserved process across all species that is necessary for the proliferation of different cell types. This process is facilitated by the unequal partitioning of apical and basal cell fate determinants during stem cell division. Although asymmetric cell division has been extensively studied, the mechanism driving the localization of these cell fate determinants to generate cell differentiation is less well understood. Jagunal is a highly conserved integral transmembrane Endoplasmic Reticulum protein that is believed to play a role in asymmetric cell division. Here, we use immunohistochemistry and confocal microscopy to understand Jagunal's role in regulating the neural cellular composition of Drosophila during early development. This experimental approach has revealed that deficiencies in Jagunal result in an increase of neuroblasts compared to differentiated neurons within the larval brain. It has also been observed that Jagunal mutant brains display a mislocalization of basal cell fate determinants, suggesting that Jagunal is a key player in maintaining a balance of self-renewal and cell differentiation during the early brain development of Drosophila. To further study this, a single-cell transcriptome atlas will be built by sequencing the central nervous system across Jagunal deficiency to further examine Jagunal's downstream impact on cell heterogeneity, and gene expression. Understanding the mechanism of cell differentiation helps us to understand the role of JAGN1, the human homolog of Jagunal, in diseases linked to the disruption of cell differentiation, such as neutropenia; an immunocompromising blood condition.

1329F **Mapping the relationship between transcription factor concentration and gene expression using scanning Fluorescence Correlation Spectroscopy** Sadia Siddika Dima, Gregory T. Reeves Chemical Engineering, Texas A&M University

Gene regulation is a crucial biological process in development, homeostasis, and disease. Despite the pivotal role of transcription factors (TFs) in controlling gene expression, mechanisms such as how DNA becomes accessible to the TFs for binding and the map between TF concentration and gene expression are still not well understood. Therefore, in this work, we measured the absolute concentrations of multiple cooperative factors in the *Drosophila* blastoderm embryo over a 1.5 h period and correlated these concentrations to gene activation.

During the earliest stages of embryogenesis, the zygotic genome in most metazoans, including the fruit fly, remains transcriptionally silent after fertilization. Transcriptional activation of the zygotic genome coordinated with the degradation of maternally provided mRNAs occurs hours after fertilization, at a period termed as maternal-to-zygotic transition. In *Drosophila melanogaster*, the pioneer factor Zelda (Zld) acts as a master regulator for the transition and transcriptional activation of the zygotic genome. Unlike most other TFs, Zld can bind to the DNA in the context of nucleosomes and makes the chromatin accessible to other TFs thus helping early gene expression. Zld has been found to facilitate the binding of the dorsal-ventral patterning factor Dorsal (Dl) and the anterior-posterior patterning factor Bicoid (Bcd). Quantitative measurements of the biophysical parameters such as the nuclear concentration of the factors and the fraction bound to DNA as well as the change of these parameters over time are required for a better understanding of the system in which Zld helps these TFs bind to their motifs. Therefore, we performed Raster Image Correlation Spectroscopy (RICS), a type of scanning Fluorescence Correlation Spectroscopy, on images of live embryos between 1 and 3 h old carrying the factors tagged with GFP and histone-RFP marker to extract information about molecular dynamics and concentrations. From the results, we hypothesize that in early nuclear cycles (ncs), higher concentrations of Zld bound to DNA help the binding of Bcd and Dl, which are present in lower nuclear concentrations. In the later ncs, Zld binding attenuates, and other pioneer-like factors as well as higher concentrations of Bcd and Dl assist the process. The disagreement of our results with standard equilibrium models of TF/DNA interactions suggests that the ability of Zld to bind the DNA changes over time.

1330F ***Cis*-element bypass (redundancy) in *Drosophila melanogaster*** Anthony Percival-Smith Biology, Univ Western Ontario

Phenotypic specificity of transcription factor function was often presumed. For example, Proboscipedia was presumed to be specifically required for maxillary palp and proboscis determination, and Ultrabithorax was presumed to be specifically required for haltere determination. Testing whether transcription factor dependent phenotypes were rescued by TFs other than the TF resident to the *TF* locus, that is non-resident TFs, uncovered extensive redundancy of TF function (phenotypic nonspecificity) challenging the presumption of phenotypic specificity of transcription factor function. The frequent rescue of seven of eight transcription factor (TF) dependent phenotypes by multiple, non-resident TFs that recognize distinct DNA binding sites indicates extensive redundancy of TF function in developmental/behavioral pathways that is not based on recognition of similar DNA binding sites. Because distinct DNA-binding sites are recognized in phenotypic nonspecificity, there is the hypothetical expectation that the *cis*-regulatory elements used by non-resident TFs in a regulatory region are different from those used by the resident TF; simply put, the redundancy of trans-acting factors should be mirrored in the redundancy of *cis*-acting regulatory sequences. The rescue of depigmentation of the *dsx* null mutant abdomen by the expression of Doublesex female (DSX^F) is also rescued by the expression of Bric a Brac 1 (BAB1), Antennapedia (ANTP), Eyeless (EY) or Oddskipped (ODD). Analysis of epistasis suggests that all four TFs are epistatic to DSX^F and that ANTP, EY, ODD are epistatic to *bab* suggesting that these three TFs act after BAB or substitute for BAB function. BAB represses Yellow (Y) expression during the patterning of female abdominal pigmentation by binding to regulatory sequence in the *y* regulatory region. The *cis*-elements required for BAB regulation of *y* expression are well-characterized; therefore, the *y* gene may provide a platform for the analysis of the requirement of *cis*-regulatory elements for phenotypic nonspecificity. Using *y* regulatory elements that have BAB binding sites and that lack BAB binding sites, I am testing whether the TFs ANTP, EY and ODD require the BAB binding sites or not for repression of *y* expression. The non-requirement of the *cis*-acting BAB binding sites of *y* (*cis*-element bypass) would suggest that other DNA binding sites in the regulatory sequence are being used to repress *y* expression indicating *cis*-element redundancy.

1331F **Interrogating mitochondria-nuclear crosstalk: A novel perspective to Single nuclei RNA Sequencing** Snigdha Gupta[1], Fan Zhang[2], Hong Xu[2] [1]Laboratory of Molecular Genetics, National Heart Lung and Blood Institute, NIH, [2]National Heart Lung and Blood Institute, NIH

Mitochondrial DNA (mtDNA) depletion syndromes (MDS) are a genetically and clinically heterogeneous group of autosomal recessive disorders representative of a severe reduction in mtDNA content. MDS arise due to defects in mtDNA maintenance caused by mutations/dysregulation **in** nuclear gene that function in either mitochondrial nucleotide regulation or mtDNA replication. We aim to identify novel pathways/candidate genes involved/associated with mitochondrial DNA depletion/ mitochondrial defects and thus contribute to various disease pathologies. We utilize an Auxin -inducible UAS/Gal4 system to express a mitochondrial targeted restriction enzyme to deplete mtDNA in a spatio-temporal manner and conduct single nuclear RNA sequencing to study the mito-nuclear crosstalk. We generated mtDNA deficiency in fly eyes at two developmental

stages: the larval eye disc that is mainly consisted of mitotic cells and adult eyes that contain terminal differentiated photoreceptor neurons. The nuclei in larval eye discs and adult eyes were marked with Lamin-gfp and isolated using FACS base sorting. The GFP positive nuclei from the control and mtDNA depleted samples were subsequently sequenced using 10x genomics. Data analyses are currently underway. We will expand our study in other energy demand tissues including muscle cells and heart, which are also frequently affected by mitochondrial DNA depletion. These analyses will allow to detect tissue specific candidates/pathways involved in pathophysiological processes of mtDNA depletion and investigate possible mtDNA and nuclear genome interactions responsible for tissue homeostasis and maintenance.

1332F **Genetic and bioinformatic analyses reveal novel transcriptional regulation of mitochondrial ETC biogenesis in *Drosophila*** Fan Zhang, Anne Lee, Anna Freitas, Zongheng Wang, Snigdha Gupta, Zhe Chen, Hong Xu NHLBI, National Institutes of Health

Mitochondria carry out energy metabolism and modulate various cellular signaling pathways, and hence are crucial for tissue development and homeostasis. Mitochondrial mass and respiration are tightly regulated in cope with the tissue and development- specific metabolic demands. Mitochondrial genome encodes handful genes of respiratory chain complexes, whereas most mitochondrial proteins are encoded on the nuclear genome. However, the mechanisms coordinating these two genomes in the regulation of mitochondrial biogenesis remain largely unknown. To identify transcription circuits involved in such regulation, we performed a candidate RNAi screen covering 638 transcription factors annotated in the fly genome. We reasoned that impaired mitochondrial biogenesis would synergistically interact with mtDNA deficiency in disrupting tissue development. By combining individual RNAi with mtDNA deficiency, we identified 77 transcription factors that may be involved in the transcriptional regulation of mitochondrial biogenesis and mtDNA genome. Additional genetic and genomic analyses comfired the pivotal role of a novel transcription factor, CG1603, and its upstream factor YL-1 in mitochondrial biogenesis. Moreover, we constructed a regulator network of positive hits using the published CHIP-seq data. The network analysis revealed extensive connections and complex hierarchical organization underlying the transcription regulation of mitochondrial biogenesis.

1333F **Decoding the regulatory role of CrebA in secretory output during salivary gland development in Drosophila melanogaster** Dorian M Jackson[1], Dan Peng[1], Matthew Slattery[2], Patrick Cahan[3], Deborah Andrew[1] [1]Cell Biology, Johns Hopkins University, [2]Biomedical Sciences, University of Minnesota, [3]Biomedical Engineering, Johns Hopkins University

Whereas secretion occurs in all cells of higher organisms, there are specialized organs uniquely dedicated to secretion, including, for example the human pancreas, mammary, lacrimal, and salivary glands. Although essential for organismal well-being, the early regulatory networks and developmental events that define their capacity to function as secretory organs are less understood. The Drosophila salivary gland (SG) – a relatively simple dedicated secretory organ – is a premier model for elucidating how high-capacity secretory function is achieved. Studies in the last ~20 years have revealed key transcription factors (TFs) controlling both secretory capacity and secretory specificity. The CrebA leucine zipper TF has been shown to coordinate increases in secretory capacity in the SG as well as in other professional secretory cells of the Drosophila embryo. Loss of CrebA results in a reduction in secreted SG lumen volume and structural defects in the cuticle secreted by epidermal cells that correspond to significant decreases in the levels of expression of the secretory pathway component genes (SPCGs) that encode the protein machinery of secretory organelles. CrebA boosts secretory capacity through direct binding and transcriptional activation of SPCGs and of other genes involved in secretion. Whereas binding of CrebA is essential for direct regulation of gene expression, binding and regulation of specific genes are not tightly correlated. A previous study showed that a subset of genes that are directly bound by CrebA had no overt changes in their expression in the absence of CrebA; indeed, studies to date suggest that CrebA binds far more genes in the SG than are affected by its loss or overexpression. Thus, we aim to discover the features of CrebA binding that distinguish genes both bound and affected by CrebA from the features of CrebA binding in genes unaffected by CrebA loss or overexpression. We have done single cell RNA sequencing (scRNA-seq) to identify the full set of SG genes whose expression change during embryonic development and chromatin-immunoprecipitation and sequencing (ChIP-seq) to identify the full set of SG genes bound by CrebA during this same period. Using computational approaches, we are now searching for correlations in binding parameters to changes in expression levels in WT versus CrebA null samples to build and test models of CrebA-dependent gene expression in the SG.

1334F **Elucidating the roles of ecdysone signaling in adult *Drosophila melanogaster*** Katherine Fhu[1], Zachary Drum[2], Joseph Coolon[3] [1]Biology, Wesleyan University, [2]University of North Carolina at Chapel Hill, [3]Wesleyan University

Ecdysone is a steroid hormone found in arthropods that is vital in coordinating life cycle transitions in *Drosophila* and other insects. Modulation of 20-hydroxyecdysone (20E) levels, the active form of ecdysone, is crucial to initiate larval molting, pupariation, and metamorphosis events. While ecdysone's role in *Drosophila* development is well studied, much less is known about the presence and function of ecdysone in adults. Previous work has revealed that ecdysone affects various processes

in adult *Drosophila*, including reproduction, lifespan, and stress responses. Here, we seek to further understand the roles of ecdysone by observing genome-wide gene expression changes in response to perturbing ecdysone signaling in fully developed flies. This was achieved in two different experiments: 1) feeding adult females excess 20E and 2) expressing a dominant-negative mutant form of the ecdysone receptor (EcR). RNA-sequencing was performed on both sets of experiments, yielding sets of significantly differentially expressed genes associated with perturbation in ecdysone abundance. These data will identify new candidate target genes of ecdysone signaling in adult *Drosophila*, further distinguishing biological and molecular processes that are affected by this essential hormone in different life stages of insects.

1335F **A proximity labeling approach to discover novel members of the Drosophila histone locus body** Casey A Schmidt[1], Leila E Rieder[2] [1]Biology, Emory University, [2]Emory University

Histone biogenesis is strictly controlled in cells. Reduced histone expression leads to developmental arrest, and excess histone production is toxic to cells; thus, there are precise mechanisms in place to ensure that histones are manufactured at the appropriate time and in the correct amount. To achieve these regulatory requirements, the Drosophila melanogaster replication-dependent histone genes are arranged in a 5kb array that is tandemly repeated over 100 times at a single genomic locus. Transcription and processing factors concentrate in a nuclear body known as the histone locus body (HLB), which forms specifically at the locus. Historically, HLB factors have been largely discovered by chance, and few are known to directly interact with DNA. It is therefore unclear how the HLB identifies and targets the histone gene locus. To expand the list of known HLB members, we are using an in vivo proximity labeling approach. We targeted the promiscuous biotin ligase TurboID to the histone locus and will identify biotinylated proteins by mass spectrometry. Our preliminary experiments show robust and specific biotinylation coincident with Mxc, which is found exclusively in the HLB. This screen will be the first to address HLB composition in the context of development. Our approach, together with our previous candidate-based bioinformatics screen, will reveal novel HLB members, allowing us to further elucidate the unique mechanism of histone gene regulation.

1336F **Amino Acid Transporter Expression Screen Across Distinct Tissues in *Drosophila melanogaster* Adults** Ymani Wright, Alissa Armstrong Biological Sciences, University of South Carolina

Dietary amino acids play important roles in metabolic processes that support normal tissue growth, repair, and development. Amino acid transporters facilitate migration of amino acids into the cell. In *Drosophila*, we have previously shown that amino acid transporter knockdown in adult adipocytes mediates ovarian responses to dietary protein input. The Drosophila genome encodes 51 genes thought to be amino acid transporters and high-throughput studies suggest differential tissue expression. We hypothesize that distinct tissues including the fat body, ovary, brain, muscle, and gut require distinct dietary protein inputs to mediate their normal physiological functions. Thus, we first set out to determine the complement of amino acid transporters expressed by several tissues using an RT-PCR screen of 26 solute carrier amino acid transporters. We find that expression of the 26 amino acid transporters tested varies between these distinct tissues. For example, the ovary expresses low levels while the brain expressed high levels of *Aralar1*. Currently, we are determining if an organism's physiological state influences amino acid transporter expression by measuring amino acid transporter transcript and protein levels in tissues across different ages, diets, and sexes. In future studies, we will focus on determining amino acid transporter expression under obesogenic conditions. The genetic screen of amino acid transporter expression will help elucidate specific amino acid requirements for distinct tissues under D. melanogaster homeostatic and non-homeostatic conditions.

1337F **Investigating the Role of Histone Chaperones in Coordinating H3 and H3.3 Function in *Drosophila melanogaster*** Lucy C Grossmann[1], Jeanne-Marie E McPherson[2], Daniel J McKay[2], Robert J Duronio[1] [1]Biology, University of North Carolina at Chapel Hill, [2]Genetics, University of North Carolina at Chapel Hill

Histones are required for packaging DNA and regulating genome function. Controlling the abundance of histones within cells is essential, as too many or too few histones disrupts development. Eukaryotic genomes encode two types of histones: canonical and variant. Canonical histones are expressed only during S-phase, whereas variant histones are expressed throughout the cell cycle. We propose that coordination between canonical and variant histones contributes to achieving proper histone abundance. Canonical histone *H3.2* and variant histone *H3.3* differ by four amino acids, three of which modulate their interactions with chaperone complexes that deposit these histones into chromatin. Through an unbiased screen, we identified a genetic interaction between histone *H3* gene copy number and *Yem*, an H3.3-specific chaperone. This finding suggests that histone chaperones play a critical role in modulating the relative levels of H3.2 and H3.3 in cells. Since Yem and other chaperones bind histones in a type-specific manner, we hypothesized that they contribute to the coordination of canonical and variant histone abundance in cells. To this end, we have generated mutants that produce the canonical H3.2 protein from the *H3.3* genes (*H3.3*$^{H3.2}$), and thus only produce H3.2 protein outside of S-phase. Our results suggest that H3.3$^{H3.2}$ is incorporated into chromatin outside of replication. To determine which histone H3 chaperones are interacting with and depositing H3.3$^{H3.2}$ into chromatin we are performing genetic interaction experiments using histone chaperone

mutations and *H3.3*$^{H3.2}$ mutant genotypes. In our initial set of experiments, we are focusing on the H3.3-specific chaperone genes *Yem*, *HIRA*, and *Daxx* and the H3.2-specific chaperone gene *Caf-1*. We anticipate these experiments will provide insight into mechanisms by which cells coordinate histone type and abundance to regulate genome function.

1338F **Contextual cures drive locus specific function of a context-dependent transcription factor** Lauren J Hodkinson[1], Julia Gross[2], Casey A Schmidt[1], Pamela P. Diaz-Saldana[2], Leila E Rieder[1] [1]Department of Biology, Emory University, [2]Emory University

Despite binding similar *cis* elements, transcription factors (TFs) can perform context-dependent functions at different genomic locations. We broadly aim to understand how TFs integrate *cis* sequence and genomic context to function uniquely at different loci. One example of a context-specific TF in the genetic model *Drosophila* is Chromatin-Linked Adapter for MSL Proteins (CLAMP), which targets similar GA-rich *cis* elements on the X-chromosome and at the histone locus but recruits very different, locus-specific TFs. On the male X-chromosome, CLAMP recruits dosage compensation factors however, at the histone locus, CLAMP promotes formation of the conserved histone locus body (HLB) to regulate expression of the replication-dependent histone genes. Here we investigate how *cis* element origin can impact CLAMP function in the context of the histone genes. We engineered flies to carry a transgenic histone array in which we replaced the natural CLAMP-recruiting GA-repeat *cis* elements in the bidirectional promoter of histone genes 3 and 4 (*H3H4*p) with CLAMP-recruiting GA-rich elements from the X-chromosome. We assessed how X-linked *cis* elements impact CLAMP function by staining third instar larval polytene chromosomes with antibodies to a core HLB protein and an X-chromosome specific factor. When we replaced the *H3H4*p with an X-linked CLAMP recruiting region, HLB factors were not recruited but an X-chromosome factor was recruited to the transgene. However, when we replaced only the natural GA-repeats with GA-rich regions originating from the X-chromosome, either the HLB factor or the X-chromosome factor was recruited to the transgene. Our observations indicate that CLAMP incorporates both sequence and local contextual cues to dictate its function.

1339F **Investigation of Distinct Adipose Tissue Classes in Adult *Drosophila melanogaster*** Isaiah H Williams, Alissa Armstrong Biological Sciences, University of South Carolina

The energy storage and thermoregulatory roles of distinct classes of fat tissue, white, brown, and beige fat, have been well characterized. However, we are just beginning to understand how the fat tissue mediates its endocrine role. In *Drosophila melanogaster*, the adipose tissue, or fat body, uses nutrient sensing pathways to relay nutritional information to the diet-responsive ovary. To determine if there are distinct adipose tissue classes that mediate inter-organ communication in fruit flies, we are characterizing the morphological and functional regionalization of the adult fat body. Using the Gal4/UAS system, our current goal is to generate a comprehensive expression atlas of fat body-Gal4 transgenic fly lines that will then be used to investigate functional regionalization. We are examining reporter gene expression in 42 driver lines in the fat body in the head, thorax, and abdomen. Additionally, we are assessing tissue specificity by determining driver expression in the gut, ovary/testis, brain, and muscle. Thus far, we have examined 16 lines in the adult and larval fat body. For some driver lines, we find previously unreported driver expression. We also observe expression differences relative to age and level. After establishing expression patterns for these driver lines, we will investigate how diet affects fat body driver expression to determine how nutritional input impacts cellular and molecular mechanisms of adipose tissue function. In future studies, we will use drivers that correlate with specific adipose tissue subtypes to genetically ablate adipocytes and assess effects on inter-organ communication, particularly fat-to-ovary. The characterization of the diverse expression patterns in the fat body will aid driver selection for more precise control in *Drosophila* adipose tissue studies.

1340F **The role of chromatin-binding proteins on the trans-regulatory impact of variation in Y-linked heterochromatin** Shane F Warland, Keegan Kelsey, Elissa J. Cosgrove, Andrew G Clark Genetics, Cornell University

In most higher order eukaryotic organisms, a substantial portion of the genome is composed of large quantities of repetitive DNA, often in the form of short tandem repeats known as satellites. These satellite repeats play essential roles in centromeres and telomeres, but despite this, satellites are among the fastest evolving regions of the genome. The high rate of turnover of satellites is accompanied by high levels of inter-individual variation in copy numbers. The Y chromosome of *D. melanogaster* consists of nearly 40 Mb of satellite repeats, and its high level of variation in repeat copy number makes it an ideal natural perturbation of the dosage of satellites in the genome. From our Global Diversity Lines of *D. melanogaster*, we derived a series of isogeneic fly lines which only differ by their geographically disparate Y chromosome. Analysis of these lines has revealed two key observations. First, that heterochromatic repeat content varies remarkably among lines, leading to more than 3-fold variation in total Y-linked satellite content resulting in over 10 Mbp of sequence lost or gained across the lines. Second, RNA-seq analysis shows differential expression of hundreds of genes, with some gene transcripts correlated with distinct satellites. Correlative evidence is consistent with individual satellites binding with some specificity to particular transcription factors, allowing the expansion and contraction of specific satellite repeats to fine-tune individual protein levels in the genome. We applied CUT&RUN to these lines to quantify binding of the pioneer factor GAF, which has been shown

to bind to AAGAG and other AG-rich repeats, and find significant differences among Y-replacement lines in local binding, correlated with Y-linked copy number of relevant satellites. The degree of specificity of repeat copy number, impacting availability of chromatin-binding proteins and concordant impact on gene expression is being explored through a series of targeted CUT&RUN experiments. Our results present a promising mechanism for the "heterochromatin sink," adding a specificity of the connection between repeat abundance, binding protein availability and target gene expression modulation. This view of the Y chromosome as a trans-regulator of the rest of the genome has implications for the evolutionary significance of the Y chromosome and for heterochromatin in general.

1341F **Transcriptional Regulation of Stochastic Cell Fate Specification in the *Drosophila* eye** Emma Steinson[1], Rina Helt[1], Robert John Johnston[1], Elizabeth Urban[2], Lukas Voortman[2] [1]Biology, Johns Hopkins University, [2]Johns Hopkins University

During development, cell fate decisions are often driven by lineage and signaling mechanisms. Generally, these mechanisms are robust, overcoming molecular noise to generate stereotypical patterns of cells. However, in some cell populations, stochastic cell fate specification harnesses molecular noise to diversify cell types to produce distinct proportions, but random patterns of cell types within tissues. Though stochastic cell fate specification is vital during development, the mechanisms that regulate these fate choices are poorly understood. Here, we investigate how cell-intrinsic mechanisms, specifically transcription and chromatin regulation, contribute to stochastic cell fate choices in the developing *Drosophila* eye. In the fly retina, R7 photoreceptors make a random, binary choice to express Rhodopsin 3 (Rh3) or Rhodopsin 4 (Rh4). The random pattern of R7 subtypes is controlled by the stochastic ON/OFF expression of a transcription factor called Spineless (Ss): Ss^{ON} R7s express Rh4 and Ss^{OFF} R7s express Rh3 in the adult retina. Although each R7 randomly chooses subtype fate, 67% choose Ss^{ON} R7 fate and 33% choose Ss^{OFF} R7 fate, generating consistent ratios of cell types yet random patterns. Our data suggest that stochastic expression of *ss* is controlled by the dynamic regulation of transcription and chromatin during development. An *early enhancer* activates expression of *ss,* and transcription opens the locus in photoreceptor precursors. Of these precursors, 67% express *ss* at high levels and 33% express at low levels. After transcription ceases, chromatin compacts in a subset of cells which eventually give rise to Ss^{OFF} R7s. In the cells that remain open, *ss* expression is re-activated by the *late enhancer* and these cells become Ss^{ON} R7s. We hypothesize that differential *spineless* expression in precursors drives the terminal Ss^{ON}/Ss^{OFF} R7 fate choice: high *ss*-expressing precursors become Ss^{ON} R7s and low *ss*-expressing precursors differentiate into Ss^{OFF} R7s. We developed reporters including the MS2 MCP system to monitor *ss* transcription initiation, elongation, and termination and the ParB/*parS* and LacI/*lacO* systems to track live chromatin compaction. Using these tools, we will investigate how variability in transcription and chromatin is harnessed to diversify cell types.

1342F **Coordinating stereotyped and stochastic patterns in the *Drosophila* eye** Alison Ordway[1], Caitlin Anderson[2], Lukas Voortman[2], Elizabeth Urban[1], Robert J Johnston[1] [1]Biology, Johns Hopkins University, [2]Johns Hopkins University

During development, stereotyped patterning produces nearly identical structures across individuals of the same genotype. In contrast, stochastic cell fate specification produces random patterns that are unique to each individual. How gene regulatory mechanisms are coordinated to generate highly regular patterns and stochastic patterns within the same tissue is poorly understood. Here, we address this question in the context of the developing *Drosophila* eye. The fly eye has a stereotypical array of photoreceptors that arises through a wave of morphogenesis driven by Hedgehog (Hh) signaling. Overlaid on this highly uniform structure is a random pattern of two R7 photoreceptor subtypes, controlled by stochastic ON/OFF expression of the transcription factor, Spineless (Ss). Here, we find that Hh regulates *ss* during stochastic R7 subtype patterning. *hh* mutants display reduction in the size of the eye and the proportion of Ss^{ON} R7s. Excitingly, Cubitus Interruptus (Ci), an effector of Hh signaling, does not seem to play a major role in regulating *ss* expression, suggesting a non-canonical mechanism of action for Hh signaling. We are investigating targets of the Hh signaling pathway including Decapentaplegic (Dpp) and Homothorax (Hth), as well as factors involved in cell cycle regulation, to identify mechanisms that regulate *ss* expression downstream of Hh signaling. Our data suggest that Hh signals from differentiating photoreceptors to activate *ss* expression in immature precursor cells, similar to how Hh signals to promote morphogenesis of the fly eye. Thus, Hh signaling coordinates the generation of stereotyped eye morphology and stochastic R7 subtype patterning during development.

1343F **BRWD3 promotes KDM5 degradation to maintain H3K4 methylation levels** Dongsheng Han[1], Samantha H Schaffner[1], Jonathan P. Davies[1], Mary Lauren Benton[2], Lars Plate[1,3], Jared Nordman[1] [1]Department of Biological Sciences, Vanderbilt Univeristy, [2]Department of Computer Science, Baylor University, [3]Department of Chemistry, Vanderbilt Univeristy

Histone modifications are essential for regulating chromatin dynamics and gene expression. Disruptions in histone modifications levels likely contribute to diseases like cancer. H3K4 methylation is a known histone modification that associated with active gene transcription. While enzymes that add or remove methyl groups from H3K4 are known, how cells balance these enzyme levels to maintain normal H3K4 methylation levels is unclear. Here, we show that the chromatin-binding protein BRWD3 (Bromodomain and WD repeat-containing protein 3), a substrate-specificity factor of the Cul4-DDB1 E3 ubiquitin

ligase complex, helps balance H3K4 methylation levels through ubiquitin-proteasome system-dependent proteolysis. We found that depleting BRWD3 not only causes an increase in H3K4me1 levels but also causes a decrease in H3K4me3 (H3 lysine 4 trimethylation) levels, indicating that BRWD3 broadly influences H3K4 methylation. Using immunoprecipitation coupled to quantitative mass spectrometry, we identified an interaction between BRWD3 and the H3K4-specific lysine demethylase 5 (KDM5/Lid), an enzyme that removes tri- and dimethyl marks from H3K4. Moreover, analysis of ChIP-seq (chromatin immunoprecipitation sequencing) data revealed that BRWD3 and KDM5 are significantly colocalized throughout the genome and H3K4me3 are highly enriched at BRWD3 binding sites. We show that BRWD3 promotes K48-linked polyubiquitination and degradation of KDM5 and that KDM5 degradation is dependent on both BRWD3 and Cul4. Critically, co-depleting KDM5 restores altered H3K4me3 levels upon BRWD3 depletion. We also show that BRWD3 is a PEV (position-effect variegation) gene and genetically interacts with KDM5. Together, our results demonstrate that BRWD3 promotes KDM5 degradation to balance H3K4 methylation levels. Future works will focus on how BRWD3 regulates KDM5 activity throughout development and its broader implications for epigenetic programming and cell differentiation processes.

1345F **It's *abo*ut time: an investigation into the role of *abnormal oocyte* (*abo*) localization, function, and interaction in embryonic histone gene regulation** Eric H Albanese, Casey Schmidt, Leila E Rieder Biology, Emory University

Abnormal oocyte (abo) is a maternal-effect gene first characterized by Larry Sandler in 1970. Loss-of-function mutations in *abo* cause defects in embryonic development. Subsequent characterizations of abo revealed that it negatively regulates histone gene expression, likely through the targeting of *histone* promoters. Interestingly, the viability defects resulting from abo mutations can be rescued by overexpression of heterochromatic regions, suggesting that heterochromatin can act as a «sponge» to absorb excess histones. Despite these important experiments, *abo* has received little attention since the early 2000s, and its precise role in histone repression remains unknown. Therefore, our goal is to define the molecular role of abo in histone gene expression and promote a clearer understanding of negative histone regulation in *Drosophila melanogaster*. To achieve this, we generated V5-tagged *abo* lines via CRISPR. Using these lines, we analyzed abo localization in polytene chromosomes and embryos. We found that Abo does not behave as previously characterized in polytene chromosomes at endogenous or over-expressed levels. However, we find, novelly, that syncytial embryos do show Abo localizes to the histone genes. Our next experiments will focus on modulating *abo* expression via genetic drivers, null mutants, and transgenic histone-array rescue lines to determine the effect on histone expression at the mRNA and protein level. We will also compare Abo to Mute, another negative regulator of histone expression to elucidate if Abo and Mute have similar mechanisms of action, and if they can functionally compensate for each other. Lastly, we seek to broaden our analysis beyond historically relevant tissues (such as salivary glands), as we seek to propose a novel candidate for Abo activity, the early embryo. This research will contribute to an understanding of negative regulation of histone genes.

1346F **Regulation of Spermatogenesis by the BTB Transcription Factor Ribbon** Madeline Hakala, Christine Severude, Jennifer Jemc Loyola University Chicago

Past research has demonstrated that the transcription factor Ribbon (Rib) plays an essential role in *Drosophila* testis development and function. Loss of function of *rib* results in a failure of somatic cells to coalesce to form a gonad in the developing embryo. More recent work from our lab has shown that increased expression of *rib* throughout development results in significant morphology defects in the adult testis. If overexpression is limited to germ cells and somatic cells in the adult, more mild defects are observed. Ultimately, we are interested in identifying Rib transcriptional targets in this context to understand how it regulates spermatogenesis. To achieve this, we began by conducting RNA-sequencing of both control testes and testes in which *rib* was overexpressed in somatic cells. Utilizing a standard differential expression analysis pipeline, gene expression levels of *rib* overexpression flies were compared to the control, resulting in the identification of approximately 300 genes with statistically significant changes in gene expression after results were filtered. Given the previously described role of Rib in the regulation of cell morphogenesis and cell-cell interactions during development, we were particularly interested in genes involved in cell adhesion and regulation of the cytoskeleton. At this time, we have confirmed that *shortstop* (*shot*), which encodes a cytoskeletal linker protein, is a transcriptional target of Rib, revealing that Rib may regulate spermatogenesis through control of the cytoskeleton. Additional validation experiments are currently being conducted for other genes encoding cell adhesion proteins and regulators of the cytoskeleton to further support the role of Rib in regulating cell shape changes throughout spermatogenesis.

1347F **Exploring the function of Kelch stop codon readthrough protein in the Drosophila brain** Yaqing Cheng[1], Andrew Hudson[2], Lynn Cooley[2] [1]Genetics, Yale University, [2]Genetics, Yale university

Stop codon recognition is essential for proper protein synthesis termination, but under specific conditions, stop codons are recognized as sense codons, enabling continued translation. This process, known as stop codon readthrough (SCR), is conserved across various organisms, including viruses, yeast, Drosophila, and mammals. While more than 400 genes in Drosophila have been predicted to undergo SCR, only a limited number have been experimentally validated and characterized.

We have discovered that SCR is subject to tissue and cell type-specific regulation, with the highest efficiency observed in the Drosophila brain. Our previous research identified Kelch, a substrate adaptor for the Cullin Ring E3 ubiquitin ligase, as a gene undergoing SCR in Drosophila, producing an evolutionarily conserved C-terminal extension. To elucidate the functional significance of Kelch readthrough, we used newly engineered promiscuous ligases, TurboID coupled with mass spectrometry to identify interacting molecules associated with Kelch readthrough protein (KelRT) in the brain. Our analysis has revealed 64 high-confidence interacting partners of KelRT, some of which play roles in nervous system development and response to external stimulus. Additionally, we utilized CRISPR-Cas9 HDR to introduce the QF protein at the C-terminus of Kel-ORF2, enabling us to map Kelch SCR-expressing neuronal cell types through in combination with neuronal-specific Gal4 drivers. In summary, our research aims to uncover the functional role of KelRT in Drosophila brains, contributing to a better understanding of the significance of SCR.

1348F **Transcriptomic Analysis of Phenotypic Non-Specificity in *Drosophila melanogaster*** Gabriella Sidhu, Anthony Percival-Smith Biology, University of Western Ontario

Phenotypic nonspecificity of transcription factor (TF) function is the redundant rescue of a TF phenotype by multiple non-resident TFs that recognize distinct DNA-binding sites. In *Drosophila melanogaster*, phenotypic non-specificity is frequently observed across many TF phenotypes of which two are important for this study. The Apterous (AP) transcription factor is expressed in the cells of the wing imaginal disc dorsal compartment and is required for determination of the dorsal compartment and adult wing development. The *ap* null wingless mutant phenotype is rescued by expression of both the resident TF AP and by three non-resident TFs, Caudal (CAD), Tramtrack (TTK) and Myb oncogene-like (MYB). The Doublesex female (DSX^F) TF is expressed in abdominal cells and is required for female differentiation. Female pigmentation, characterized by an abdominal zebra stripe-like pattern of pigmentation, can be rescued in *dsx* null mutants by the expression of DSX^F and four non-resident TFs: Antennapedia (ANTP), Eyeless (EY), Bric à brac 1 (BAB1), and Odd-skipped (ODD), but not by expression of Forkhead box O (FOXO), and Squeeze (SQZ). ANTP, EY and ODD are not required for normal female abdominal pigmentation. DSX^F activates BAB1 expression, and ANTP, EY, ODD, have been shown to either substitute for, or work downstream of, BAB1. I am using the AP and DSX^F examples of phenotypic non-specificity to determine the sets of genes regulated by resident and non-resident TFs. The sets of regulated genes are identified using RNAseq, and compared to distinguish between three possible patterns: independence, partial overlap, or co-regulation. DSX RNAseq data has shown that the patterns of genes regulated by DSX^F, BAB1, ANTP, ODD and EY partially overlap with one another, and indeed the genes regulated by SQZ and FOXO which do not rescue abdominal pigmentation also partially overlap with all other TFs tested. RNAseq and subsequent characterization of the regulated sets of genes of the AP resident and non-resident TFs is currently in progress. The results of both examples of phenotypic non-specificity will, if similar, limit the models that can be used to explain phenotypic nonspecificity and the regulation of the initiation of transcription.

1349F **RNA-binding Protein Nocte Regulates mRNA translation and decay during *Drosophila* Development** Tianyi Zhang[1], Yutong Xue[1], Jennifer Martindale[1], Seung-Kyu Lee[2], Weiping Shen[3], Myriam Gorospe[3], Weidong Wang[3] [1]Laboratory of Genetics and Genomics, National Institute on Aging, [2]Laboratory of Genetics and Genomics, National Institute of Aging, [3]National Institute of Aging

RNA-binding proteins (RBPs) play essential roles in mRNA splicing, translation, and decay. To study the functions of an RBP and identify its targets, it is important to have reliable methods to detect the genome-wide changes at mRNA levels and at translation levels. Furthermore, the methods need to be sensitive enough for the samples that are laborious and difficult to collect, such as specific fly tissues. RNA-seq is an established method to measure mRNA levels with small amounts of samples, while Ribo-seq (also known as ribosome profiling) can detect ribosome footprints of the mRNAs to measure their translation efficiencies (TEs). In our recent studies of the RBP Nocte, we adapted the current Ribo-seq method and quantitatively detected ribosome footprints in *Drosophila* eye discs. Knockout of *nocte* leads to lethality, and its eye-specific depletion impairs eye size and morphology. Our Ribo-seq and RNA-seq results in eye discs show that Nocte preferentially enhances translation of mRNAs with long upstream open reading frames (uORFs). One of the key Nocte targets, *glass* mRNA, encodes a transcription factor critical for differentiation of photoreceptor neurons and accessory cells. Mechanistically, Nocte counteracts long uORF-mediated translational suppression of *glass* by promoting translation reinitiation downstream of the uORF. We are currently studying the mechanisms of mRNA decay caused by translation suppression in Nocte-depletion eye discs and the functions of Nocte in brains, forguts/midguts, hindguts/malpighian tubules and fat bodies with RNA-seq and Ribo-seq methods.

1350F **Lysine 36 of *Drosophila* histone H3.3 supports adult longevity** Benjamin D. McMichael[1,2], John C. Brown[2], Vasudha Vandadi[2], Aadit Mukherjee[1], Harmony R. Salzler[2], A. Gregory Matera[1,2,3,4] [1]Department of Biology, University of North Carolina at Chapel Hill, [2]Integrative Program for Biological and Genome Sciences, University of North Carolina at Chapel Hill, [3]Department of Genetics, University of North Carolina at Chapel Hill, [4]RNA Discovery Center, Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill

Aging is a multifactorial process that disturbs homeostasis, increases disease susceptibility, and ultimately results in death. Although the definitive set of molecular mechanisms responsible for aging remain to be discovered, epigenetic change over time is proving to be a promising piece of the puzzle. Several posttranslational histone modifications (PTMs) have been linked to the maintenance of longevity. Here, we focus on lysine 36 of the replication-independent histone protein, H3.3 (H3.3K36). To interrogate the role of this residue in *Drosophila* developmental gene regulation, we generated a lysine to arginine mutant that blocks the activity of its cognate modifying enzymes. We found that an *H3.3B*^{K36R} mutation causes a significant reduction in adult lifespan, accompanied by dysregulation of the genomic and transcriptomic architecture. Transgenic co-expression of wild-type *H3.3B* completely rescues the longevity defect. Because H3.3 is known to accumulate in non-dividing tissues, we carried out transcriptome profiling of young vs aged adult fly heads. The data show that loss of H3.3K36 results in age-dependent misexpression of NF-κB and other innate immune target genes, as well as defects in silencing of heterochromatin. We propose H3.3K36 maintains the postmitotic epigenomic landscape, supporting longevity by regulating both pericentric and telomeric retrotransposition and by suppressing aberrant immune signaling.

1351F **The requirement of Dosage Compensation in Drosophila development and aging** Kaitlyn M Cortez, Gunjan Singh, Nathan Ningrin, Zining Chen, Erica Larschan Molecular Biology, Cell Biology, and Biochemistry, Brown University

Dosage compensation (DC) is an essential conserved process that amplifies the expression of thousands of genes encoded on the single male X-chromosome two-fold. Although the onset of Dosage Compensation is at the mid-embryo stage, it is not known when DC is required for proper development and aging because it has not been knocked down at specific time points. Thus, I will knock down DC function in Drosophila embryos, larvae, and adults by disrupting the MLE component (RNA helicase A) of the master regulator of DC, the Dosage Compensation Complex (DCC). Utilizing the MLE-CRY2 optogenetic system to knock down MLE will allow me to investigate the effects of DC disruption at different time points while bypassing the early lethality seen in males. I will analyze sex-specific survival and longevity to investigate the role of DC in development and aging. My preliminary data suggests that DC is continuously required for the development of embryos into larvae and normal lifespan in adult males.

1352F **Ectopic heterochromatin triggered by insertion of repetitive DNA is temperature-sensitive** Melissa K. Sawyer, Alix Hathaway, Andrew M. Arsham Bemidji State University

Heterochromatin is a key genomic defense against invasive genetic elements, mitigating damage by inhibiting transposition, silencing gene expression, and reducing recombination at insertion sites. How a cell's epigenetic machinery recognizes and neutralizes novel threats, prior to establishing sequence-specific adaptive defenses like piRNAs is poorly understood. Here we show that the recognition and silencing of an exogenous tandem array of repetitive DNA is highly location-dependent. To investigate genome defense against novel repetitive DNA we carried out a transposition mutagenesis screen, mobilizing a reporter construct expressing the white gene adjacent to a 256-copy tandem array of the lac operator sequence from E. coli. We isolated insertional mutants with variegated eye color suggesting silencing by heterochromatin. Most recovered transgenic flies had full reporter gene expression and uniform red eye color - only ~1% of recovered flies had variegated eye color, indicating that the repeat array was not itself sufficient to trigger silencing. Surprisingly, the observed variegation is exceptionally sensitive to rearing temperature despite different genomic locations and chromatin contexts. Suppression of variegation at lower growth temperatures may provide clues to the genetic and biochemical mechanisms of genome defenses against novel invasive DNA. A clearer understanding of what cis-acting genomic features distinguish euchromatin that is sensitive to repeat-induced silencing from that which is not will provide insight into genomes' innate pathogen-sensing mechanisms as well as senescence and disease caused by disordered heterochromatin.

1353F **Determining the Regulatory Effects of Wolbachia on Heterochromatin in Drosophila Melanogaster** Nkechi Aman, Andrew Arsham Bemidji State University

Wolbachia is an intracellular bacterial parasite common in insects including Drosophila and mosquitoes. Wolbachia infection has profound effects on the metabolism, gene expression, and reproduction of insects and is poised to become an important tool to combat mosquito-borne diseases. Because Drosophila melanogaster is a common host for Wolbachia, the tools of Drosophila genetics can be used to understand the host- parasite relationship. Wolbachia has recently been shown to increase homologous recombination in D. melanogaster, but the mechanism by which it accomplishes this is unknown. We hypothesized that because heterochromatin inhibits recombination, it could be playing an intermediary role in Wolbachia's effects on recombination. Female flies from two wild type lines from the Drosophila Genetic Reference Panel that normally carry Wolbachia, and genetically matched controls that have been cured of Wolbachia by antibiotic treatment, were crossed with PEV flies and the ability of Wolbachia infection to modify the PEV phenotype was assessed. We find that, while there is marked variation between the two DGRP lines and between the different PEV stocks, Wolbachia infection can suppress variegation, suggesting that Wolbachia can inhibit heterochromatin formation pointing towards a possible mechanism for

Wolbachia's effect on recombination.

1354F **Brain specific microRNA mediated regulation of fat storage via Neuropeptide like Precursor 1 in *Drosophila melanogaster*** Pushpa Sharma, Davie Van Vactor Cell Biology, Harvard Medical School

Metabolism is a complex process. To maintain an optimal metabolic balance, an organism needs to match its food intake and energy storage in the form of fat with appropriate energy mobilization. These metabolic processes need to be finely regulated to fulfill timely physiological needs and to maintain the overall well-being of an organism. Misregulation of metabolism often results in diseases such as obesity, diabetes, cardiovascular diseases, or elevated triglycerides and cholesterol, which cause high mortality throughout the current world population. Small non-coding microRNAs (miRNAs) are well-suited as regulators of physiological and adaptive biological processes that require rapid and/or local control over gene expression. miRNAs control gene expression by inhibiting protein translation and destabilizing mRNA targets.

In our current research, we have been exploring the brain specific microRNA regulation of metabolic processes using *Drosophila melanogaster* as a model system. We have recently identified a novel neural circuit that controls metabolic homeostasis in *Drosophila* by a conserved Central Nervous system (CNS)-specific miRNA, *miR-1000* (ortholog of human *miR-137*). We find that miR-1000 regulates body weight, fat storage, survival under nutrient deprivation, and longevity, by targeting the Neuropeptide Like Peptide 1 (*Nplp1*) gene in the CNS. Loss of miR-1000 and consequent increase in Nplp1 expression results in flies with increased fat storage and extended survival in the absence of nutrients. The biological function of Nplp1 neuropeptides is largely unknown. Here, we define an important and novel biological function of *Nplp1* in maintaining metabolic homeostasis in *Drosophila*. miR-1000 and Nplp1 levels also change dynamically during refeeding after a period of starvation, suggesting an important adaptive function in metabolism.

1355F **Antisense transcription within the *histone* locus feeds into small RNA pathways and contributes to regulating *histone* mRNA expression during embryogenesis** Samantha A Russell[1,2], Fabio A Lefebvre[1,3], Ashley Chin[1,4], Louis PB Bouvrette[1,3], Julie Cardin[1], Gabrielle Deschamps-Francoeur[1], Eric Lécuyer[1,3,4] [1]RNA biology, IRCM, [2]Experimental Medicine, McGill, [3]Université de Montréal, [4]McGill

Endogenous small interfering RNAs (endo-siRNAs) are generated from a variety of sources, including long structured loci, transposable elements, and natural antisense transcripts (NATs). NATs are expressed from many loci in several organisms, including from a few of the *histone* (*his*) loci in *Drosophila, C. elegans,* and *Leishmania major*. In *Drosophila, his* mRNAs are encoded by tandemly arrayed gene units of the five *his* genes, and we find NATs express from all five *his* loci. Similar to *his* mRNAs, *his* NATs lack a polyA tail and transcriptomic analysis of mutant embryos indicates that dSLBP is necessary for *his* NAT expression. To characterize where *his* NATs localize to within the cells in the early embryo, we utilized a subcellular fractionation approach followed by RNA deep-sequencing. We find that *his* NATs are more cytoplasmic and mimic their mRNA counterparts, which suggests that *his* NATs contribute to the formation of double stranded precursors leading to siRNA molecules. Consistent with this idea, siRNA precursors are cleaved to 21-nt lengths during biogenesis, and small RNA-sequencing found small RNA reads at all *his* genes, with peaks at 21-nt lengths. In addition, analysis of RNA-seq data of small RNAs pulled down with AGO2, but not with AGO1, shows an enrichment of reads derived from the *his* locus. Finally, RNA-seq on embryo progeny from *AGO2^{414}/Df* mutant females reveals that loss of AGO2 specifically upregulates several *his* mRNAs, which suggests that AGO2-linked *his* endo-siRNAs contribute to the clearance of maternal *his* mRNAs during early *Drosophila* embryogenesis. Altogether, this work identifies a group of NATs, describes how they are regulated, characterizes where they localize to within the cell, and provides evidence that *his* NATs generate *his* endo-siRNA. We propose a working model where *his* NATs generate siRNA that interact with AGO2 in the early embryo, and target their corresponding genes to clear maternal *his* mRNAs.

1356F **Murine genetic reference population reveals the regulation and function of *Rpl3l* in the heart** Akhilesh K Bajpa[1], Qingqing Gu[1], Buyan-Ochir Orgil[2,3], Neely Alberson[2], Jeffrey A Towbin[2,3], Enkhsaikhan Purevjav[2,3], Lu Lu[1] [1]Genetics, Genomics and Informatics, University of Tennessee Health Science Center, [2]Pediatrics, University of Tennessee Health Science Center, [3]Children's Foundation Research Institute, Le Bonheur Children's Hospital

Background: Cardiomyopathy, a disease of heart muscles, is a common cause of heart failure. Recently, biallelic variants in ribosomal protein L3-like (*RPL3L*) have been reported in patients with dilated cardiomyopathy (DCM) and heart failure. This study aimed to employ a systems genetics approach to understand the regulatory mechanisms underlying *RPL3L* function in DCM.

Methods: The well-known murine genetic reference population, the BXD mice were used for genetic correlation and expression quantitative trait loci (eQTL) mapping. DCM patient and normal heart samples were used for identifying

differentially expressed genes. Functional enrichment analyses of the *Rpl3l*-correlated genes in BXD heart and differential genes in DCM patient versus normal heart samples were performed. Cardiac gene expression and echocardiography parameters in BXD mice were correlated to understand gene-phenotype associations. Furthermore, infiltration analysis of 24 different immune cells was performed using DCM patient and control heart gene expression data to reveal the associations between DCM, immune cell types and *RPL3L* expression.

Results: Systems genetics analysis identified high expression of *Rpl3l* mRNA, which ranged from 11.31 to 12.16 across BXD mice with ~1.8-fold difference. Pathways such as "DCM", "focal adhesion", "MAPK signaling" and "PI3K-Akt signaling" were significantly associated with *Rpl3l*-correlated as well as differentially expressed genes. The eQTL mapping suggested *Myl4* (Chr 11) and *Sdha* (Chr 13) as the upstream regulators of *Rpl3l*. The mRNA expression of *Rpl3l, Myl4* and *Sdha* was found to be significantly correlated with different echocardiography traits, such as ejection fraction, fractional shortening, cardiac output, left ventricular volume and end-systolic diameter in BXD mice. Immune cell infiltration analysis revealed a significant association of *RPL3L* and *SDHA* with seven immune cells (CD4 and CD8 naïve T, CD8 T, macrophages, cytotoxic T cell, Gamma delta T cell and Exhausted T cell) that were also differentially infiltrated between DCM patient and normal heart samples.

Conclusions: Expression of *Rpl3l* and its upstream regulators, *Myl4* and *Sdha,* correlate with multiple cardiac function traits in BXD mice, while *RPL3L* and *SDHA* correlate with immune cell infiltration in DCM patient hearts. These results suggest important roles for *RPL3L* in the development of DCM and heart failure.

1357F **Increased hemimethylation levels correlate with methylation reductions in DNA methyltransferase mutant mouse embryos** Chloe Tang[1], Tamara Davis[2] [1]Bryn Mawr College, [2]Biology, Bryn Mawr College

Mammals have evolved to have many forms of gene regulation. Genomic imprinting is one form that only allows the expression of one parental allele from an organism's genome. Imprinted genes are regulated epigenetically through DNA methylation, facilitated by DNA methyltransferase (DNMT1), where a methyl group (CH_3) is added to one parental allele to generate a differentially methylated region (DMR). Differential methylation results in differential gene expression of the parental alleles and the proper establishment of methylation patterns is crucial for embryonic development as abnormal methylation patterns can lead to inappropriate gene expression, developmental disorders, and diseases such as cancer. Methylation at primary DMRs, which is inherited at fertilization, is stable and symmetric throughout development whereas methylation at secondary DMRs, which is acquired during early embryogenesis, is less stable and asymmetric. In addition, previous research suggested that methylation is well maintained at primary DMRs in mouse embryos with a hypomorphic mutation of *Dnmt1* but is dramatically reduced at secondary DMRs and non-imprinted loci. These pieces of evidence suggest that DNMT1 might function differently at different loci. We hypothesize that reduced DNMT1 fidelity leads to an increase in hemimethylation, resulting to the observed methylation loss at secondary DMRs and non-imprinted loci. To test this hypothesis, I am analyzing the methylation patterns at both non-imprinted and imprinted loci in 12.5 days post conception (dpc) wild-type and *Dnmt1* mutant mouse embryos. Analysis of methylation patterns at three paternally methylated loci associated with imprinted genes indicated that the paternally methylated primary DMR was minimally affected but methylation was dramatically reduced at both secondary DMRs in *Dnmt1* mutant vs. wild-type embryos. In addition, the hemimethylation level at secondary DMRs was significantly higher in mutants than in wild type but this difference was less pronounced at the primary DMR. This inverse correlation between methylation and hemimethylation levels suggests that DNMT1 is essential in maintaining methylation patterns, especially regarding methylation symmetry during fetal development and that its inconsistent function leads to a loss of methylation and increase in hemimethylation. I'm currently extending my analysis to maternally methylated DMRs and non-imprinted loci to see if the pattern is generalizable.

1358F **Evolution of programmed DNA elimination in parasitic nematodes** James R Simmons[1], Brandon Estrem[1], Maxim V Zagoskin[1], Ryan Oldridge[1], Sobhan Zadegan[2], Jianbin Wang[1,2] [1]Biochemistry & Cellular and Molecular Biology, The University of Tennessee, [2]Genome Science & Technology, The University of Tennessee

A growing list of metazoans undergo programmed DNA elimination (PDE), where a significant amount of DNA is selectively lost from the genome during development. In nematodes, PDE leads to the removal of the ends of all germline chromosomes. In some species, PDE also eliminates sequences in the interior of the chromosomes, leading to an increased number of somatic chromosomes. The biological significance of these karyotype changes associated with PDE and the origin and evolution of nematode PDE remain largely unknown. Here, we assembled the single pair of germline chromosomes of the horse parasite *Parascaris univalens* and compared the karyotypes, gene organization within the chromosomes, and PDE features among ascarids. We showed that *Parascaris* converts an XX/XY sex-determination system in the germline into an XX/XO system in the somatic cells. Our analyses of the parasitic nematodes *Ascaris*, *Parascaris,* and *Baylisascaris* suggest that PDE existed in the ancestor of these parasites, and their current drastically different germline karyotypes were derived from fusion events of the same ancestral smaller chromosomes. PDE resolves these fused germline chromosomes and restores their pre-fusion

karyotypes, leading to alterations in genome architecture and gene expression in the somatic cells. Cytological and genomic analyses further reveal the dynamic organization of the *Parascaris* germline chromosome during meiosis and a potential function for the satellite DNA and the heterochromatin arms. Overall, our results show that PDE enables two karyotypes to exist within an individual, with both the fused germline chromosomes and the split somatic chromosomes contributing to genome organization and functions.

1359F **Sulforaphane disrupts lepidopteran epigenetic systems** Marisa Arreola, Ashley Groff, Whitney Finney, David B. Kushner, Thomas M. Arnold, Dana J. Somers Biology, Dickinson College

Sulforaphane (SFN), an inhibitor of histone deacetylases (HDACs), has been seen to disrupt enzyme activity, DNA-histone binding, and gene expression upon consumption in humans. In an ecological context, SFN is produced by cruciferous plants and works as a defense against grazers by disrupting their epigenetic systems. Experiments in different insect species showed that SFN reduces HDAC activity and slows the development of the beet armyworm (*Spodoptera exigua*), a generalist feeder. In contrast, the cabbage looper (*Trichoplusia ni*), a specialist that feeds exclusively on SFN-producing plants, has partial resistance to the effects of SFN. Experiments demonstrated that SFN slowed HDAC activity and growth of *S. exigua* whereas there was no significant change in *T. ni.* The gene expression of both grazers was also examined using RNA-seq analysis to classify genes and map them to metabolic pathways. Genes involved in energy production were downregulated in *S. exigua* that fed on SFN. To test whether SFN had transgenerational effects, a second generation of *S. exigua* and *T. ni* were produced from the generations that fed on SFN. Initial data suggests that SFN had minimal transgenerational effects in both species. This research suggests that SFN, and HDAC inhibitors in general, disrupt epigenetic systems within grazers who consume cruciferous plants, which could have broader implications for human health.

1360F **Revealing early cell cycle dynamics in epithelial ovarian cancer cells with CDK4/6 inhibition** Karl L Schneider[1], Paul D Goetsch[2] [1]Biology, Michigan Technological University, [2]Michigan Technological University

Despite decades of research and the development of initially effective treatment strategies, epithelial ovarian cancer remains a leading cause of cancer death for women worldwide. Quiescent, stem-like side populations of cancer cells within the tumor microenvironment could be the culprit behind the recurrence of the disease following remission in the majority of ovarian cancer patients . The pocket proteins pRb and p130, along with the DREAM complex, coordinate the repression of late G1 and S phase gene expression which is essential for maintaining quiescence. Cell cycle regulatory proteins are often mutated during oncogenesis, and it remains unclear what minimal functional components are necessary for cancer cells to retain the ability to quiesce. We used the CDK4/6 inhibitors palbociclib, abemaciclib, and ribociclib to induce quiescence and synchronize populations of cell lines in culture (2 epithelial ovarian cancer cell lines SKOV3 and HEYA8 and 1 immortalized primary fallopian tube epithelial cell line FT282). We performed flow cytometry and western blotting to confirm the effective induction of quiescence following treatment with CDK4/6 inhibitors. Analysis of the transcriptome via mRNA sequencing revealed the genes actively expressed as well as the relative changes in gene expression during and following this period of artificially induced quiescence. Finally, chromatin immunoprecipitation exposes the spatiotemporal dynamics of DNA binding by relevant transcription factors, including pRb and the DNA binding components of the DREAM complex. Taken altogether, these analyses enable a deeper understanding of the mechanisms underlying quiescence in epithelial ovarian cancer. Also, the establishment of a model for cell cycle synchronization with CDK4/6 inhibition and the subsequent analytical pipelines described herein can be expanded to later phases of the cell cycle, protein targets within other relevant signaling pathways, and other types of cancer. Novel data pertaining to the maintenance of quiescence in epithelial ovarian cancer will hopefully contribute to the development of better diagnostics and treatments for the detection and prevention of recurrent tumors.

1361F **Small RNAs in Nematode Programmed DNA Elimination** Maxim Zagoskin[1], Richard E. Davis[2], Jianbin Wang[3] [1]BCMB, The University of Tennessee, Knoxville, [2]Biochemistry and Molecular Genetics, University of Colorado School of Medicine, [3]Biochemistry & Cellular and Molecular Biology, The University of Tennessee, Knoxville

Programmed DNA elimination (PDE) is an exception to the DNA constancy rule, where an individual's germline and somatic genomes maintain identical DNA content. In some metazoans, nuclear DNA is selectively excised from the somatic genome, leaving the germline genome intact. In the parasitic nematode *Ascaris*, PDE leads to comprehensive chromosome end-remodeling, increased chromosome number, and loss of 18% of the germline genome including ~1000 genes. The mechanisms governing PDE and its broader implications for genome stability and metazoan evolution remain largely enigmatic.

Small RNAs are known to play a role in ciliate PDE. However, PDE is diverse and has distinct features in different taxa. Here we examined small RNAs in a nematode undergoing PDE, to ascertain their association with retained, eliminated DNA, or DNA breaks. We identified Argonaute proteins in *Ascaris* and characterized small RNAs associated with seven of these Argonautes. Immunostaining revealed that two of these Argonaute proteins, WAGO-2 & WAGO-3, are associated with PDE. Notably,

WAGO-3 staining was found to be enriched on eliminated DNA which was corroborated by ChIP-seq data. Through RNA chromatin immunoprecipitation assay, we identified specific sets of small RNAs that associate with nascent RNAs specific to WAGO-3 in the eliminated regions. These WAGO-3 secondary small RNAs are likely generated from primary siRNAs originating from double-stranded RNA derived from extensive bidirectional transcription in eliminated regions.

We suggest WAGO-3-associated small RNAs mark eliminated regions, binding to nascent RNAs on eliminated chromatin, thereby regulating gene expression in these regions. Conversely, WAGO-2 predominantly stains retained regions during the PDE process, and a subset of its associated small RNAs specifically targets repetitive sequences within these retained regions. WAGO-2 small RNAs may directly interact with the repetitive chromatin within the retained regions to ensure the suppression of potentially deleterious repeats during PDE. In conclusion, our data suggests that two Argonaute proteins, WAGO-2 and WAGO-3, along with their associated small RNAs, distinguish retained and eliminated DNA by selectively targeting specific chromosome regions, possibly in response to chromatin changes triggered by PDE.

1362F **Function and regulation of the Mediator complex kinase subunit Cdk8** Sara McPherson[1], Bhuvan Anbalagan[1], Mary-Elizabeth Raymond[1], Ivan Sadowski[2], Maria Aristizabal[3] [1]Biology, Queen's University, [2]University of British Columbia, [3]Queen's University

In eukaryotes, transcription is performed by one of several RNA polymerases (RNAP), RNAPII synthesizing the most significant portion of RNAs. RNAPII transcription regulation is complex, as such, is poorly understood. The Mediator complex is a significant transcriptional regulator, organized into the head, middle, tail, and the dissociable Cdk8 kinase module. Cdk8 is a Mediator subunit and an evolutionarily conserved kinase with well-known roles in transcriptional activation and repression. These transcriptional activities are mediated by Cdk8's ability to phosphorylate several components of the transcriptional machinery and sequence-specific transcription factors. In budding yeast, this includes the RNAPII C-terminal domain (CTD), several Mediator complex subunits, and the sequence-specific transcription factors Gal4, Gcn4, Ste12, and Phd1. For example, Cdk8 can repress context-specific gene expression by phosphorylating Gcn4, Ste12, and Phd1, targeting them for proteolytic degradation and blocking the activation of their respective target loci in response to nutrient availability. By contrast, Cdk8 activates transcription by phosphorylating Gal4 and its target loci in response to the presence of galactose in the growth media. Although well studied, deletion of Cdk8 in budding yeast produces more gene expression alterations than can be accounted for by its known substrates. Findings suggest an incomplete understanding of the factors that Cdk8 targets to regulate transcription, and how Cdk8 activity is regulated remains unknown. My project leverages recent structural insights and results from our recent high-resolution gene expression time course analysis before and several time points after nuclear depletion of Cdk8 to close these knowledge gaps. This work will reveal significant aspects of Cdk8 function, uncovering mechanisms by which organisms respond to changing environments. Understanding how Cdk8 regulates transcription will also show how a single factor can integrate several distinct signals to produce tightly regulated transcriptional outputs, a fundamental question in the field. Revealing aspects of normal Cdk8 function will also shed insight into the role of Cdk8 as an oncogene and tumor suppressor, informing efforts to develop Cdk8 inhibitors for anti-cancer treatment.

1363F **The exonic promoter of *Saccharomyces cerevisiae HKR1*, which encodes a mucin-like multidomain protein, makes for divers expression patterns** Toshihiro Kondo, Ryotaro Ozawa, Yuna Hosokawa, Shin Kasahara Food & Agricultural Sciences, Miyagi University

HKR1 was originally isolated from the genome of *Saccharomyces cerevisiae* as a gene that confers resistance to HM-1 killer toxin produced by the killer yeast *Lindnera mrakii* (synonym *Hansenula mrakii*). *HKR1* is an intronless gene with a 5.4 kb ORF encoding a mucin-like multidomain transmembrane protein, Hkr1p. Hkr1p contains a consensus sequence of EF hand, a calcium-binding motif and the DNA-binding leucine zipper motif in its cytoplasmic tail, and has actually been known as an osmosensor of the HOG MAP kinase complex.

We recently found that *HKR1* has another cryptic promoter in its exon and is transcribed not only from the promoter in the 5' upstream region but also from the region around the 3330th nucleotide (nt. #3330) from the translation initiation site. In addition, it has been confirmed that the transcriptional activity of the exonic promoter is silenced by its upstream sequence within the exon of *HKR1*. In this study, we investigated whether the suppressed transcription is restored by external conditions such as osmotic pressure by using reporter assay systems.

Plasmids containing various length of the exonic promoter region were constructed and a fluorescence protein gene or the *lacZ* gene of *Escherichia coli* was ligated to each promoter sequence, introduced into *S. cerevisiae* cells, then expression levels were evaluated by measuring the fluorescence intensity or beta-galactosidase activity. The maximum transcriptional activity was observed when the reporter genes were ligated to the 360 bp-long region of *HKR1* starting at the nt. #3050 through the ATG (^{3409}ATG) which corresponds to the internal translation initiation site (^{1137}Met). A significantly lower

transcriptional activity was detected when the reporter genes were ligated to the region between the nt. #2600 and ^{3409}ATG. These results suggest that the region between the nt. #3050 and the nt. #3330 is the core of the *HKR1* exonic promoter and its upstream sequence functions as a silencer-like regulator. Interestingly, the suppressed transcription was partially restored when the transformants were cultured under high osmotic pressure conditions.

These observations suggest a novel mechanism of eukaryotic gene regulation with multiple promoters, one of which is even located within an exon and is conditionally activated to express a latter portion of the protein. It could be a remarkable example of how a limited number of genes can generate more complex biological phenomena.

1364F **ChIP'ing away at Set1 regulation during meiosis** Johanna Maioriello, Michael Law Stockton University

Temporally and spatially restricted gene expression programs are required for differentiation. For example, in the budding yeast Saccharomyces cerevisiae, meiosis-specific genes are repressed during mitosis and must be expressed in waves of transcription, generally termed early, middle, and late. Transcriptional regulation relies upon extensive interactions between the RNA polymerase holoenzyme complex and post-translational histone modifications. The holoenzyme is comprised of multiple, highly-conserved protein subunits that include the cyclin C/Cdk8 kinase module. Previous studies have demonstrated functionally distinct structural and catalytic roles for Cdk8 in regulating gene expression, suggesting that complex mechanisms are in place for transcription during differentiation. Histone H3Lys4 methylation, catalyzed by the Set1-containing COMPASS complex, is one of the most well characterized of the histone modifications. While many studies have focused on determining the role of specific H3Lys4 methylation levels in controlling gene expression, less is known about how Set1 is targeted during differentiation. Our recent publications indicate that locus-specific Set1 recruitment and H3Lys4 me are antagonized by cyclin C/Cdk8 but the mechanism of this antagonism remains unknown. The goal of this study is to identify the spectrum of loci demonstrating meiosis-specific, Cdk8-dependent Set1 inhibition. To identify loci that are subject to control by Cdk8, we will use ChIP-seq. In these experiments, we will compare Set1 occupancy and activity in three different yeast strains; wild-type, cdk8Δ or cdk8 catalytic mutants, cultured in three different conditions; vegetative, pre-meiotic, or meiotic. Following crosslinking and chromatin fragmentation, Set1 occupancy will be measured using immunoprecipitations directed towards myc-Set1. Similarly, Set1 activity will be measured using immunoprecipitations directed towards histone H3Lys4 me1, me2, or me3. Next generation sequencing on purified DNA will be performed with the Illumina platform which will identify Cdk8- and growth condition-dependent Set1 regulation. In the wild-type strain, we will identify the regulatory pattern for meiosis-specific Set1 binding and H3Lys4 methylation. In our mutant strains, we will distinguish between the structural and catalytic functions of Cdk8. These studies will identify consensus promoter motifs regulated by Cdk8 and Set1 that are important for efficient meiotic transcription.

1365F **Characterization of histone mutants associated with recently described human neurodevelopmental disorders using the yeast model system** Agustin Kalinowski, Lillian Francis, Joseph Beard, Reece Forrest, Will Griffin, Jackson Parks, Caroline Tackett, Andrea Duina Department of Biology, Hendrix College

FACT is a highly conserved complex that plays critical roles in various chromosomal processes, including transcription elongation. During elongation, the histone chaperone complex FACT, which in *S. cerevisiae* is composed of two proteins, Spt16 and Pob3, contributes to the disassembling of nucleosomes in front of Pol II and their reassembly following Pol II passage. In previous work, we identified a nucleosomal region, which we refer to as ISGI (Influences Spt16-Gene Interactions), that plays a role in ensuring proper interactions between yeast FACT (yFACT) and transcribed genes. More specifically, mutations within this region cause an accumulation of yFACT at the 3' ends of genes, an effect we attribute to impaired yFACT dissociation following transcription.

Two recent studies have unveiled an association between mutations within genes that encode the human histone H3.3 protein and newly described neurodevelopmental disorders in patients. One of these mutants, H3.3 L61R, is within the ISGI region, providing a possible link between the neurodevelopmental disorders and yFACT-gene disassociation defects. To further explore this potential link and to gain a more general understanding of the effects of human H3.3 mutants on chromatin biology, we generated yeast cells that express several of these H3.3 mutants and we are currently testing them for possible defects in yFACT-gene interactions. We are also assaying the mutant cells for phenotypes indicative of nucleosome reassembly defects, DNA replication, and DNA repair. In this poster, we report our progress on these projects and describe our experimental plans moving forward.

1366F **Laboratory evolutions lead to reproducible mutations in *PDR3* conferring resistance to MCHM** Michael Ayers[1,2], Taizina Montareen[3], Daniel Judge[2], Dionysios Patriarcheas[2], Set Poziviak[2], Griffen Leombruno[2], Makaela Quinn[2], Camryn Lowery Lowery[2], Sarah McCulloch[2], Nathan Dale[2], Liam McCarthy[2], Felix Jonas[4], Jen Gallagher[2] [1]University of Rochester, [2]West Virginia University, [3]Biology, West Virginia University, [4]Constructor University

The solubility of protein complexes and membraneless compartments is maintained by liquid-liquid phase separation (LLPS). Phase transition is induced or dissolved by biological hydrotropes such as ATP and RNA. 4-methylcyclohexane methanol (MCHM), an alicyclic alcohol, is a synthetic hydrotrope that induces a starvation response by upregulation of biosynthetic pathways despite the availability of nutrients. To investigate how cellular metabolism can tolerate changes in LLPS, we evolved eight MHCM-resistant strains of *S. cerevisiae*. Knockouts of mutated genes were generated in the ancestral and evolved strains. These genes encoding proteins in flocculation, glutathione and SAM metabolism, and sugar transport and they mildly affected growth in MCHM. Among coding variants in the strains that change protein sequence and thereby may alter function, only one gene showed a protein-coding mutation in every resistant strain while showing no variants at all in the control strains. This gene, *PDR3*, controls transcription for the pleiotropic drug response and is the most significant driver of adaptive MCHM resistance in yeast. While many of the evolved alleles of *PDR3* would likely produce functional proteins, a knockout in the ancestral strain, YJM789, was sufficient to produce resistance to MCHM. Normal catabolism of amino acids uses the Pleiotropic Drug Response (PDR) pathway to export breakdown products and amino acid levels are elevated in MCHM exposed yeast. The *pdr3* resistance is mediated through Med15, a component of the Mediator complex which regulates activation by transcription factors of RNA pol II. Med15 contains two polyQ tracts that will transition into LLPS during stress and variation in length of the tracts changes the cellular response to MCHM. Pdr3 can homodimerize or dimerize with Pdr1, another transcription factor and loss of Pdr1 also confers MCHM resistance. Mutations in *PDR3* are first known to increase resistance to this novel hydrotropic chemical.

1367F **Flipping the script: How meiotic transcription controls the Set1 histone methyltransferase** Yasmin Mourad, Jayne E Seitz, Michael Law Stockton University

In all sexually-reproducing organisms, meiosis is a specialized cell division that is characterized by one round of DNA replication, homologous pairing and recombination, and two rounds of division (meiosis I and II) to give rise to four genetically distinct haploid gametes. This process requires faithfully executing a meiosis-specific gene expression program. In the budding yeast, Saccharomyces cerevisiae, three genes, IME1, IME2, and NDT80, are central components of the meiotic transcriptional cascade. IME1 is required for meiotic entry, IME2 coordinates multiple steps during early meiosis including homologous recombination and NDT80 activation, and NDT80 is required for cell commitment to divide. Previous work by our lab and others demonstrated that the histone H3Lys4 methyltransferase, Set1, is required for early meiosis with a critical role in genetic recombination, but that it represses transcription of a subset of Ndt80-dependent genes. These data indicate that Set1 inactivation is a critical factor for cells to commit to meiosis. Consistent with this model, we have recently found that Set1 is degraded during meiosis, suggesting that this is a key molecular switch for meiotic progression. Here we aim to identify how Set1 degradation is integrated into the meiotic transcriptional program. In this study, we combine genetic deletion mutations and conditional alleles to determine the requirement of IME1, IME2, and NDT80 in triggering Set1 degradation. To do this, we will measure Set1 protein levels during meiosis in three yeast mutant strains. The first strain harbors an ime1Δ mutation, which will allow us to determine the requirement of meiotic induction for Set1 degradation. Similarly, we have generated yeast harboring ime2 analog sensitive alleles. When grown in the presence of the ATP analog, 1-NA-PP, Ime2 activity is selectively inhibited. This will allow us to pinpoint when Ime2 kinase activity is required for Set1 degradation. Finally, we will utilize an estradiol-inducible form of NDT80. Yeast harboring this promoter will arrest prior to MI in the absence of beta-estradiol and will synchronously transition through meiotic commitment upon its addition. These experiments will determine the requirement of NDT80 expression and meiotic commitment in the Set1 degradation process. Together, these data will allow us to understand how Set1 activity is required for progression through recombination and meiotic division.

1368F **Using Budding Yeast to Model and Characterize Human Oncohistone Mutants** Celina Y Jones[1], Kirti Sad[2], Milo B Fasken[1], Jennifer M Spangle[2], Anita H Corbett[1] [1]Biology, Emory University, [2]Radiology Oncology, Emory University

Packaging genetic material into the nucleus is a major challenge that all eukaryotic organisms face. This packaging is accomplished by wrapping the genome around histone proteins. Hence, histones control chromatin accessibility and gene expression, which are largely regulated by histone post translational modifications (PTMs). Recently, recurrent missense mutations in genes encoding histones were found to drive oncogenesis in humans, creating oncohistones. Understanding how these pathogenic missense mutations alter histone function is challenging in humans as the four core histone proteins are each encoded by 12 – 15 genes, while budding yeast only contain two genes encoding each protein. Thus, engineering genetically homogenous strains that solely express the oncohistone mutant of interest is less technically challenging in yeast, facilitating clean characterization of altered PTMs and downstream mutant-driven molecular disruptions. To more faithfully model the dominant effects observed in humans, yeast can be engineered to express both a mutant and wild type histone copy. Our group has leveraged the strengths of budding yeast to model and characterize known and putative oncohistone mutants. We previously performed a high copy suppressor screen to identify suppressors of growth defects in histone H3K36 mutant cells, which model the oncohistone H3K36M. This study revealed connections to histone modifying enzymes, with investigations underway to define the mechanisms of suppression. Additionally, modeling putative oncohistones in yeast is

useful for characterizing the mechanism of action of these new mutations. The H3K36 mutant suppressors were expressed in the putative oncohistone H3E50K and revealed minimal suppression of growth defects, suggesting a different mode of molecular disruption as compared to H3K36 mutant cells. The H3E50K cells also displayed growth sensitivity when exposed to cellular stress and induced DNA double strand breaks. An added benefit to studying these mutations in yeast is how amenable this model organism is to undergraduate research, enabling us to prepare young scientists for careers in biological research. Employing yeast to investigate oncohistones promotes rapid discovery in disease-driving mutation research.

1369F **Investigating the function for the yeast lysine methyltransferase Set6 in proteostasis** Luke Mason, Erin Green, Deepika Jaiswal University of Maryland Baltimore County

Post-translational modifications (PTMs) of proteins facilitate control over cellular processes such as signaling cascades, allowing the cell to respond to changing environments. Methylation of lysine residues is a key regulatory mechanism that controls protein function. Lysine methyltransferases catalyze methylation on target proteins in response to signaling cues. One subset of lysine methyltransferases are the SMYD family of enzymes, which are well conserved and implicated in muscle development and differentiation in mammals. One of the SMYD enzymes in *Saccharomyces cerevisiae* is known as Set6, however, very little is known about its biological functions, catalytic activity, and protein-protein interactions. While lowly expressed under standard conditions, Set6 is upregulated during stress, such as nitrogen starvation. Based on phenotypes of *SET6* mutants, we have uncovered a role for Set6 in the proteostasis network, particularly autophagy. Proteomic screens have identified potential interaction partners of Set6 such as the GimC/Prefoldin complex and the Hsp70 co-chaperone Ydj1. Further proteomic screens have also identified candidate substrates for Set6 methyltransferase activity. Altogether, we identified the first known functions of the orphan lysine methyltransferase Set6 and characterized it as a new regulator of proteostasis.

1370F **Genetic analysis of the epigenetic regulation of liver development using a novel transgenic zebrafish epigenetic reporter line** Miranda Marvel, Yehyun Abby Kim, Kiyohito Taimatsu, Daniel Castranova, Allison Goldstein, Aniket V Gore, Brant M. Weinstein NICHD/NIH

Despite the critical importance of epigenetic mechanisms such as DNA and histone methylation in gene regulation and cell and tissue differentiation during development, most vertebrate tissue-specific epigenetic regulators are still unknown. Large-scale genetic screens performed in fruit flies and nematode worms have been very successful in identifying epigenetic regulators in invertebrates, but comparable screens have not been carried out in vertebrates. Our lab recently developed a novel “EpiTag” zebrafish transgenic epigenetic line that reliably reports changes in tissue-specific epigenetic silencing based on the dynamic expression of destabilized green fluorescent protein (GFPd2). We used this line to perform the first large-scale forward genetic screen for epigenetic-related mutants in a vertebrate, uncovering several mutants with persistent EpiTag reporter activation in the liver. We mapped one of these mutants to *ppat,* a gene coding for a phosphoribosyl pyrophosphate amidotransferase involved in purine nucleotide biosynthesis. The *ppat* gene is highly and specifically expressed highly in the liver, and CRISPR/Cas9-mediated targeting of the *ppat* locus phenocopies the liver activation of the EpiTag transgene. Surviving mutant animals develop dysfunctional, fatty livers. Preliminary results reveal transcriptomic and epigenetic changes in the livers of *ppat* mutants compared to wild-type animals that we are further characterizing in order to understand how epigenetic changes linked to *ppat* control critical liver development pathways.

1371S **A SID-1-dependent gene within a retrotransposon enhances heritable RNA silencing** Aishwarya Sathya, Nathan Shugarts, Andrew Yi, Antony Jose University of Maryland

RNAs in circulation carry sequence-specific regulatory information between cells in animal, plant, and host-pathogen systems. Such extracellular RNAs can function across generational boundaries in *C. elegans*. Double-stranded RNA (dsRNA) from neurons or the body cavity can enter the cytosol through the dsRNA importer SID-1 and silence genes of matching sequence in the germline and in progeny. Here we show that such SID-1-dependent regulation reduces heritable RNA silencing by downregulating a gene located within a retrotransposon. Using RNA-seq of wild-type, *sid-1(-)* mutant, and reverted *sid-1(+)* animals, we identified a *sid-1*-dependent gene *sdg-1*, which is located within a copy of the Cer9 retrotransposon. Changes in SDG-1 expression upon loss of SID-1 can last for more than 100 generations after SID-1 is restored. Perturbations of RNA-mediated regulation within the germline result in opposite effects on *sid-1* and *sdg-1*. Animals that lack SID-1 or that overexpress SDG-1 both show enhanced initiation of heritable RNA silencing upon mating. Furthermore, the SDG-1 protein is abundant within the germline and colocalizes with perinuclear condensates called Z granules, which are required for heritable RNA silencing. Since such silencing targets retrotransposons, these results suggest an auto-inhibitory loop that limits silencing of the *sdg-1*-containing retrotransposon. Intriguingly, SDG-1 (encoded by *F07B7.2/W09B7.2*) has two other paralogs *ZK262.8* and *C03A7.2*, both of which are encoded by genes located within Cer8 retrotransposon sequences. Furthermore, loss of *ZK262.8* has been reported to be synthetic lethal with loss of the miRNA-associated Argonaute ALG-2. Therefore, we speculate that inclusion of genes that regulate RNA silencing enables some retrotransposons and

retrotransposon-derived sequences to persist over evolutionary time.

1372S **Functional Characterization of systemic RNA interference in *C. elegans*** Faith Akoachere[1], Sarah E. Hall[2] [1]Syracuse University, [2]Biology Department, Syracuse University

Environmental stress during critical periods of development can result in altered gene expression and phenotypes in adulthood, which are sometimes inherited over generations. However, the exact mechanisms establishing and maintaining changes in gene expression due to environmental stress are not well understood. We showed previously that *C. elegans* hermaphrodite adults that had transiently passed through the dauer diapause stage due to crowding (postdauers) had significantly more progeny than continuously developed adults. Interestingly, this phenotype required the transmembrane channel protein SID-1 (systemic RNA interference defective). SID-1 is a vital effector of systemic RNAi (RNA interference) because it imports double-stranded RNAs (dsRNAs) into cells and signals the onset of gene silencing. To investigate mechanisms of endogenous systemic RNAi, we used a strain that carries a pan-neuronal, extrachromosomal *rab-3p::mut-16* overexpression transgene that results in progressive sterility over several generations. Additionally, hermaphrodites that have lost the extrachromosomal transgene continue to exhibit significantly reduced progeny numbers for three generations. We hypothesized that the overexpression of MUT-16 triggers the overproduction of small interfering RNAs (siRNAs) in neurons that are transported to the germ line resulting in aberrant gene expression that negatively affects reproduction. To test this hypothesis, we examined the transgenerational progeny number of animals carrying the *rab-3p::mut-16* overexpression transgene in a *sid-1* mutant background. Our results showed that SID-1 is not required for the transgenerational sterility phenotype, suggesting that MUT-16-dependent siRNAs in neurons are affecting germline function through a different mechanism. To determine how SID-1 is required for increased progeny number in postdauer adults, we are generating a strain with auxin-induced degradation and 3xFLAG epitopes inserted at the endogenous *sid-1* locus using CRISPR/Cas-9 genomic editing. We will attempt to immunoprecipitate SID-1 from control and postdauer adults, followed by RNA-seq to identify endogenous RNAs that pass through the channel to regulate gene expression across cell and tissue types. Together, these experiments will further characterize the role of SID-1 and endogenous RNAi in the regulation of developmentally programmed gene expression in C. elegans.

1373S **A major regulator of germline transcription, LSL-1, contributes to developmental defects when histone methylation is inappropriately inherited** Benjamin Nguyen, Brandon Carpenter Kennesaw State University

Histone methylation is a post-transcriptional modification to the N-terminal tails of histone core proteins that regulates DNA accessibility, and consequently, gene expression. Like DNA, histone methylation can be inherited between generations, and is highly regulated during embryonic development. At fertilization, histone methylation must undergo maternal reprogramming to reset the epigenetic landscape in the new zygote. During maternal reprogramming of histone methylation in the nematode, C. elegans, H3K4me (a modification associated with active transcription) is removed by the H3K4 demethylase, SPR-5, and H3K9me (a modification associated with transcriptional repression) is subsequently added by the histone methyltransferase, MET-2. Maternal loss of SPR-5 and MET-2 results in ectopic expression of germline genes in somatic tissues and a range of developmental phenotypes, including a severe developmental delay. Using a combination of RNA-seq and ChIP-seq experiments, a recent study identified a major regulator of germline transcription, LSL-1, that binds and turns on germline genes in the germline during development. From our own transcriptional analysis performed on C. elegans lacking SPR-5 and MET-2, we find that lsl-1 is significantly upregulated in somatic tissues. Together these data suggest that LSL-1 may be turning on germline genes aberrantly in somatic tissue and contributing to developmental delay. To test this hypothesis, we knocked down lsl-1 using RNA interference (RNAi) and found that the developmental delay in spr-5; met-2 mutants is significantly rescued. Using RNA-seq, we further demonstrate that knocking down LSL-1 in spr-5; met-2 mutant rescues ectopic expression of MES-4 germline genes. Together, our findings provide mechanistic insight into how inappropriate inheritance of epigenetic states perturb germline versus somatic cell fates specification during development and how this perturbation contributes to developmental phenotypes.

1374S **Selecting genes for analysis using historically contingent progress: RNA silencing in *C. elegans* as a case study** Farhaan Lalit[1], Antony Jose[2] [1]University of Maryland, [2]Cell Biology and Molecular Genetics, University of Maryland

Progress in biology has generated numerous lists of genes that share some property. However, detailed analysis of the genes is often required to discern mechanism(s) that could explain a list. With limited time and resources, prioritizing such regulated genes for detailed analyses is a key challenge faced by individual research labs and entire fields. Here we report a general approach for comparing tables of data accumulated by a field to identify genes of interest for further study. We apply this approach to RNA silencing in *C. elegans* and identify genes that appear to be selectively regulated but are understudied. We compared ~500 lists of genes reported in 113 studies as having significant changes in mRNA or antisense small RNA, or as encoding proteins interacting with a regulator of RNA silencing. The most selectively regulated genes or those encoding

proteins that interact with selective complexes were identified by their presence in shorter lists. Extent of co-occurrence of such regulated genes across studies was captured as historical mutual information (HMI) and used as a quantitative measure of the partially subjective links between genes revealed by the studies. Clustering the top 100 selectively regulated genes based on their HMI scores revealed three clear communities. Better studied genes were together in one cluster, suggesting that choosing other genes in that cluster for detailed analysis could also be illuminating. Most other genes in this cluster encode proteins reported as physical interactors of proteins that had been selected for study by the field, likely reflecting the need for study before being able to identify interacting partners. Intriguingly, many of these interactors have been implicated in other processes, providing regulatory links between RNA silencing and processes like the cell cycle. The other two clusters include genes and pseudogenes that have been described as targets of RNA regulation. These genes, which are present in many lists, could be regulated by multiple regulators independently and/or be jointly regulated by a connected set of regulators, making them potentially general sensors of perturbation in RNA silencing. These insights suggest that a similar analysis of genes in any field could aid progress from the initial implication of a set of genes in a process to understanding their roles in the process.

1375S **The relationship between period protein homolog LIN-42 and the conserved kinase KIN-20** Eileen McCleary[1], Collin Parrow[1], Benjamin Godbout[1], Joan Jatto[1], Michelle Coluzzi[1], Katherine McJunkin[2], Priscilla Van Wynsberghe[1] [1]Biology, Colgate University, [2]NIDDK NIH

The *C. elegans* heterochronic pathway, which regulates developmental timing, is thought to be an ancestral form of the circadian clock in other organisms. An essential member of this clock is the Period protein whose homolog, LIN-42, in *C. elegans* is an important regulator of developmental timing. LIN-42 functions as a transcriptional repressor of multiple genes including the conserved lin-4 and let-7 microRNAs. Like other Period proteins, levels of LIN-42 oscillate throughout development. In other organisms this cycling is controlled in part by phosphorylation. KIN-20 is the *C. elegans* homolog of the Drosophila Period protein kinase Doubletime. Worms containing a large deletion in kin-20 have a significantly smaller brood size, develop slower than wild type *C. elegans*, and display an uncoordinated phenotype. We have previously shown that KIN-20 impacts *lin-42* phenotypes. In addition, KIN-20 is important for post-transcriptional regulation of mature let-7 and lin-4 microRNA expression. However, the mechanisms by which KIN-20 regulates LIN-42 and microRNA biogenesis are unclear. Using epitope-tagged variants of LIN-42 and KIN-20, we have found that KIN-20 impacts LIN-42 expression. Current work aims to determine how KIN-20 causes these effects by analyzing phosphorylation target mutants of LIN-42 and a KIN-20 mutant deficient in kinase activity. Altogether, these findings further our understanding of the mechanisms by which these conserved circadian rhythmic genes interact to ultimately regulate rhythmic processes and developmental timing in *C. elegans*.

1376S **The effect of environmental factors on core circadian clock genes in *C. elegans*** Carson Hobler, Bronwen Rees-Wiedemann, Julia Shavo, Mason Caldwell, Kendall Mueller, Jenna Borovinsky, Michelle Coluzzi, Priscilla Van Wynsberghe Biology, Colgate University

Circadian rhythms are entrained by environmental cues like light and typically follow a 24-hour cycle. These rhythms are dictated by circadian clock genes and are vital for regulating internal functions and processes. Central to the circadian clock is the Period protein, a transcription factor whose levels oscillate. *C. elegans* exhibit many rhythmic behaviors and express some of the core circadian clock genes. However, limited information is available regarding how environmental factors like light impact *C. elegans* core clock genes. LITE-1 and GUR-3 are both 7-transmembrane gustatory receptors in *C. elegans*. Though LITE-1 lacks a typical chromophore, it is important for detecting both UVA and UVB light, and can sense and mediate responses to high concentrations of hydrogen peroxide. Meanwhile GUR-3 is able to distinguish small changes in hydrogen peroxide at lower concentrations. In addition to sensing these external factors, LITE-1 and GUR-3 are also critical for the synchronization of *C. elegans* behavior to daily light cycles and are required for light-induced avoidance behavior. Here we sought to understand the role of LITE-1, if any, in regulating the core circadian Period protein, LIN-42, in *C. elegans*. Since LITE-1 is important for UV light avoidance, we first analyzed light avoidance phenotypes in young adult *lin-42* and *lite-1* mutant worms. As expected, WT N2 worms migrated away from the light stimulus while *lite-1* mutant worms demonstrated less UV light avoidance. Interestingly, both *lin-42* and *lite-1;lin-42* mutant worms exhibited less UV light avoidance than *lite-1* mutant worms. We also found that when directly exposed to UV light, *lin-42* mutant worms exhibited more paralysis compared to WT N2. This suggests that LIN-42 plays some role in the photosensation pathway. Analysis of LIN-42 protein levels in *lite-1* mutants by western blotting shows that LITE-1 impacts LIN-42 protein expression. We further find that PRDX2, an antioxidant enzyme peroxiredoxin that alters behavior in response to hydrogen peroxide, impacts expression of the conserved miRNA let-7. Current work aims to better understand how LITE-1 and GUR-3 impact core circadian clock genes and the LIN-42 target let-7. Altogether, this work will help us understand the mechanism by which *C. elegans* core clock genes respond to environmental cues.

1377S **HIF-1c, an oxygen-insensitive HIF-1 isoform in *C. elegans,* is expressed tissue-specifically via an internal promoter.** Amir Sabeti Aghabozorgi[1], Kate Locsin[1], Chelsey Torres[1], Carlos Egydio de Carvalho[2] [1]Biology, University of

Saskatchewan, [2]University of Saskatchewan

Hypoxia-Inducible Factor-1 (HIF-1) is a conserved protein family of transcription factors in metazoans that evolved to cope with hypoxic stress by activating the expression of genes required for adaptation to low oxygen levels. Among animal cells, neurons are particularly susceptible to hypoxia-induced damage. Thus, unraveling how neurons differentially mobilize HIF-1 to cope with hypoxia is of clinical relevance. We identified a shorter *hif-1* transcript (*hif-1c*) in *C. elegans* with extensive expression almost exclusively in the nervous system. Aside from neurons, only a few muscle cells in the head region, the distal tip cell (DTC) in the somatic gonad and the two neuroendocrine uv1 cells express *hif-1c*. Using reporter lines, we identified and mapped a region within intron 4 of the *hif-1* locus that acts as an internal promoter to drive *hif-1c* transcription. Similar to the canonical HIF-1 isoform (HIF-1a), *hif-1c* predicts a protein unstable at room air, but unlike HIF-1a, without DNA binding activity. Expression and phenotypic characterization so far suggest that HIF-1c indeed cannot transactivate *hif-1* target genes, but it is unexpectedly oxygen-insensitive, despite its predictive oxygen-dependent degradation domain. Surprisingly, we find HIF-1c::GFP localizing specifically at the basal body of cilia of labial sensory neurons that control several behavioural responses in *C. elegans*. We are currently exploring possible sensory roles for HIF-1c in neurons.

1378S **Chemotaxis defect and developmental delay phenotypes in *spr-5;met-2* mutants may be caused by the ectopic expression of meiosis genes in somatic tissues.** Rhea Rastogi, Monica Reeves, Jaely Chavez, Juan Rodriguez, David J Katz Department of Cell Biology, Emory University

The proper formation of a zygote requires extensive epigenetic reprogramming to enable appropriate inheritance of histone methylation. In *C. elegans*, this reprogramming is partly mediated by two enzymes: H3K4me2 demethylase SPR-5/LSD1/KDM1A and H3K9 methyltransferase MET-2/SETDB1. Progeny of mutants lacking both SPR-5 and MET-2 suffer from a severe chemotaxis defect, L2 developmental delay, and sterility. These phenotypes are caused by the ectopic expression of germline genes in somatic tissues due to a synergistic increase in H3K4me2. Previously, we found that *spr-5* and *met-2* single mutants each have a transgenerational accumulation of H3K4me2, resulting in a germline mortality phenotype across generations. To determine if the chemotaxis defect in *spr-5;met-2* double mutants might be caused by H3K4me2 accumulation, we asked whether *spr-5* and *met-2* single mutants have a decrease in chemotaxis across generations. Although *spr-5* and *met-2* single mutants have a slight chemotaxis defect, it does not change across generations and is far less severe than that of *spr-5; met-2* double mutants. This suggests that the severe chemotaxis defect in *spr-5; met-2* mutants requires the loss of both enzymes. However, the lack of a severe chemotaxis defect in the single mutants provides an opportunity to identify molecular pathways underlying the behavioral defect in the double mutant by identifying gene expression changes that occur in the double mutant but not the single mutants. Thus, we performed RNAseq on L4 *spr-5* and *met-2* single mutants at F7, F13, and F22, from which we identified 460 genes that are uniquely upregulated in *spr-5; met-2* mutants. Gene ontology analysis indicates that this gene set is enriched in meiotic genes, raising the possibility that it is specifically the inappropriate expression of meiosis genes in somatic tissues causing the chemotaxis defect and developmental delay. Consistent with this, we find in *spr-5; met-2* mutants that while germline genes are ectopically expressed beginning in the embryonic stages, the meiotic genes are only ectopically expressed later in development when the chemotaxis defect and developmental delay are observed. Intriguingly, patients with neurodevelopmental disorders caused by mutations in histone-modifying enzymes also have meiotic genes ectopically expressed in the nervous system. Thus, it is possible that we have identified a conserved mechanism. We are currently pursuing this possibility using an LSD1 mouse model.

1379S **Characterization of NHR-25 genome-wide binding reveals role for combinatorial transcription factor action** Alexander Sinks, Leah Flautt, Kimberley Tanatswa Muchenje, Belle Ange Itetere, Deborah M Thurtle-Schmidt Biology, Davidson College

Terminal cellular differentiation and maintenance into distinct cell types is due in part to sequence-specific transcription factors (TFs) directing proper transcriptional regulation. TFs bind to response elements, establishing the proper gene regulatory network for that cell type. Thus, binding site recognition and subsequent regulation of the TF target gene to establish and maintain the correct gene regulatory network is critical for proper genomic functioning. However, how a TF recognizes its binding site and subsequent target genes remains poorly understood. *C. elegans* provides an excellent model to study transcriptional regulation due to its compact genome and highly conserved TFs. To investigate how a transcription factor identifies its binding site to target the correct target gene we profiled genome-wide binding of an endogenously tagged, highly conserved TF, NHR-25, using ChIP-seq and CUT&RUN in L1 worms. We identified 1140 NHR-25 enriched sites. 78% of these sites overlapped with previous NHR-25 ChIP-seq of a multi-copy integrant NHR-25 from the modERN resource, however the multi-copy integrant resulted in 5x as many enrichment sites, suggesting TF expression level is critical for binding. Motif analysis of NHR-25 occupied regions identified 23 enriched motifs, including the presumed NHR-25 binding site and a GAGA motif like the EOR-1 binding motif. Correlation with *C. elegans* chromatin domains (Evans et al 2016) showed enriched regions containing the NHR-25 motif at regions designated as enhancer-type chromatin. To identify the NHR-25 responsive genes and

correlate target genes to NHR-25 enriched regulatory elements, we performed RNA-seq of *nhr-25* knockdown worms and correlated differentially regulated genes to the nearest enriched peak. Many peaks were proximal to, but not directly adjacent to a differentially expressed gene. To directly correlate target genes of identified regulatory elements, we deleted NHR-25 enriched regions using CRISPR/Cas9 and profiled gene expression by RNA-seq. For a single deleted regulatory element, we identified two nearby genes with altered expression. However, only one of these adjacent genes showed NHR-25 dependent expression. Taken together, these data suggest combinatorial action of multiple TFs are required to direct proper gene regulation.

1380S **Characterizing the regulation of piRNA expression by the CSR-1 Argonaute** Victoria Murphy, Jessica Kirshner, Margaret Starostik, Sadhana Pani, John Kim Johns Hopkins University

In metazoans, germline gene expression is tightly controlled by small RNA pathways to promote germline development and animal fertility. The piRNA pathway suppresses foreign genetic elements, such as transposons, through base-pairing between the piRNAs and their target mRNAs. In opposition to this silencing pathway, a non-canonical endo-siRNA pathway, governed by the Argonaute, CSR-1, functions to promote expression of target genes in the germline. Together, the CSR-1 gene licensing pathway and piRNA-mediated gene silencing pathway tune germline gene expression. Despite the opposing functions of the CSR-1 and piRNA pathways, mechanisms of cross-regulation between them remain unknown. Here we show that CSR-1 suppresses the piRNA pathway through direct silencing of mRNAs encoding piRNA biogenesis factors. The piRNA biogenesis machinery is significantly enriched in the small subset of genes directly sliced by CSR-1. Therefore, in *csr-1* mutants, the piRNA biogenesis machinery becomes significantly upregulated during both spermatogenesis and oogenesis and is accompanied by the ectopic upregulation of piRNAs. Using small RNA sequencing, we observe a perdurance of spermatogenesis-specific piRNAs into oogenesis. Ongoing work will examine the impact of csr-1 defects on piRNA target silencing, chromatin defects at piRNA target loci, and defects in biogenesis of other classes of small RNAs resulting from elevated piRNA biogenesis factors. Finally, we are investigating the consequence of inappropriate expression of sex-specific piRNAs on germline development. Together, our data offer evidence of how gene licensing and silencing small RNA pathways are coordinated in *C. elegans* to regulate germline gene expression.

1381S **Identification of transcriptional regulators impacted by a glucose-supplemented diet in *C. elegans*** Jose Robledo, Mary Ladage, Rajeev Azad, Pamela Padilla Biological Sciences, University of North Texas

Type 2 diabetic patients display various metabolic changes (e.g. hyperglycemia, insulin resistance, increase in free fatty acids) that contribute to dysfunction in multiple organs. For example, hyperglycemia leads to permanent gene expression changes to organs that persist even after treatments regulate glucose levels. Genetics and environment play a huge role in the development and progression of type 2 diabetes. Change in gene expression is one underlying factor contributing to the physiological changes associated with diabetes. However, how factors such as hyperglycemia or a sugar-supplemented diet affect whole animal gene expression remains to be further explored. Our lab focuses on using the genetic model system *Caenorhabditis elegans* to study the impact a glucose-supplemented diet has on physiology, stress responses and gene expression. Previously, we showed that a glucose-supplemented diet impacts the expression of 2,370 genes, increases lipid accumulation, and increases sensitivity to stress. To further understand the gene expression differences due to a glucose-supplemented diet, we analyzed the transcriptomic data to identify potential glucose responsive genes. One such gene, the transcription factor acs-2, was then further investigated using qPCR and an analysis of an acs-2::GFP reporter strain. Here, we show acs-2 transcript to be a glucose-responsive gene. Additional bioinformatic analysis on our transcriptomic data also revealed 140 transcription factors (TFs) that were altered in response to a glucose-supplemented diet. In an effort to identify glucose responsive transcription factors, we developed a targeted RNA interference screen using the *acs-2::GFP* reporter strain. Our RNAi screen identified 45 transcription factors that significantly impact the expression of *acs-2* in a glucose diet dependent manner. We further classified our glucose-responsive TFs according to DNA binding domains and found 16 NHRs, 12 ZF, 5 bZip, 5 bHLH, and 7 unknowns TFs. Together, these studies add to our understanding of the molecular network that is impacted in response to a glucose supplemented diet.

1382S **Imprinting in *C. elegans*: maternal *sid-1* expression alleviates silencing of paternal *sid-1*.** Andrey Shubin, Craig P Hunter Harvard University

Genes transmitted by oocytes or sperm usually contribute equally to the development and function of progeny. An exception is imprinting in mammals, which is caused by gamete-specific DNA methylation patterns at targeted genes resulting in parent-of-origin effects on gene expression. Our studies identify a case of imprinting for the *sid-1* gene in *C. elegans*: crosses between wild-type males and *sid-1* deletion hermaphrodites produce only Sid progeny. Our analysis reveals that maternal *sid-1* mRNA or agents derived from it, are required to activate constitutively silenced paternal *sid-1.* This silencing is not observed in the progeny of *prg-1*-mothers or fathers, does not require chromatin-level interaction between alleles in the zygote for initiation or

maintenance of *sid-1* silencing, but simply depends on the absence of maternal *sid-1* transcripts. Furthermore, in the absence of an expressed allele, the silenced state can persist for four generations. Unlike the multi-generational silencing caused by the extrachromosomal *sid-1* promoter transgene array[1], which affects the entire locus (*sid-1* and two upstream genes), the paternal imprinting affects only the *sid-1* gene.

Our findings suggest a crucial role for maternal mRNA transcripts in the transcriptional activation or licensing of paternal genes in *C. elegans* that can otherwise be a subject to imprinting mediated by PRG-1-associated piRNAs. These results imply a regulatory interaction between transcriptional suppression mechanisms that protect against the expression of potentially harmful paternally derived alien genes or selfish genetic elements such as transposons and licensing of paternal genes by maternal mRNA.

1383S **Characterizing the miRNA Argonaute isoforms in C. elegans** James P Davis, Rima Sakhawala, Katherine McJunkin NIDDK, NIH

MicroRNAs (miRNA) are short, non-coding RNAs that regulate gene expression post-transcriptionally. MicroRNAs are loaded into an Argonaute protein which makes up the RNA-induced silencing complex (RISC) that leads to the repression of target mRNAs. A recent study focusing on the CSR-1 Argonaute has found that the csr-1 locus encodes two isoforms, CSR-1a and CSR-1b. These isoforms show tissue specific functions with CSR-1a regulating immunity and pathogen response genes while CSR-1b regulates spermatogenesis genes. In C. elegans, two of the miRNA Argonautes, ALG-1 and ALG-2, encode two isoforms. We are interested in examining if ALG-1 and ALG-2 have isoform-specific functions. We have fluorescently labeled the ALG-1 long isoform with mKate and crossed that into a strain that had both ALG-1 isoforms tagged with GFP. Heterozygotes from this cross were imaged to identify where the long isoform is expressed. We found that the long isoform is expressed in the head ganglia, ventral nerve cord, and tail ganglia. We have designed strains in which we mutated either the long or short isoform of ALG-1 and ALG-2. We are crossing these strains into an ALG-1(-/-) or ALG-2 (-/-) background to determine if a specific isoform alone is sufficient for development, since ALG-1 and ALG-2 are functionally redundant. When only the ALG-1 long isoform was expressed we observed bursting and protruding vulvas in the young adult population. We hypothesize that the long and short isoforms have different miRNA loading profiles, which may explain the mutant phenotype when only one isoform is expressed. We are currently in the process of generating the other strains to determine if they have differing phenotypes as well. Thus far, we conclude that there may be an isoform specific function between the ALG-1 long and short isoform, and further characterization is needed. Further study is needed to determine if there is isoform specific function between the ALG-2 long and short isoform as well.

1384S **Identification of the EOR-1 and NHR-25 shared transcriptome** Amanda Fuenzalida, Shawn An, Tiffany Haydt, Deborah M Thurtle-Schmidt Biology, Davidson College

Correct gene regulation is critical for establishing and maintaining correct cellular identity. Transcription factors (TF) are regulatory proteins that bind to motifs across the genome, regulating gene expression. In *C. elegans*, NHR-25 is an essential TF involved in somatic cell differentiation and gonadal development. ChIP-seq of NHR-25 revealed that in addition to NHR-25's own known binding motif, a GAGA motif was also enriched at NHR-25 associated sites in the genome. EOR-1 is a transcription factor in the Ras/ERK signaling pathway thought to act as both a potential activator and repressor. Previous literature in *C. elegans* and orthologs of EOR-1 in other organisms suggest that this transcription factor may act as a pioneer factor. Here we hypothesize that EOR-1 is a necessary pioneer factor for NHR-25 and coordinates correct gene regulation. To investigate this hypothesis, we profiled the transcriptome of *eor-1(cs28)* and *nhr-25(ku217)* mutants at two different developmental times (L1 and L3) and temperatures (20˚C and 25˚C). Differential expression analysis will identify shared regulated genes sets, revealing the potential extent of EOR-1's ability to act as a pioneer factor.

1385S **Exploring How Cells Randomly Choose Between Fates in the Fly Eye** Christina Im, Alison Ordway, Robert Johnston Biology, Johns Hopkins University

Development of an organism is complex and requires many different processes to occur simultaneously. Although many developmental processes are carefully regulated, some occur stochastically. A stochastic process refers to one that involves a random variable. These mechanisms diversify cell types and generate additional functions.

The fly eye provides an excellent model to study stochastic patterning during development. The *Drosophila* (fruit fly) eye consists of ~800 unit eyes, or ommatidia. Each ommatidium is composed of eight photoreceptors (R1-R8). The R7 photoreceptor has two distinct subtypes, defined by expression of light detecting Rhodopsin proteins: Rhodopsin 3 (Rh3) or

Rhodopsin 4 (Rh4). A stochastic choice between expression of these Rhodopsin proteins is controlled by the transcription factor *spineless* (*ss*). In Ss^{ON} cells, Rhodopsin 4 is expressed whereas in Ss^{OFF} cells, Rhodopsin 3 is expressed. In wild-type flies, *ss* is on in about 67% of R7s.

During development of the eye, photoreceptor specification occurs in a wave across the developing eye field. *ss* is expressed dynamically during development. This dynamic expression is controlled by three elements at the *ss* gene locus: the *promoter*, the *early enhancer*, and the *late enhancer*. The *early enhancer* drives early expression in all R7 precursor cells and the *late enhancer* drives late expression in a subset of terminally differentiated R7 cells, but how they regulate *spineless* remains poorly understood. My research project focuses on the role of the *late enhancer* in regulating *ss* expression during stochastic cell fate specification.

1386S **Modulation of tumor growth by Yorkie and Wingless** arushi rai[1], Amit Singh[2,3,4], Madhuri Kango-Singh[1,3,4] [1]Growth Regulation and Signalling Laboratory, Department of Biology, University of Dayton, [2]Drosophila Development and Disease Laboratory, Department of Biology University of Dayton, [3]Premedical Program, University of Dayton, [4]Integrative Science and Engineering Center, University of Dayton

Studies with *Drosophila* Ras^{V12}, $scrib^{-/-}$ tumor models have shown that Yorkie, the effector molecule of the Hippo pathway, interacts with other signaling pathways to form a dynamic transcriptional network within cancer cells. Previously, we have shown that in Ras^{V12}, $scrib^{-/-}$cells Wingless (Wg) acts upstream of Caspases, JNK, and Yki forming a tumor-specific network that regulates tumor growth and development. By studying this complex network, we aim to unravel the key players that regulate tumor growth. Wg appears upstream of the molecular network and is also a transcriptional target of Yorkie. Wg expression is ectopically induced in Ras^{V12} and Ras^{V12}, $scrib^{-/-}$ tumor clones. However, accumulation of Wg is reduced in tumor clones with both heterozygous loss of *yki* ($yki^{B5}/+;Ras^{V12},scrib^{-/-}$) or downregulation of Wg signaling ($dTCF^{DN};Ras^{V12},scrib^{-/-}$). Heterozygosity of *yki*($yki^{B5}/+;Ras^{V12},scrib^{-/-}$) and downregulation of Wg signaling ($dTCF^{DN};Ras^{V12},scrib^{-/-}$) both resulted in reduced tumor clone size in comparison to $Ras^{V12},scrib^{-/-}$ tumor clones. To further understand the molecular mechanism by which Wg and Yki promote tumor growth, we will investigate the effect of downregulation of Wg pathway and Hippo pathway on (a) the transcriptional network of $Ras^{V12},scrib^{-/-}$ tumor clones by analyzing the mRNA expression by qRT-PCR, (b) hallmarks of cancer such as invasion, cell adhesion, and survival signaling by immunohistochemistry-based approach, and (c) analyzing the Hippo pathway (Mst, p-MST) JNK pathway (JNK, p-JNK) and Wg pathway activity by Western blot assay. Here, we present our progress on the organization of the molecular network that involves Wingless and Yorkie.

1387S **Understanding the role of Embargoed in the specification of muscle fiber fates in *Drosophila*** Alexis Guzman, Richard Cripps Biology, San Diego State University

Understanding the mechanisms that lead to the specification of muscle fiber fates during Drosophila development remain unclear. The homeodomain proteins Extradenticle (Exd) and Homeothroax (Hth) are normally expressed in the adult fibrillar indirect flight muscles but not in the tubular jump muscles. Knocking down Exd and Hth converts flight muscles into jump muscles. Exd and Hth are initially expressed within the myoblasts of the jump muscle cells, but these proteins are no longer detected upon the initiation of myoblast fusion. We have thus sought to determine how the expression pattern of these proteins changes during development. Embargoed (Emb), which encodes an exportin involved in nuclear export, is proposed to play a role in transporting Exd and Hth out of the nucleus of the jump muscle cells. Indeed, knockdown of Emb expression using RNAi transforms the jump muscles into a flight muscle fate. We hypothesize that when Exd or Hth are phosphorylated in the flight muscle myoblasts, Emb cannot bind and export these proteins out of the nucleus. In the jump muscles, Exd and Hth are not phosphorylated by this kinase, which allows Emb to bind and transport them to the cytoplasm. By knocking down the kinase that phosphorylates Exd or Hth in the jump muscles via RNAi, we expect to see ectopic expression of Exd and Hth in the jump muscles after myoblast fusion, as well as a conversion to a flight muscle identity. To further confirm this, we will stain for flight and jump muscle markers to quantify the extent of this muscle fiber switch. The mammalian ortholog of Emb, Exportin 1 (XPO1), is also a protein that mediates the nuclear export of proteins and RNAs which suggests that a similar mechanism in the specification of muscle fiber fates may be conserved.

1388S **Effects of mutation in the P38 docking domain of MEF2 on its function** Bhumika Gode, Richard Cripps Biology, San Diego State University

MEF2, or Myocyte enhancer factor, is a conserved transcription factor with a critical role in human muscle gene expression, as well as Drosophila muscle development. Our study focuses specifically on Drosophila muscle development, which serves as a model organism due to its compact size, ease of maintenance, and suitability for research in resource-constrained laboratories. MEF2 plays a crucial role in differentiation of all muscle types including dorso-longitudinal indirect flight muscles (DLMs), jump muscles (TDT - tergal depressor of trochanter), and leg muscles. In mammalian tissue culture studies, P38, a mitogen-activated protein kinase (MAPK), enhances MEF2 activity by phosphorylating it via binding to a P38 docking site. Our study aims to

investigate how a mutation in the P38 docking site affects MEF2 function. Using CRISPR, we induced a 7-amino acid (or 21-base pair) deletion in the P38 domain of Mef2. We conducted immunostaining on longitudinal and transverse sections of mutant Drosophila thoraces to visualize the structures of jump muscles and DLMs, respectively. Additionally, we analyzed the relative gene expression of genes that are transcriptional targets of MEF2 like Actin 57B (Act57B), Myosin heavy chain (MHC), and Troponin I (TnI). Immunostaining revealed significant patterning defects in the jump muscle structure in mutant flies compared to wild-type, while there was no difference in the number of DLM fibers. We plan to perform mutagenesis experiments to examine the potential binding of human P38 to a mutated Drosophila MEF2 protein gene. We also want to further investigate additional significant effects of the mutation, particularly on their ability to jump and other developmental factors. These studies identify a conserved and functionally significant interaction between MEF2 and P38.

1389S **Analysis of chromatin modifications at *Dmef-2* enhancer during myogenesis** Sara Khadraoui[1], Sarah Anglin[2], Scott Nowak[2] [1]Kennesaw State University, [2]KSU

The nuclear transcription cofactor Akirin plays a key role in the regulation of *Dmef2* (Drosophila myocyte enhancer factor 2) during the early steps of embryonic myogenesis. Akirin is thought to help regulate *Dmef2* expression levels by mediating an association between chromatin remodeling complexes and Twist transcription factor activity. Previous work by the Nowak laboratory has determined that Akirin genetically and physically interacts with either the Brahma (SWI/SNF) chromatin remodeling complex, or through genetic interactions with the Nucleosome Remodeling and Deacetylase Complex. These interactions are essential for proper cardiac and skeletal patterning and development during embryogenesis. While both complexes have seemingly contradictory activities, the exact nature of covalent histone modifications that occur at *Dmef2* enhancers during myogenesis remains unknown. Using a variety of antibodies targeting various covalent histone modifications in chromatin immunoprecipitation we have begun an analysis of chromatin modifications that occur at the *Dmef2* enhancers during early, mid, and late embryonic myogenesis in both wild-type and *akirin* mutant backgrounds. Our results indicate that the histone modification landscape at the *Dmef2*enhancer is highly varied in *akirin* mutant backgrounds, which supports previous studies indicating that recruitment of chromatin remodeling complexes to these loci during myogenesis is key for their proper expression levels.

1390S **Unveiling the role of Hippo Interactors in Glioma Progression in Drosophila glioma model** Venkata Satya Devi Burugupalli[1], Madhuri Kango-Singh[2,3,4], Arushi Rai[1], Amit Singh[3,4,5] [1]Growth Regulation and Signalling Laboratory, Department of Biology, University of Dayton, [2]Growth Regulation and Signalling Laboratory, Department of Biology University of Dayton, [3]Premedical Program, University of Dayton, [4]Integrative Science and Engineering Center University of Dayton, [5]Drosophila Development and Disease Laboratory, Department of Biology University of Dayton

Signalling interactions play an important role in tumorigenesis. The Hippo signalling pathway originally identified for its role in organ size maintenance also plays a key role in tumor progression. Using the previously published Drosophila glioma model in which coactivation the EGFR receptor and Phospho-inositol 3 kinase (PI3K) pathways in the CNS glia using repoGAL4, we plan to study the role of interactions of Yorkie (YAP/TAZ in human), the downstream effector of the Hippo pathway, with other pathways in promotion of glioma growth. Given the conservation of genes and cell biological pathways, finding from our studies are expected to be extrapolated to higher vertebrates. Initial studies showed the role of Yorkie in neural stem cells in the growth of glioma. Here we present our progress with evaluating the role of other Yki interacting pathways using immunostaining, western blots and qPCR analyses to investigate which pathways are important for glioma progression.
Keywords: Hippo pathway, GAL4-UAS, Glioma and signalling.

1391S **Establishing the Role of the Conserved TN Domain in Tinman** Cayleen Bileckyj, Richard Cripps San Diego State University

Congenital heart disease (CHD) is a major factor in mortality and morbidity in children and adults. To improve our ability to identify and manage CHD, we need to further understand the key genetic factors involved in causing these disorders.

Drosophila melanogaster, a model organism with cardiac developmental mechanisms analogous to those that occur in human cardiac development, has been an essential vehicle in furthering our understanding of the proteins and pathways involved in cardiogenesis. Tinman (Tin), a transcription factor in *Drosophila* vital for cardiac cell differentiation, and its mammalian ortholog NK2 Homeobox 5 (Nkx2.5) share two conserved regions: the homeobox and the tin (TN) domain. Although the TN domain is completely conserved between these two proteins, there is little known about its significance.

The goal of my research is to establish how the TN domain impacts the ability of Tin to function during development. To do this, I observe how the removal of the TN domain from Tin effects expression of various proteins in cardial, pericardial, and precursor cardial cells during embryogenesis. Data generated for this portion has come from a line of *Drosophila* I generated using CRISPR/Cas9 gene editing that contain an in-frame deletion of the TN domain. My project also focuses on describing how the deletion of the TN domain effects Tinman's ability to physically interact with other proteins. Transfection of plasmids containing wild type Tin, Tin with the TN domain removed, and the suspected co-repressor Groucho (Gro) into Drosophila S2 cells, followed by co-immunoprecipitation, will elucidate if the TN domain is necessary for Tin and Gro to interact. Lastly, again using CRISPR/Cas9 gene editing, I established two fly lines that contain two different known mutations that occur in the TN domain in the human Nkx2.5 protein. Immunohistochemistry of these fly lines will reveal the impact these mutations have on Drosophila development, and therefore possible insight into how humans with these mutations could potentially be affected.

While the TN domain is completely conserved between Tinman and Nkx2.5, it can also be found partially conserved in other mammalian proteins involved in the different aspects of development. Therefore, not only can delineating the role of the conserved TN domain in Tin improve our understanding of cardiac formation and maturation, but it has the potential to inform upon other areas of developmental biology as well.

1392S **The role of epigenetic regulators in muscle specification during development** Elizabeth Barajas Alonso, Richard M. Cripps San Diego State University

Polycomb Group (PcG) proteins are chromatin modulators that have been shown to have an essential role in developmental processes by maintaining cell fate across different organisms. PcG proteins function as transcriptional repressors to remodel chromatin to a condensed state in which target genes become inaccessible from the transcriptional machinery. Furthermore, genetic screens in *Drosophila melanogaster* identified PcG proteins as regulators of *Hox* genes to ensure correct body patterning. Notably, de-regulation of PcG proteins has implications in several congenital disorders and cancers however, the role of these epigenetic regulators in muscle diseases and development, such as fiber type specification, has not been fully elucidated. We, therefore, seek to determine the effect of PcG loss of function upon muscle identity in *Drosophila.* To test this, we performed an RNAi screen of members in the Polycomb Repressive Complex (PRC) 1 and 2 using tissue specific drivers to target expression of the PcG RNAi in the flight and jump muscles, respectively. The screening revealed that expressing RNAi for *P55*, *Pcl*, *Sce*, and *Scm* resulted in a partial transformation of the flight muscles to a jump muscle fate. This was evidenced by a change in the expression of the fiber-specific reporter *TpnC41C-lacZ* in which expression expanded into the knockdown flight muscles. In addition, we also saw an altered myofibril striation pattern in the knockdown flight muscles where the z-discs appeared to be stacked, indicative of a tubular identity. Overall, our preliminary data suggests that PcGs play an essential role in regulating flight muscle fate.

1393S **Dude, where's my locus? Alternative methods of genomic targeting for specialized transcription factors.** Thomas OHaren, Skye Comstra, Leila Rieder Biology, Emory University

While many transcription factors recognize consensus DNA motifs and target many genomic loci, some are extremely specialized and bind only a single or few regions of the genome. Additionally, some specialized transcription factors do not bind or recognize DNA sequence, so it remains unclear what cues allow effective targeting of specialized factors to their regions of activity. One such factor is Multi sex combs (Mxc), a scaffolding protein of the Histone Locus Body (HLB), a collection of factors that assist in the specialized regulation and processing of histone mRNAs. The Drosophila melanogaster genome contains a single histone locus harboring 100+ copies of the canonical, replication-dependent histone genes, and Mxc is one of the earliest localizing factors to the locus. Many factors of the HLB are unique to histone gene regulation and target only the singular locus. However, none of the HLB-specific factors, including Mxc, bind DNA, and such, how the histone genes are identified in early development remains unknown. A deficiency Drosophila line in which the entirety of the histone locus is removed is heterozygous viable. Interestingly, Mxc and HLB factor FLASH continue to colocalize and form nuclear puncta in the fraction of homozygous early embryos that lack the histone genes. We hypothesize that the regions of the genome where HLB factors are misrecruited will reveal clues about what contributes to the identification of the locus and more generally how transcription factors behave when their target locus is removed. Genomic cues such as histone marks, chromatin state, and non-specific transcription factors could contribute to localization of extremely specialized factors that do not bind DNA. By utilizing Dam-ID and fusing a Dam (DNA adenine methyltransferase) domain to Mxc to circumvent the lack of direct DNA binding, we are labeling regions of aberrant Mxc localization in histone deficient embryos. We will then compare the genomic characteristics of novel sites to uncover similarities that might explain how Mxc is recruited to the histone genes. Additionally, by performing Mxc Dam-ID in wild type embryos, we will capture regions of the genome that contact the histone genes in three-dimensional space. Overall, our experiments will reveal new factors that contribute to transcription factor localization other than DNA sequence.

1394S **Teasing apart a bi-level neuronal function for Tip60 HAT at the chromatin and RNA level.** Christina M. Thomas,

Akanksha Bhatnagar, Felice Elefant Biology, Drexel University

The histone acetyltransferase (HAT) Tip60 is an essential epigenetic mediator of neuronal transcriptional regulation that is implicated in Alzheimer's disease (AD). Tip60 contains a catalytic HAT domain that promotes histone acetylation mediated chromatin control and a chromodomain (CD) that interacts with methylated histone lysine residues. Recently, our lab reported a novel RNA binding function for Tip60 that is localized within its CD that partakes in neuronal RNA alternative splicing (AS) regulation in the brain. Cognition and memory formation is governored by protein diversity that is possible through AS of RNA. Recent reports highlight defects in RNA splicing of genes in the brains of AD patients, thus making splicing disruptions a widespread hallmark of AD. Unfortunately, causes for these splicing disruptions in the brain are currently unknown. To further elucidate Tip60's RNA binding/splicing function, we carried out high resolution homology modeling and molecular visualization of Tip60's chromodomain (CD) that strongly predicted an RNA binding loop within Tip60's CD that's critical for direct Tip60-RNA interaction. To tease apart Tip60's RNA versus histone binding function in neural gene control and cognition, we mutated highly conserved amino acids (a.a) in Tip60's CD strongly predicted to specifically interact with either histones ($Tip60^{mutHis}$) or RNA ($Tip60^{mutRNA}$) and generated transgenic flies carrying these inducible mutant Tip60 constructs. These transgenic $Tip60^{mutRNA}$ and $Tip60^{mutHis}$ fly models will serve as powerful tools to tease apart neural functions dependent upon histone vs. RNA binding or both. We will induce expression of mutant Tip60 in the brain and carry out functional assays to assess cognitive ability using both larval and adult learning and memory assays as well assess brain morphology using immunohistochemistry. We will also assess gene expression using RNA-Seq, Tip60 splicing activity using rMATs on RNA-Seq data, and chromatin and RNA binding using ChIP and RIP, respectively. We anticipate that RNA versus histone binding functions are required for specific functional outputs and some neuronal processes will be more dependent on a given Tip60 binding function than others. Our results will elucidate a new bi-level regulatory role for Tip60 in chromatin and RNA that has potential to transform how researchers view Tip60 HAT mediated neural gene control in the context of cognition and AD.

1395S **Dissecting the functions of the RNA-binding, LCD-containing protein Rbfox1 in Drosophila ovaries** Ona Marija Singh[1,2], Halyna R Shcherbata[1,2] [1]Shcherbata Lab, Mount Desert Island Biological Laboratory, [2]Institute of Cell Biochemistry, Hannover Medical School

Drosophila Rbfox1 is a human RBFOX protein family homolog, deregulation of which is associated with various multiple human diseases, such as autism, diabetes, obesity, epilepsy and spinocerebellar ataxia. Rbfox1 is an RNA-binding protein and has been previously shown to participate in alternative RNA splicing in the nucleus; however, its role in forming liquid granules has been less studied. We have previously demonstrated that Rbfox1 is included in various different types of ribonucleoprotein (RNP) granules, such as nucleoli, Cajal bodies, stress granules and P bodies. We have also shown that Rbfox1 dysregulation leads to abnormal stress response and that its expression is regulated by a stress-related microRNA, miR-980. Furthermore, it has been demonstrated that Rbfox1 contains a highly conserved RNA recognition motif (RRM), which binds a specific UGCAUG nucleotide sequence. In addition, our data indicate that Rbfox1 has multiple low complexity sequence domains (LCDs), which are important for liquid-liquid phase separation into membrane-less organelles in the cytoplasm as well as in the nucleus. To understand the role of Rbfox1 domains, we have generated CRISPR mutant flies that lack either the RRM or one of the LCDs. We found that these mutants have different survival rates at different developmental stages. Furthermore, the observed phenotypes in CRISPR/Cas9 mutants are cell- and differentiation state-specific and also depend on the presence of stress. This demonstrates that different Rbfox1 domains and their respective roles are differentially required in different cell types in vivo. We have also generated Rbfox1 overexpression constructs to verify a cell-autonomous effect of Rbfox1 dysregulation. Overexpression of these constructs in several tissue types results in lethality, which underlines the importance of regulation to maintain proper Rbfox1 levels. A further analysis of CRISPR/Cas9 mutants and animals with tissue-selective Rbfox1 overexpression will help to dissect the functional role of Rbfox1 domains and a potential interaction through its binding partners. This knowledge will help to further our understanding of how the deregulation of Rbfox1 contributes to deleterious symptoms, which comprise a vast spectrum of human disorders.

1396S **Transvection and analysis of allele-specific expression as a pairwise contest** Andrew G Clark[1], Elissa J Cosgrove[2] [1]Molecular Biology and Genetics, Cornell Univ, [2]Molecular Biology and Genetics, Cornell University

Transvection is a genetic phenomenon whereby a heterozygote for two different defective alleles may have wild-type function, and disruption of somatic homolog pairing disrupts this rescue. While transvection has been amply demonstrated at a handful of genetic loci in Drosophila (e.g. *bicoid, yellow*), an outstanding question in genetics is whether the entire genome has this property. Here we apply deep and well replicated RNA-seq to female head tissue from progeny of a grid cross of five founder lines from the Drosophila Synthetic Reference Population, and test how often allele-specific expression levels suggest any inter-allelic interaction. The read counts can be thought of as a pairwise contest between alleles, and we fitted the Bradley-Terry model to assess goodness-of-fit to the null hypothesis of no interaction. Of the 10,139 genes detected, 8,053 had sufficient data to call allele-specific expression across the F1 hybrids and fit the Bradley-Terry model. The majority of genes

fail to reject the Bradley-Terry model (consistent with zero inter-homolog interaction), but there is an interesting subset of 147 genes that reject the model (at FDR < 0.1), sometimes in striking ways. These cases imply that there may be some form of cross-talk among alleles, possibly including transvection, that perturb allele-specific expression. Such non-independence of allelic expression could impose some interesting properties on the evolutionary fate of mutant alleles, as their marginal fitness effects would depend in a frequency-dependent manner on other alleles in the population.

1397S **Using proximity labeling with TurboID to study Polycomb Repressive Complexes in *Drosophila*.** Enya J Selders[1], Mitzi I Kuroda[2,3], Janel Cabrera[4] [1]Biology, Emmauel College, [2]Medicine, Brigham and Women's Hospital, [3]Genetics, Harvard Medical School, [4]Biology, Emmanuel College

Polycomb repressive complexes (PRCs) play an important role in regulating gene silencing during development and differentiation. These complexes establish and maintain the silent state by catalyzing repressive histone modifications. There are two major canonical complexes, PRC1 and PRC2, that have been extensively studied from *Drosophila* to mammals. Mammalian studies have also identified five variant PRC1 (vPRC1) complexes that function in gene repression. These vPRC1 complexes have been implicated in initial Polycomb group protein (PcG) targeting, a step that is currently not well understood. Recent findings from our lab have discovered that *Drosophila* has vPRC1 complexes that are homologous to the complexes seen in mammals. We propose utilizing a new method, TurboID, to analyze these subunits in early developmental time windows. The promiscuous BirA enzyme is able to biotinylate interacting proteins rapidly at a temperature suitable for *Drosophila* culture. Using this system, we tagged known proteins in *Drosophila* S2 cells in order to identify new interactors as proof of concept for earlier time frames of development. Using this approach, we study the Pc and MSL3 proteins which are subunits of chromatin modifying complexes in different pathways to determine the specificity in our system. In preliminary data, TurboID has been successful in biotinylating the proteins of interest and interactors in S2 cells. Dissecting the composition and function of vPRC1 complexes through TurboID labeling in a simple model organism like *Drosophila* will provide an important complementary approach to mammalian studies of Polycomb repressive complexes in development and disease.

1398S **The Role of the Drosophila Muscle Gene CG42319 in Muscle Development and Function** Ebru Robinson, Richard M. Cripps Biology, San Diego State University

Z-discs, fundamental elements of muscle structure, play a pivotal role in anchoring actin filaments using α-actinin molecules. The Z-disc serves as a crucial anchoring point for thin filaments during muscle contraction. Consequently, discerning the constituents of the Z-disc is important to gain a comprehensive understanding of myofibril assembly and its functional mechanisms. While the complete structure and functions of mature Z-discs remain partially understood, they are thought to require numerous proteins for assembly and maintenance. Mutations in Z-disc-related proteins have been linked to myofibrillar myopathy (MFM), a group of heterogeneous chronic neuromuscular disorders. The Drosophila gene *CG42319* is an ortholog of human PDZ LIM genes and is the focus of our study. We aim to elucidate the structural and functional role of CG42319 in Z-disc formation and function. Our research seeks to determine if the CG42319 protein is essential for the interaction between α-actinin and the Z-disc in flight muscles, as well as for maintaining normal sarcomere structure. To investigate the function of the CG42319 gene further, we generated several mutant alleles using CRISPR/Cas9 gene editing technology, aiming to uncover the gene's underlying mechanisms. Our initial findings reveal that these mutant alleles markedly disrupt α-actinin structure, causing muscle dysfunction in the indirect flight muscles of Drosophila. Importantly, mutations in human orthologs (PLIM2) of this gene have been associated with severe muscle dysfunction and structural abnormalities observed in myopathies and muscular dystrophies. Our research holds the potential to advance our understanding of the PDZ domain protein CG42319 and its significance in the field of muscle biology.

1399S **Genome-wide screening of miRNA's involved in birth defects in eye** Manivannan Subramanian[1], Madhuri Kango-Singh[1,2,3,4], Amit Singh[1,2,3,4,5] [1]Department of Biology, University of Dayton, [2]Premedical Program, University of Dayton, [3]Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, [4]Integrative Science and Engineering (ISE), University of Dayton, [5]Center for Genomic Advocacy (TCGA), Indiana State University

Aniridia, a birth defect in eye, is caused by mutation(s) in paired-box gene 6 (PAX-6), and is manifested as visual impairment. A highly conserved PAX-6, encodes a DNA-*binding* transcription factor, whose loss-of-function exhibits loss-of-entire-eye or part-of-eye. Surprisingly, the understanding of the molecular genetic basis of Aniridia is far from complete. Our hypothesis is that the retinal loss observed in aniridia can be due to post transcriptional regulation such dysregulation of miRNAs that plays a pivotal role in regulating genes post transcriptionally. miRNAs are the short hairpin like structure with 20-25bp which modulates the gene expressions post-transcriptionally by binding to 3'UTR of mRNAs. miRNA serves a vital role in the retina throughout development and in eye diseases. We employed *Drosophila eye* as a model system for genome-wide screening of miRNAs involved in eye defects. We have identified a *miRNA* which exhibits strong eye enlargement phenotype. Using bioinformatic approaches, followed by validation using molecular and genetic studies, we identified PAX-6 homolog *eyeless*

(ey) as target of this mi-RNA. Here, we provide a mechanism of how this newly identified *miRNA* modulates eye phenotype, and results from these studies will be presented.

1400S **Fat cadherin cleavage releases a transcriptionally active nuclear fragment to regulate target gene expression** Jannette Rusch[1], Chikin Kuok[2], Nattapon Thanintorn[1], Yonit Tsatskis[2], Helen McNeill[1] [1]Developmental Biology, Washington University St Louis School of Medicine, [2]Lunenfeld-Tanenbaum Research Institute, Mt Sinai Hospital

The conserved atypical cadherin *fat* (*ft*) controls cellular processes such as growth via the Hippo pathway, planar cell polarity, and mitochondrial function, in organisms ranging from fruit flies to mammals. The intracellular domain of the Ft protein, FtICD, binds to and regulates a variety of partners to execute these functions. We have found that FtICD is present in the nucleus in tissue culture cells as well as in embryonic and larval tissues, and have identified nuclear localization and nuclear export signals in FtICD required for this localization. A membrane-bound version of FtICD, fused to a Gal4VP16 transactivation domain, is able to activate a reporter construct in imaginal discs, demonstrating that FtICD can be cleaved and enter the nucleus *in vivo*. To determine if Ft regulates transcription we used CRISPR to endogenously label Ft, and conducted ChIP-Seq. Ft target genes identified through ChIP experiments on *Drosophila* embryonic and larval tissues include genes involved in signaling pathways including the Hippo pathway, chromatin organization, pattern formation, neural development and others. A subset of these genes are differentially regulated in *ft* mutants and/or animals overexpressing FtICD, as determined by RNAseq experiments. The anti-apoptotic gene, *Diap1*, a target of the Hippo pathway, is upregulated in *ft* mutants, and *in vivo* analysis of a fragment of the *Diap1* enhancer, HRE (Hippo Response Element), indicates that FtICD can activate HRE, further supporting a nuclear function for *ft*. We propose that the modulation of Hippo pathway activity constitutes one of the nuclear functions of Ft, complementing its established function as an upstream regulator of Hippo signaling.

1401S **Head-specific gene dynamics during embryonic development** Priyanshi H Borad[1], Kelli Fenelon[1], Theodora Koromila[1], Parisa Boodaghimalidarreh[2], Jacob Luber[3] [1]Biology, University of Texas at Arlington, [2]Computer Science, University of Texas at Artlington, [3]Computer Science, University of Texas at Arlington

Genomic regulation in cell development is primarily based on noncoding regulatory sequences called enhancers, in coordination with promoter activities. Chromatin accessibility is essential for interaction of transcription factors (TFs) with accessible regulatory elements. Enhancers are available to bind with the proteins that regulate gene expression once chromatin is accessible. Although the biological importance of enhancers has been previously described, it remains unclear how head-expressed transcription factors (TFs) control gene expression. In a previous study, we found that during MBT pioneer transcription factor *Opa* and Drosophila's homolog of the *Otx* family known to regulate neural development in mice, Ocelliless *(Oc/Otd)*, expression domains overlap with both factors being simultaneously transcribed within the pre-gastrula cells in the overlapping region. Here, we provide insights into *Opa*'s and *Oc*'s mechanisms of action in head-specific gene regulation by preparing *Opa/Oc* knockdown sc-RNA-seq and scATAC-seq libraries to understand how these temporal TFs regulate expression of *kdm5 (*Lysine-specific demethylase 5)/*lid* (Little imaginal discs), *hb* (hunchback), *dll* (Distal-less) genes via the 5'*lid*, *hb*_VT38545, and *Dll*_VT22064 enhancers in the *D. melanogaster* embryo. Predicted binding sites for both *Opa* and *Oc* factors were identified in the aforementioned enhancers and upon mutagenesis the gene expression patterns exhibit dynamic changes in the width of reporter-driven expression outputs. To assess these phenotypes systematically, we devised a live imaging quantitative approach to measure the spatiotemporal outputs across the entire embryo. In conclusion, our results demonstrate that *Opa* and *Oc* play temporally-distinct roles and contribute to dynamic gene expression in the developing embryonic head.

1402S **Analyzing the role of BCOR and RSF1 in variant Polycomb Repressive Complex 1.1 in *Drosophila*.** Cynthia E Brito[1], Camila A Moreno-Bo[1], Mitzi I Kuroda[2,3], Janel Cabrera[1] [1]Biology, Emmanuel College, [2]Medicine, Brigham and Women's Hospital, [3]Genetics, Harvard Medical School

Polycomb repressive complexes (PRCs) play an important role in regulating gene silencing during development and differentiation. These complexes establish and maintain the silent state by catalyzing repressive histone modifications, histone H3 lysine 27 methylation (H3K27me) and histone H2A lysine 118 ubiquitylation (H2AK118ub). There are two major canonical complexes, PRC1 and PRC2, that have been extensively studied from *Drosophila* to mammals. Mammalian studies have identified several variant PRC1 (vPRC1) complexes that function in gene repression. Until recently, it was believed that *Drosophila* did not possess similar vPRC1 complexes. However, recent findings from our lab have discovered that indeed *Drosophila* has vPRC1 complexes that are homologous to the complexes seen in mammals. This study focuses on understanding the role of vPRC1.1. We have identified two novel subunits, Remodeling and Spacing Factor 1 (RSF1) and BCL6 Corepressor (BCOR) as subunits of vPRC1.1. Previous studies in *Drosophila* and mammals have found that RSF1 (CG8677) regulates repressive chromatin assembly by reading the PRC histone modification (H2AK118ub) and through incorporation of the variant histone H2Av. Mammalian BCOR has been implicated in many human cancers including acute myeloid leukemia

and is essential for PRC1.1 function and stem cell pluripotency. In *Drosophila*, BCOR (CG14073) is a novel gene that has not been characterized. To test whether RSF1 and BCOR are Polycomb group proteins (PcG), we are conducting genetic crosses between mutant Polycomb, RSF1, and BCOR lines to analyze homeotic transformations of the sex combs of male *Drosophila*. We will also analyze the role of these proteins during development by generating null mutants and analyzing the effects on embryonic development. Dissecting the function of the vPRC1.1 complex by studying RSF1 and BCOR in a simple model organism like *Drosophila* will provide an important complementary approach to mammalian studies of Polycomb repressive complexes in development and disease.

1404S **Molecular mechanisms underlying neural-specific splicing and 3'UTRs** Xin Yu Zhu Jiang[1,2], Lu Wei[3], Seungjae Lee[3], Eric C. Lai[3] [1]BCMB, Weill Cornell Graduate School, [2]Development Biology, Memorial Sloan Kettering Cancer Center, [3]Developmental Biology, Memorial Sloan Kettering Cancer Center

The conserved family of ELAV/Hu RNA binding proteins (RBPs) regulates mRNA processing in neurons. They expand transcriptional diversity by inducing alternative splicing (AS) of internal exons and alternative polyadenylation (APA) to lengthen 3'UTRs. Ectopic assays show that ELAV/Hu RBPs are sufficient to confer neural-like splicing and 3'UTR isoforms in a non-neural setting, and are correlated with direct binding at targets. However, mechanistic insights for how ELAV/Hu RBPs direct all of these neural isoform programs is elusive. To understand this, we propose to conduct immuno-precipitation and proteomics for ELAV/Hu partners, which may include the spliceosome complex and/or cleavage and polyadenylation (CPA) factors. Furthermore, building on data that Elav binds to U-rich regions in regions flanking alternative neural exons, or at alternative pA sites, we will map specific binding sites and characterize their regulatory grammar that can direct alternative neural isoform programs.

1405S **Investigating age-associated histone modification patterns as a regulator of lifespan** Devonique L Brissett[1], Jeff Leips[1], Erin Green[2] [1]Biological Sciences, University of Maryland Baltimore County, [2]University of Maryland Baltimore County

Aging is accompanied by dynamic changes in the levels of histone modifications. While the prevalence of histone modifications can directly regulate lifespan, this effect is often tissue-specific. Substantial variation in lifespan exists both across and within several species. Genetic differences between *Drosophila melanogaster*lines have been implicated in lifespan variation. Previous studies using young and old flies revealed that expression of a putative *Drosophila* histone methyltransferase, *SmydA-5,* was shown to increase with age in a short-lived genotype of the *Drosophila* Genetic Reference Panel (DGRP) 73, while histone deacetylase *Sirt2*expression was shown to increase in a long-lived genotype, DGRP 304, during aging. Whether these differences in histone modification abundance contribute to differences in lifespan between the genotypes is currently unknown. In this study, we are using mated males and females from three genotypes with differing lifespans to quantify the abundance of H3K4me3 and H4K16ac in the fat body tissue and thorax at three ages. Preliminary findings have revealed that global levels of H3K4me3 increase during aging in the fat body tissue in both males and females. We observed that females from the longest-lived line had stable levels of H3K4me3 with age, while the two shorter-lived lines had modest increases of H3K4me3. Upon analyzing global levels of H4K16ac with age, we found that levels increased during aging in the fat body tissue in males and females. Among males, the shortest-lived line had the highest increase of H4K16ac, while the two longer-lived lines showed lower increases of the mark. Current studies are underway to determine patterns of these marks in the thorax during aging. This work provides the basis for understanding tissue-specific histone modification changes during aging and determining how epigenetic regulation contributes to lifespan variation.

1406S **Understanding the gene regulation dynamics in embryonic heart development** Shiva Abbasi[1], Lisa Phan[1], George Tegousis[2], Theodora Koromila[1] [1]Biology, The University of Texas at Arlington, [2]Biology, Aristotle university of Thessaloniki

Embryonic patterning systems direct a set of initially uncommitted pluripotent cells to differentiate into a variety of cell types and tissues. Cell-type specification and differentiation occur early in development, and the core network of Transcription Factors (TFs) that lead to organogenesis are conserved in evolution. The *Drosophila* embryo is adapted for speedy development, as the early embryo is composed of a syncytium lacking cellular compartments until fourteen cycles of synchronized nuclear divisions have occurred. Thus, *Drosophila* is a powerful system to study genes involved in heart formation and the mechanisms of heart failure. Recent studies have shown during cellularization zygotic activation is regulated by pioneer factors such as, Odd-paired (Opa) and GAGA factor (Gaf) and other transcription factors, such as Twist (Twi) and Runt. Our hypothesis is Opa, Twi, Gaf are present in the cellularized embryo at the same time and regulating cardiac genes, such as early and late enhancers in *sloppy paired* (*slp*), *paired* (*prd*), and *tailup* (*tup*) genes. Opa have long been known to be involved in heart development and mutations in this TF produce heart defects in humans, mice, and flies, however its role in the early embryo is still unclear. Combining fluorescent In situ hybridization, live-imaging microscopy, and multi-omics, we provide insights on how cellularization-expressed transcription factors regulate heart cell specification in the early embryo.

1407S **A polycistronic non-coding RNA locus regulates germline differentiation and testis morphology in Drosophila** Travis

D Carney[1,2], Halyna R. Shcherbata[1,2] [1]Mount Desert Island Biological Laboratory, [2]Institute of Cellular Biochemistry, Hannover Medical School

Using the Drosophila testis as a model to investigate novel functions of non-coding RNAs, we found that the microRNA *miR-317* plays a role in the differentiation of germline stem cell progeny. *miR-317* and its neighbor, the lncRNA *Peony,* originate and are co-expressed from a singular polycistronic non-coding RNA locus, with alternative polyadenylation implicated in the regulation of their differential expression. While the increased expression of *Peony* causes a disruption of the muscle sheath covering the testis and leads to a dramatic enlargement of the testis apex, the absence of *miR-317* results in the emergence of germline tumors in young flies. These tumors arise near the testis apex during development, migrate basally in adult flies, and finally degrade near the terminal epithelium region of aging testes. The deficiency of *miR-317* increases Notch signaling activity in somatic cyst cells, which promotes germline tumorigenesis, while reducing Notch signaling strength decreases the incidence of tumors. Germline tumors also result from somatic upregulation of several predicted targets of *miR-317*, among which are regulators of the Notch pathway. This work demonstrates that *Peony* is a functional lncRNA regulating testis structural integrity and implicates *miR-317* as a novel tumor suppressor that simultaneously represses multiple target genes and modulates Notch signaling strength in that role.

1408S **Nucleotide-level distance metrics to quantify alternative splicing implemented in *TranD*** Adalena Nanni[1], James Titus_McQuillan[2], Kinfeosioluwa Bankole[1], Alison Morse[1], Rebekah Rogers[2], Ana Conesa[1], Lauren McIntyre[1] [1]University of Florida, [2]University of North Carolina

Advances in affordable transcriptome sequencing combined with better exon and gene prediction has motivated many to compare transcription across the tree of life. In this work, we develop a mathematical framework that uses distance metrics to calculate complexity and compare transcript models from a structural perspective. Structural features, i.e., intron retention (IR), donor/acceptor site variation, alternative exon cassettes, alternative 5'/3' UTRs, are compared and the distance between transcript models is calculated with nucleotide level precision. All metrics are implemented in a PyPi package, *TranD*, that can be used to summarize splicing patterns for a transcriptome (1GTF) and between transcriptomes (2GTF). *TranD* enables quantitative comparisons between: annotations augmented by empirical RNA-seq data and the original transcript models; transcript model prediction tools for longread RNA-seq (e.g., FLAIR vs Isoseq3); alternate annotations for a species (e.g., RefSeq vs Ensembl); and between closely related species. In both annotation and long read RNA-seq for *C. elegans, Z. mays, D. melanogaster, D. simulans* and *H. sapiens*, alternative exons were observed more frequently in combination with an alternative donor/acceptor than without. Data from *D.melanogaster* and *D.simulans* suggest that both species are under-annotated and single transcript genes are likely to share the same transcript model.

1409S **The roles of lncRNAs in the expression and processing of Y chromosome mega-genes** Matthew Jachimowicz[1,2,3], Lingfeng Ma[1,2,3], Zhantao Shao[2], Jack Hu[2], Chun Hu[2], Julie A. Brill[1,3], Henry M. Krause[1,2] [1]Molecular Genetics, University of Toronto, [2]Donnelly Centre, University of Toronto, [3]Cell Biology Program, The Hospital for Sick Children

In *Drosophila* and mammals, long non-coding RNA (lncRNA) abundance and diversity is highest in male reproductive tissues, yet their potential roles in male reproduction are largely unexplored. To address this nascent field, I have begun characterizing a group of testis-expressed lncRNAs, that we have shown to spatially associate with megabase-long genes or 'mega-genes'. These novel nuclear associations suggest that lncRNAs may regulate mega-genes at a transcriptional or post-transcriptional level. Additionally, these lncRNAs may directly interact with mega-genes by complementary hybridization, or indirectly by hybridizing to an intermediate lncRNA. To test my hypothesis, I have computationally identified complementary sequences between mega-gene associated lncRNAs and simultaneously compared their expression patterns using fluorescent in situ hybridization (FISH). Indeed, mega-gene associated lncRNAs sharing complementary sequence colocalize, maintaining the possibility of an interaction. To further investigate these associated lncRNAs, I will test whether this is a functional association between mega-genes and lncRNAs using a CRISPR knockout approach. Furthermore, lncRNA functions will be further characterized by identifying their interactors and interacting sequences using a hybridization-dependent biotinylation method. Ultimately, my results will potentially contribute to our understanding of mega-gene regulation in human contexts, such as in the regulation of *dystrophin* and human Y-linked mega-genes, and begin addressing the roles of lncRNAs in male reproduction.

1410S **Study of piRNA clusters, loci involved in genome stability** Zoheir Ziriat, Teysset Laure, Carré Clément UMR7622, Sorbonne Université

piRNA clusters are heterochromatic loci involved in the maintenance of genome integrity by ensuring the control of transposable elements (TE) *via* the production of small noncoding RNAs called piwi-interacting RNAs (piRNAs). Despite the important role of these loci in genome stability, we know really few things about their transcription and regulations. In our lab we're studying 2 models of germinal piRNA clusters of *Drosophila melanogaster.* The sub-telomeric 1A locus, which

contains sequences unique amongst piRNA clusters that could be used to mimic the cooptation of a new transposon in *Drosophila* genome. In the other hand, BX2 is an artificial piRNA cluster that exists in 2 different epigenetic states: either active for the production of piRNAs (ON), or inactive for piRNA production (OFF) while still being transcribed. Studying these 2 loci using functional tests, molecular tools and 3rd generation sequencing approaches will allow us to decipher the complex biology of piRNA clusters

1411S **Pilot screen to identify genes that participate with H4K20 methylation in controlling cell proliferation in *Drosophila*** Kelli Jancay[1], Marybeth Slack[1], Aaron Crain[2], Robert J Duronio[2,3,4,5], Lisa M Antoszewski[1] [1]Biology, Grove City College, [2]Integrative Program for Biological and Genome Sciences, University of North Carolina at Chapel Hill, [3]Biology, University of North Carolina at Chapel Hill, [4]Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, [5]Genetics, University of North Carolina at Chapel Hill

Control of cell proliferation is essential for organismal development and survival and occurs through a series of steps called the cell cycle. During the cell cycle, the genome is copied before the cell divides and, if this process is compromised, DNA damage and death can result. The ability to effectively replicate DNA and therefore control cell proliferation is affected by chromatin structure and accessibility, which is influenced by post-translational modifications to histone proteins including methylation. Data suggest that cell proliferation is compromised when H4K20 methylation is disrupted. However, the exact mechanism behind a requirement for H4K20 methylation in the cell cycle is still unknown. Our goal is to identify genes on the third chromosome of *Drosophila* that regulate cell proliferation through H4K20 methylation. Using a histone deletion on the second chromosome and a transgene on the third chromosome that expresses either wild type or H4K20R mutant histone, we will utilize the FLP/FRT system to create histone mutant clones in the adult eye. Wildtype cells will be marked with GFP and histone mutant cells with RFP, and the size of histone mutant clones relative to wildtype clones will be determined with fluorescence microscopy. To identify genes that interact with H4K20 methylation, we plan to perform a pilot screen with Set8-interacting proteins. Set8 is the only known H4K20 histone mono-methyltransferase in eukaryotes, and the action of Set8 is required for subsequent di and tri methylation of H4K20. The size of histone mutant clones will be analyzed when heterozygous loss of function mutations in genes encoding Set8-interacting proteins are introduced. Following the completion of this pilot screen, a forward genetic screen using the 3rd chromosome deficiency kit will be executed.

1412S **Investigating the *in vivo* functions of Histone 3 (H3) monoaminylation using *Drosophila*** Harim Delgado-Seo[1], Gary Huang[2], Herman A. Dierick[2], Ian S. Maze[3], Shinya Yamamoto[4] [1]Neuroscience, Baylor College of Medicine, [2]Molecular and Human Genetics, Baylor College of Medicine, [3]Departments of Neuroscience and Pharmacological Sciences, Icahn School of Medicine at Mount Sinai, [4]Department of Molecular and Human Genetics, Baylor College of Medicine

Breakthroughs in epigenetic discoveries have revealed epigenetic mechanisms that can induce lasting changes in both the structure and function of the nervous system, thereby influencing a spectrum of neurological and psychiatric disorders. Recent work has found that biogenic monoamines like dopamine and serotonin can post-translationally modify Histone 3 (H3) at two specific glutamine (Q) residues, H3-Q5 and H3-Q19. Initial studies of this process, known as H3 monoaminylation, found that transcriptional and behavioral patterns of cocaine-dependent rats were partially reversible by overexpressing a monoaminyl-deficient H3-Q5 variant in the reward circuit. Although H3 monoaminylation has been henceforth linked to mood disorders and other drug addictions, its overall physiological importance and the functional significance of the second monoaminyl site (H3-Q19) remains unclear. Therefore, this study aims to probe the functional significance of both H3 monoaminylation sites *in vivo* by using throughput genetic and behavioral techniques in the fruit fly. To investigate the effects of monoaminylation on H3-Q5 and H3-Q19, *Drosophila* strains with H3 variants mimicking unmodifiable glutamine (Q) residues were designed. This was achieved by amino acid substitutions replacing glutamine (Q) residues with alanine (Q>A) or asparagine (Q>N), in the individual (Q5 or Q19) or combined (Q5+Q19) monoaminylation sites using phiC31-mediated targeted integration. Thus far, we have found that ubiquitous overexpression of individual H3-Q>A and H3-Q>N variants resulted in comparable semi-lethality patterns, suggesting that monoaminyl deficiency rather than specific amino acid substitutions is responsible for this phenotype. Moreover, pan-neuronal overexpression of H3-Q>A variants causes defects in wing expansion behavior, which is regulated by a genetically and neurobiologically traceable neuro-hormone signaling cascade. Therefore, we have found a potential pathway for further exploration into the precise function of this novel epigenetic mark *in vivo*.

1413S **Nutrient-dependent regulation of the *Drosophila melanogaster* Estrogen Related-Receptor (ERR)** Sophie A Fleck, Hongde M Li, Maria C Sterrett, Jason M Tennessen Department of Biology, Indiana University Bloomington

Animal development is acutely sensitive to environmental conditions including dietary nutrients, temperature stress, and xenobiotic compounds. One of the key sensors involved in coordinating environmental cues with developmental events are the highly conserved family of nuclear receptor transcription factors. In this regard, the Estrogen-Related Receptor (ERR) family of orphan nuclear receptors play a key role in coordinating cellular metabolism with developmental gene expression programs.

We previously demonstrated that the *Drosophila melanogaster* ortholog of ERR activates a metabolic program known as aerobic glycolysis prior to the onset of larval development, thus establishing a metabolic state that supports rapid juvenile growth. During this embryonic switch, which occurs approximately 12 hours before hatching, accumulation and activation of ERR protein directly activates transcription of genes encoding enzymes within glycolysis and the pentose phosphate pathway (PPP). Intriguingly, we've found that expression of ERR protein earlier in embryonic development does not drive precocious activation of aerobic glycolysis. However, premature expression of a constitutively active ERR-VP16 fusion protein is capable of inappropriately activating target gene expression. Together, these findings indicate that ERR activity is controlled at a post-translational level via an unknown mechanism. Consistent with these embryonic studies, we've also demonstrated that ERR activity during larval development tightly correlates with nutrient availability, as ERR become inactive when *Drosophila* larvae are fed a nutrient poor diet. Further analysis by western blot revealed an approximate 40 kDa shift in the weight of ERR when larvae are starved. These findings indicate that ERR may be regulated through inhibitory post-translational modification(s) (PTMs) when environmental conditions are inadequate for *Drosophila* development. Considering that ERR family members are orphan receptors that are highly conserved across evolutionary time, our findings are important because they hint at an unknown mechanism that controls post-translational ERR activity. Finally, our studies indicate that ERR coordinates developmental metabolism with nutrient availability.

1414S **Layered regulation of the Drosophila CTLH complex during the maternal-to-zygotic transition controls maternally-deposited RNA binding protein clearance** Chloe Briney[1], Jesslyn Henriksen[2], Olivia Rissland[1] [1]University of Colorado Anschutz Medical Campus, [2]University of Colorado, Anschutz Medical Campus

The maternal-to-zygotic transition (MZT) is a conserved and essential early developmental process that ensures embryogenesis occurs properly after fertilization. Importantly, prior to zygotic genome activation, the early Drosophila embryo proteome consists mainly of maternally deposited proteins. During the MZT, maternal gene products are cleared to make way for newly transcribed and translated zygotic gene products. A key step of the MZT is therefore the removal of specific maternal proteins. One well-characterized example is the clearance of the maternally deposited ME31B-Cup-TRAL RNA binding protein complex, which we recently found to be cleared by the translationally-upregulated E2 Kondo and CTLH E3 complex (Zavortink et al 2020). However, ME31B and many components of the CTLH complex are ubiquitously expressed in flies, so why and how is ME31B clearance so tightly regulated during the MZT? Our findings reveal a complex gene regulatory network that mediates the developmental specificity of ME31B degradation. This network relies on the modularity of the ubiquitin proteasome system and its ability to exert precise control by restricting expression of its components to specific timeframes. This network involves at least four layers of control. First, E2 Marie Kondo mRNA is only translated at the start of the MZT. Second, the CTLH subunit Muskelin is required for substrate recognition and is only expressed during oogenesis. Third, recognition of ME31B by the CTLH complex and its interaction with Muskelin changes during the MZT. Finally, Marie Kondo and some CTLH components, including Muskelin, are themselves degraded at the end of the MZT. Our results provide evidence for an elegant network of regulatory mechanisms controlling degradation of specific deposited maternal proteins with precise developmental timing.

1415S **BRD4 binds to active cranial neural crest enhancers to regulate RUNX2 activity during osteoblast differentiation** Trevor V. Shumate, Karl Shpargel Department of Genetics, University of North Carolina

Cornelia de Lange syndrome (CdLS) is a congenital disorder featuring facial dysmorphism, postnatal growth deficits, cognitive disability, and upper limb abnormalities. CdLS is genetically heterogeneous with cases arising from mutation of BRD4, a bromodomain protein that binds and reads acetylated histones. In this study we have modeled CdLS facial pathology through mouse neural crest cell (NCC) specific mutation of BRD4 to characterize cellular and molecular function in craniofacial development. Mice with BRD4 NCC loss of function died at birth with severe facial hypoplasia, cleft palate, mid-facial clefting, and exencephaly. Following migration, BRD4 mutant NCCs initiated RUNX2 expression for differentiation to osteoblast lineages but failed to induce downstream RUNX2 targets required for lineage commitment. BRD4 bound to active enhancers to regulate expression of osteogenic transcription factors and extracellular matrix components integral for bone formation. RUNX2 physically interacts with a carboxy-terminal (C-terminal) domain in the long isoform of BRD4, can co-occupy osteogenic enhancers, and this association is required for RUNX2 recruitment and appropriate osteoblast differentiation. We conclude that BRD4 controls facial bone development through osteoblast enhancer regulation of the RUNX2 transcriptional program.

1416S **Interrogating the roles of KMT2C and KMT2D in chondrocyte differentiation and endochondral ossification** Gabrielle A Quickstad[1], Dimitri V Bikas[2], Karl B Shpargel[1] [1]Genetics, UNC Chapel Hill, [2]UNC Chapel Hill

Chromatin-modifying enzymes associated with enhancer function are frequently mutated in human craniofacial disorders. Kabuki syndrome (KS) is a craniofacial development disorder characterized by mutations in KMT2D, a histone H3 lysine 4 (H3K4) methyltransferase. Neural crest cells (NCCs) are the stem cells from which anterior facial bone and cartilage originate. Our preliminary studies show that mouse NCC deletion of KMT2D results in a lack of cranial base chondrocyte hypertrophic

differentiation. Many craniofacial disorders linked to mutations in enhancer-associated chromatin-modifying enzymes, including KS, present with a wide range of skeletal abnormalities in humans including shortened long bones, scoliosis, and joint abnormalities. As these patients present with skeletal defects that may result from abnormal chondrocyte differentiation, understanding the mechanism of KMT2D function in this differentiation process is crucial to a better understanding of both craniofacial disorders and skeletal development. A conditional loss of KMT2D and its functional homolog KMT2C (KMT2C/D DKO) in mouse chondrocytes yields a dramatic reduction in weight at weaning, shorter fore and hindlimb bone lengths, and a decrease in size of the presphenoid and basisphenoid regions of the cranial base. Safranin O-fast green FCF staining of cartilage in mouse hindlimbs reveals a loss of columnar epiphyseal growth plate chondrocyte organization, thickening of epiphyseal growth plates of the tibia and femur, and overgrowth of articular cartilage into the intercondylar fossa. Subsequent high-resolution imaging will shed light on bone composition, type, and density alterations in KMT2C/D DKO mice as compared to wildtype. We are currently exploring KMT2D's molecular mechanism by interrogation of KMT2C/D-deficient NCCs and primary mesenchymal stem cells in culture for changes in KMT2D genome binding, chromatin accessibility, differential gene expression, and localization of enhancer histone-methylation during chondrocyte differentiation. We will ascertain the novel functional roles that KMT2C and KMT2D play in regulating chondrocyte differentiation and the results of this study will implicate epigenetic modifiers in the progression and treatment of skeletal development disease.

1417S **Mechanisms of acute exercise on brain health** Tiffany Chin, Hume Akahori Stroud Neuroscience, UT Southwestern Medical Center

Exercise has long been stated as beneficial for neural health by reducing anxiety, promoting neuroplasticity, and preventing neurodegeneration. Long-term exercise mouse models have been shown to recapitulate these aforementioned benefits. However, the specific pathways involved in promoting these benefits in brain and behavior have not been clearly defined. To address this, I utilized a short-term exercise mouse model to study the immediate molecular and cellular effects of exercise on brain health. Strikingly, I found that a single bout of exercise is sufficient to stimulate neural activity of many cells in the hippocampus, a brain region critical for learning and memory. As transcriptional changes may play a role in promoting brain health in response to exercise, I aim to reveal how transcription is modulated across different cell types of the hippocampus. RNA sequencing and assay for transposase-accessible chromatin (ATAC) sequencing will be performed to observe gene expression and chromatin accessibility changes at single cell resolution, respectively. By studying transcriptional variations and chromatin conformation changes, I expect to uncover how downstream pathways are regulated and mediate the benefits of exercise.

1418S **Receptor choice in the olfactory system of ants** Bogdan Sieriebriennikov[1], Olena Kolumba[1], Aurore de Beaurepaire de Louvagny[1], Hua Yan[2], Claude Desplan[1] [1]New York University, [2]University of Florida

In both flies and vertebrates, smell is perceived by olfactory sensory neurons (OSNs) that rely on the expression of a single odorant receptor (*Or*) gene per cell to discriminate between odors. Flies have few *Or* genes (~60), while mammals have many (>1,000 in mice), which is reflected in different specification mechanisms of developing OSNs in these species. The simple olfactory system of flies uses deterministic specification of cell fates by a transcription factor code, while the complex olfactory system of mammals relies on stochastic choices, including stochastic enhancer-promoter interactions, complemented by negative cross-regulation between *Or*s. Ants, which extensively rely on smell to navigate their physical and social milieu, lie in the middle of this spectrum. The jumping ant *Harpegnathos saltator* has an order of magnitude more *Or* genes than *Drosophila melanogaster* (~400). The additional genes have evolved via tandem duplications, creating large genomic arrays of *Or* genes positioned head-to-tail, an arrangement reminiscent of *Or* arrays in mammals. We investigated the expression pattern of *Or*s in individual OSNs in *H. saltator* by performing single-nucleus sequencing on the antennae. Unexpectedly, we observed that all genes in tandem *Or* arrays are co-expressed in a "stair step" fashion where either the most 3' gene is expressed alone, or the two most downstream genes are co-expressed, or the last three genes are co-expressed etc. Additionally, the expression levels of multiple co-expressed genes show a decreasing trend towards the most 3' transcribed *Or*, suggesting that such co-expression may result from RNA polymerase readthrough. We propose that a single *Or* promoter is stochastically chosen from a cluster, activating the transcription of the corresponding gene. However, RNA polymerase fails to terminate at the end of this gene, producing long RNAs. While they include all the downstream *Or* sequences, those cannot be translated due to their distance from the 5' cap. At the same time, upstream *Or* genes are repressed through additional mechanisms which we are currently investigating. Thus, genomic clusters of ant *Or*s, which have evolved to accommodate an expanded repertoire of odors related to the ants' lifestyle, may rely on a unique mechanism to produce singular OR protein expression in each OSN.

1419S **Transcriptomic analysis reveals regulation of adipogenesis via long non-coding RNA, alternative splicing, and alternative polyadenylation** Salwa Mohd Mostafa[1], Luyang Wang[2], Bin Tian[2], Joel Graber[3], Claire Moore[1] [1]Tufts University, [2]The Wistar Institute, [3]MDI Biological Laboratory

Obesity is characterized by dysregulated adipogenesis leading to increased number and/or size of adipocytes. Understanding the molecular mechanisms governing regulation of adipogenesis is therefore key to designing therapeutic interventions against obesity. In our study, we analyzed 3'-end sequencing data generated from sequencing of human preadipocytes and adipocytes, as well as data from publicly available databases, to propose mechanisms of molecular regulation of adipogenesis. We discovered lncRNAs that have not been previously characterized but may be key regulators of both brown and white adipogenesis. We also demonstrated possible mechanisms of direct or indirect regulation of adipogenesis through alternative splicing. Finally, we show that usage of alternative polyadenylation sites of key adipogenesis genes leads to isoform diversity, which can have significant biological consequences on differentiation efficiency. Therefore, our research reveals potential therapeutic avenues for obesity through manipulation of long non-coding RNA levels, alternative splicing and usage of alternative polyadenylation sites.

1420S **Probing nuclear HSATII RNA biomolecular condensates** Thembalami Dube[1,2,3], Christina A Rabeler[1], Dawn M Carone[1] [1]Biology, Swarthmore, [2]Biology, Swarthmore College, [3]Physics, Swarthmore College

Human satellite sequence II (HSATII) is a tandemly repeated pericentric and heterochromatic sequence that is transcriptionally silent in normal human cells, yet in cancer cells HSATII RNA is aberrantly expressed and accumulates large nuclear foci that remain in cis at their sites of transcription. Expression and aggregation of HSATII RNA is concomitant with sequestration of key chromatin regulatory proteins known to phase separate including MeCP2. While HSATII expression is highly correlated with higher grade tumors in various epithelial cancer cell lines, the effect of its nuclear misregulation is poorly understood. Due to the upregulation of HSATII RNA expression in cancer, accumulation of the HSATII RNA in cis, sequestration of key regulatory phase-separating proteins, and its repetitive nature, we hypothesized that HSATII RNA is a molecular scaffold that nucleates and forms phase-separated biomolecular condensates in vivo. Condensates are increasingly recognized as important for cellular function and dysfunction. Here, we present evidence that HSATII RNA assembles into biomolecular condensates via in vitro assays. We also employ an in vivo disruption assay that utilizes doxorubicin and 1,6-hexanediol, both drugs known to specifically target and disrupt condensates in vivo. Treatment with both these drugs resulted in significant redistribution of HSATII RNA in living cells. Characterizing HSATII RNA focal accumulations as condensates provides a mechanistic account for pathological phenotypes in cancer. While this study serves to demonstrate that HSATII RNA foci can form condensates, it also has broader implications for drug development in cancer therapeutics.

1421S **Search for proteins with roles in promoting yFACT dissociation from 3' ends of transcribed genes** Will Griffin, Reece Forrest, Michaela Edwards, Joseph Beard, Lillian Francis, Agustin Kalinowski, Sydney Ozersky, Caroline Tackett, Andrea Duina Department of Biology, Hendrix College

Eukaryotic cells use histone chaperones to manipulate chromatin for a variety of processes. FACT (Facilitates Chromatin Transactions) is a highly conserved histone chaperone complex, composed of Spt16 and Pob3 in *S. cerevisiae*, that during transcription elongation has roles in the disassembly of nucleosomes in front of RNA polymerase II (Pol II) and in nucleosome reassembly in the wake of Pol II passage. Our previous research identified a region on nucleosomes known as ISGI (Influences Spt16-Gene Interactions), whose integrity is necessary for proper dissociation of yeast FACT (yFACT) from the 3' ends of transcribed genes. In addition to causing yFACT dissociation defects, the more severe ISGI mutants confer a variety of growth phenotypes, including slow growth, cold sensitivity, and in some cases lethality. Current studies in the lab aim at identifying proteins with possible roles in promoting yFACT dissociation from genes. Using a synthetic gene array strategy with cells expressing an ISGI mutant as the query strain, we identified ~150 proteins as candidates for contributing to yFACT dissociation from genes. We are currently validating these genetic interactions and are using chromatin immunoprecipitation (ChIP) assays to test the most promising candidates for possible roles in promoting yFACT-gene dissociation. We expect that these experiments will lead to the identification of one or more factors that promote yFACT dissociation from chromatin, which would in turn provide new insights into yFACT-chromatin dynamics.

1422S **RNA polymerase II-general transcription factor interfaces function in transcription start site selection in *Saccharomyces cerevisiae*** pratik basnet[1], Yunye Zhu[2], Irina O. Vvedenskaya[3], Payal Arora[2], Staci Hammer[4], Shawn Alex[5], Brittany McVicar[2], Bryce E. Nickels[6], Craig D. Kaplan[2] [1]Bio-Science, University of Pittsburgh, [2]University of Pittsburgh, [3]Rutgers University, [4]Loras College, [5]Texas A&M, [6]Waksman Institute, Rutgers University

During transcription initiation in *Saccharomyces cerevisiae*, Pol II and its general transcription factors (GTFs) assemble upstream of transcription start sites (TSSs) to form the pre-initiation complex (PIC). The PIC then selects TSSs by a unidirectional scanning mechanism. Structural studies show that a TFIIH component Tfb3 links TFIIH to the rest of the PIC via its interactions with Pol II and TFIIE. Activities within the PIC that influence TSS selection can do so by control of initiation efficiency at individual TSSs and by control of TSS scanning (either rate of scanning or scanning processivity). How factors in the PIC at the interface of Pol II and TFIIH contribute to these different activities is not clear. We demonstrate that a

specific connection between Tfb3 and Rpb7 is critical for proper TSS selection. Furthermore, we report the identification of *tfb3* and *tfa1* alleles from genetic screens for putative TSS selection mutants and demonstrate that a subset confers TSS defects in vivo by analysis of the model *ADH1* promoter. These alleles, many of which have residues conserved from budding yeast to human, show TSS shifts at the model promoter *ADH1* and genome-wide (TSS-sequencing). Promoter-level data from our genome-wide TSS mapping provides a quantitative window into phenotypic classes of different initiation mutants. We aim to determine if Pol II-TFIIH interface mutants work with the Pol II active site to promote initiation efficiency or contribute to TFIIH functions and promoter scanning efficiency.

1423S **Identifying the network of genes influenced by the NAD+ dependent deacetylase Sir2 to allow adaptation to low NAD+ stress in the yeast *Kluyveromyces lactis*** Mahasweta Acharjee[1], Kristen Humphrey[1], Vincent Lactaoen[1], Laura Rusche[2] [1]University at Buffalo, [2]State University of New York at Buffalo

Metabolites such as NAD+, which are cofactors in enzymatic reactions, can be synthesized by some species but for other species must be obtained from the environment. For example, most budding yeasts encode *BNA* genes to synthesize NAD+, but *Kluyveromyces* species lack these genes and instead scavenge the precursor, nicotinic acid, from the environment. This project explores how *Kluyveromyces lactis* adapted to the loss of the NAD+ biosynthesis pathway thorough transcriptional rewiring of a gene network repressed by the NAD+-dependent deacetylase Sir2, which is thought to be a sensor of NAD+ availability. We previously compared the genes repressed by Sir2 in *K. lactis* and *Saccharomyces cerevisiae*, which synthesizes NAD+. Interestingly, in *K. lactis,* KlSir2 represses thirteen genes encoding transcription factors, whereas these genes are not repressed by a sirtuin in *S. cerevisiae*. We hypothesized that when these transcription factors are derepressed under low NAD+, they induce additional genes, sustaining and amplifying the response to fluctuating NAD+ levels. To examine how NAD+ levels affect Sir2-regulated gene expression, we grew *K. lactis* cells in varying levels of the precursor nicotinic acid and measured intracellular NAD+ levels and expression of Sir2 target genes. We found that as NAD+ levels decreased, acetylation of histones at target promoters increased, and expression of these genes increased. Interestingly, we found that the drop in NAD+ that is sufficient to induce a transcriptional response is smaller than the drop that affects growth rate. Thus, the cells start responding to falling NAD+ levels early, presumably to buffer against the reduced NAD+. Hence an organism facing stress can modify its gene expression network as a survival strategy before or as soon as its viability and growth is threatened.

1424S **Characterization of Med15-Transcription Factor Interactions and Phase Separation** Shulin Liu[1], David Cooper[2], Emma Grunkemeyer[1], Jan Fassler[1] [1]Biology, University of Iowa, [2]Butler University

Med15 is a glutamine-rich general transcriptional regulator that resides within the tail module of the RNA Pol II Mediator Complex. Strains lacking Med15 are compromised in their ability to grow on many kinds of media, under stress conditions, and in fermentation, reflecting its importance in gene expression. Naturally occurring yeast strains specialized for growth in specific environments (e.g., wine, beer, clinical) vary in their glutamine tract lengths, suggesting that the length of glutamine tracts may influence Med15 function in a manner that is adaptive for a specific environment. The *S. cerevisiae* Med15 protein is one of the most intrinsically disordered subunits of the yeast Mediator Complex and its IDRs likely underlie the role of Med15 as an interaction hub, making contact with a large number of transcription factors. Med15 undergoes liquid-liquid phase separation together with the Gcn4 transcription factor *in vitro*. In this work we map the domain(s) of Med15 that are sufficient for phase separation, examine the contribution of certain amino acid features within that region, and manipulate the length and composition of this region of Med15 to test for a correlation between effects on gene expression and growth and effects on phase separation. In related studies, we examine the nature of the interaction between the different parts of the intrinsically disordered Med15 protein and other transcription factors to determine if phase separation is a general mechanism for Med15 mediated transcriptional activation. Finally, we examine the possibility that the IDRs might also mediate intramolecular interactions. We propose that the IDRs may influence the shape of the Med15 protein, thus indirectly affecting the propensity for phase separation and interactions with transcription factors.

1425S **Induction of budding yeast MFS transporter Tpo1 by anticancer ruthenium complex KP1019 depends on transcription factor Pdr1** Millena Chirillo[1], Lizbett Ocana[1], Hagen Mancuso[2], Pamela Hanson[1] [1]Furman University, [2]Birmingham Southern College

Indazolium *trans*-[tetrachlorobis(1*H*-indazole)ruthenate(III)], also known as KP1019, is an anticancer ruthenium complex with promising anticancer activity in a Phase I clinical trial. KP1019 may serve as an alternative to platinum-based chemotherapies, as it causes fewer side effects. The drug has similar impacts on budding yeast *Saccharomyces cerevisiae* and cancer cells, causing DNA damage and oxidative stress in both. Notably, KP1019 also maintains potency against yeast and cancer cell lines that are multidrug-resistant due to overexpression of ATP-binding cassette (ABC) and/or major facilitator superfamily (MFS) transporters. Thus, yeast can serve as an effective model for studying KP1019.

Published transcriptomic data suggest that KP1019 induces expression of the evolutionary conserved transporter Tpo1 in yeast. Here we verified this drug-dependent induction by using flow cytometry to quantify expression of Tpo1-GFP. Since *TPO1* induction by herbicides and other drugs was previously shown to be controlled by the transcription factor Pdr1, one of the TFs that controls the pleiotropic drug response, we measured the expression of Tpo1-GFP in yeast lacking *PDR1* and/or *PDR3.* Whereas KP1019 treatment increased Tpo1-GFP expression roughly 2-fold in wild-type yeast, compared to untreated controls, deletion of *PDR1* reduced this induction by more than 50%. To verify that *PDR1* is a regulator of *TPO1* expression, we measured Tpo1-GFP levels in yeast with the gain of function allele, *PDR1-11*. The *PDR1* mutant strain displayed a roughly 4-fold increase in Tpo1-GFP levels relative to wild-type controls. Since *PDR1-11* mutants were previously shown to be hypersensitive to KP1019, we examined whether its phenotype was related to *TPO1*. Upon deleting *TPO1* in the *PDR1-11* strain, the tolerance of KP1019 returned to near wild-type levels. Moreover, the deletion of *TPO1* in a wild-type background caused KP1019 resistance.

These results support the hypothesis that KP1019-dependent induction of *TPO1* depends on *PDR1*. Moreover, Tpo1-GFP levels display an inverse relationship with KP1019 resistance, as yeast lacking this transporter are resistant to the drug, but *PDR1-11* yeast that overexpresses *TPO1* are hypersensitive. Given that publicly available datasets show that cancers expressing low levels of MFSD10, the human orthologue of *TPO1*, are resistant to platinum-based chemotherapeutics, we propose that *TPO1* is an evolutionarily conserved modulator of metal drug sensitivity.

1426S **Why are the GABA shunt lower and upper pathway genes regulated differently in *Saccharomyces cerevisiae*?** Terrance G. Cooper[1], Jennifer J. Tate[2] [1]Microbiology, Immunology & Biochemistry, University of Tennessee Health Science Center, [2]Microbiology Immunology and Biochemistry, University of Tennessee Health Science Center

In nitrogen excess, TorC1 phosphorylates Nitrogen Catabolite Repression (NCR)-sensitive transcription activator Gln3, and Tap42, and inhibits charged tRNA-sensitive Gcn2 kinase, and TorC1-bound, phosphorylated Tap42-Sit4/PP2A phosphatase complexes. This results in cytoplasmic Gln3 sequestration and minimal NCR-sensitive transcription. Conversely, nitrogen limitation or starvation down-regulates TorC1 activity, activates Gcn2, permitting Tap42-Sit4/PP2A-dependent Gln3 dephosphorylation, nuclear localization and increased NCR-sensitive transcription. Glutamine levels determine Gln3 binding to its NCR-sensitive target promoters. In low, but not high glutamine, Gln3 must bind to its target promoters before exiting the nucleus. Free Sit4/PP2A dephosphorylate Gln3 exiting from the nucleus in nitrogen excess, whereas Tap42-Sit4/PP2A complexes do so in low nitrogen. Sit4, PP2A and Ure2 are all required to achieve the cytoplasmic Gln3 phosphorylation level. Two Gln3-Torc1 interacting sites exist in Gln3. The C-terminal site functions negatively for sequestering Gln3 in the cytoplasm in excess nitrogen, whereas the N-terminal site responds positively to rapamycin-dependent Gln3 dephosphorylation and nuclear localization. Recent data show Whi2-Psr1/2 suppresses TorC1 activity following a shift from high to low amino acids, but that suppression has little influence on overall NCR-sensitive protein production. This abridged view of Gln3 control applies to how the lower GABA shunt pathway genes are regulated but not the *GAD1* gene encoding the first enzyme in the GABA shunt. However, unlike the lower pathway genes, GAD1 responds to rapamycin inhibited TorC1 kinase but does so independently of Gln3 and Gat1. We demonstrate, using a nickel probe, the integrated, TorC1-dependent, NCR-sensitive-dependent/independent, and GABA-dependent regulation of the upper and lower GABA shunt, retrograde, peroxisomal glyoxylate cycle, and β-oxidation pathways and distinct functions of Gad1. Supported by Harriet S. VanVleet Chair of Excellence and NIH grant GM35642-27.

1427S **Chromatin-mediated hypoxic stress response by Set4 in *S. cerevisiae*** Winny Sun, Yogita Jethmalani, Maraki Negesse, Isabella Justice, Shandon Amos, Erin M Green University of Maryland, Baltimore County

Stress responses in yeast are often mediated by changes in gene expression that allow the cells to adapt. This dynamic signaling occurs through changes in transcriptional regulation, often dependent on the chromatin environment. Set4 is a chromatin-associated protein that is protective in hypoxic stress, during which its expression is induced. Set4 is part of the SET domain family of lysine methyltransferases but appears to lack catalytic activity. Besides its paralog Set3 in yeast, there are other orthologs that share this feature, including in worms, fruit flies, and mammals.

The mechanism by which Set4 promotes survival under hypoxic stress has yet to be determined. Set4 regulates expression of subtelomeric genes, including stress response genes and cell wall components such as the *PAU* family, which are known to be highly induced under hypoxia. Here, we will present our current investigation on Set4 interactions with chromatin modifiers and transcription regulators at stress response genes. We have shown that loss of *SET4* leads to changes in local chromatin environment in hypoxia, including an increase in acetylation at H3K9 at the *PAU* promoters where Set4 localizes during hypoxic stress. This correlates with our observation at these regions that loss of *SET4* affects the localization of the histone deacetylase Rpd3, which can deacetylate H3K9. We also investigate the effect of *SET4* on the association of histone acetylase Gcn5, a catalytic subunit of the SAGA chromatin remodeling complex, which can acetylate H3K9 and has been shown to

regulate *PAU* expression during hypoxia.

Upc2 is a transcription factor that induces *PAU* gene expression upon the switch from aerobic to hypoxic conditions, as well as the induction of *SET4* expression, which then represses *PAU* expression. We have shown that in the absence of *SET4*, *PAU* gene expression is derepressed under hypoxia, and this is dependent on the presence of *UPC2*. Additionally, we show using chromatin immunoprecipitation that *SET4* affects the association of Upc2 to *PAU* promoters.

Altogether, this work provides insight into chromatin regulators that work with Set4 to control gene expression in response to hypoxia and identifies new chromatin regulatory pathways that may also function more broadly to control stress responses in other organisms.

1428S **A Novel Transgenic Reporter to Study Vertebrate Epigenetic Reprogramming During Wound Healing and Regeneration** Jian Ming Khor, Aniket V Gore, Kiyohito Taimatsu, Miranda Marvel, Daniel Castranova, Allison Goldstein, Gennady Margolin, Brant M Weinstein National Institutes of Health

Epigenetic reprogramming plays a pivotal role in reactivation of otherwise silent developmental programs during wound healing and regeneration in adults. Unlike most vertebrate model organisms, zebrafish possess the ability to faithfully regenerate many complex organs and appendages throughout their lifespan. However, the mechanisms regulating the epigenetic changes that permit robust regeneration following injury have yet to be elucidated. This is in part due to the lack of tools for studying epigenetic changes in a tissue- and cell-specific manner. We have generated an “EpiTag” zebrafish transgenic reporter line that permits easy and rapid visualization of tissue-specific loss or gain of epigenetic silencing in living animals at cellular resolution. We observe early and dramatic activation of the EpiTag reporter in regenerating cells of many different tissues including amputated caudal fin rays and cryo-injured hearts and skeletal muscle. We have already used single-cell RNA-seq of regenerating caudal fins at various time to show that multiple cell types undergo major shifts in their global gene expression patterns during fin regeneration. We are currently studying the epigenetic changes taking place in regenerating cells using the expression of the EpiTag reporter as a marker to highly enrich for actively reprogramming cells at the very earliest stages of regeneration. The ability to isolate and study these cells opens the door to important insights into the role of epigenetic reprogramming within the broader context of regenerative processes.

1429V **Targeting Regulatory Factors Associated with the *Drosophila Myc cis*-Regulatory Modules (Myc-CRMs) by Reporter Activity Study, Gel Shift Assay, and Mass Spectrometric (MS) Analysis** Jasmine Kharazmi[1], Cameron Moshfegh[2], Thomas Brody[3] [1]Reproductive Endocrinology, [2]Department of Health Sciences and Technology, ETH Zurich, Laboratory of Applied Mechanobiology, [3]National Institutes of Health (NIH)

Transcription factor MYC is highly responsive to mitogenic stimuli to modulate the expression of several targets involved in cell growth, protein biogenesis, proliferation, and differentiation. However, the regulation of MYC at the level of transcription is still incompletely understood. In previous work, we showed that most of the regulatory elements associated with *Drosophila Myc* are located within the 5’ UTR and the intergenic regions of *Myc*. In this study, we developed a highly sensitive and selective Solid Surface Magnetic Enrichment Protocol (SSMEP) and used it to enrich DNA-Protein complexes compounded with the *Myc cis*-elements. Using smaller truncations, Electrophoretic-Mobility Shift Assay (EMSA) and protein identification by Mass Spec, we identified a cis-regulatory module (CRM) within the proximal 5’-UTR that might be sufficient to activate lacZ reporter in the ovary and embryos. Furthermore, each of the CRMs from the upstream or In2 region in conjunction with the proximal 5’-UTR regulatory unit recapitulates the missing expression in the larval tissues, the ovary, and in embryos. Finally, the Downstream Promoter Element (DPE) shows promoter activity and mimics the *Myc* wild type expression when the adjacent cluster of binding sites is fused to in, in frame to it. *In vivo* functionality tests can be conducted to confirm the relevance of associated factors and identified signaling cascades as *Myc* regulators. In addition, the highly selective and sensitive protocol can be used for other model organisms and biomedical research projects and/or synthetic biological studies.

1430V **Interplay between the Bithorax complex and Wnt signaling in regulating lipid homeostasis in *Drosophila*** Rajitha Udakara Sampath Hemba-Waduge[1], Mengmeng Liu[1], Xiao Li[2], Jasmine Sun[1], Elisabeth Budslick[1], Jun-Yuan Ji[1] [1]Biochemistry and Molecular Biology, Tulane University School of Medicine, [2]Lewis-Sigler Institute of Integrative Genomics, Princeton University

Adipocytes are distributed throughout the human body, playing critical roles in lipid metabolism and energy homeostasis. Notably, excessive visceral fat in the abdominal cavity poses a higher risk of diseases such as diabetes, cardiovascular diseases, and various cancers compared to subcutaneous fat elsewhere. However, the mechanisms governing the regional differences of adipocytes remain poorly understood. Using *Drosophila* as a model organism, we discovered a novel connection between the bithorax complex (BX-C) and the Wingless/Wnt signaling pathway in regulating the regional heterogeneity in larval adipose tissue. The *Drosophila* BX-C comprises three homeotic genes - *Ultrabithorax* (*Ubx*), *abdominal A* (*abd-A*), and *Abdominal B* (*Abd-B*). While the BX-C proteins are known for their roles in regulating the embryonic segmental body

plan, their functions in larval adipocytes have been unexplored. Our research has revealed a distinct heterogeneity between larval adipocytes in the abdominal and thoracic regions, with additional heterogeneity within abdominal adipocytes. We have observed that *abd-A* and *Abd-B* are predominantly expressed in the abdominal adipocytes, exhibiting heterogeneous expression patterns among these adipocytes. Depleting BX-C genes in larval adipocytes resulted in reduced fat accumulation, delayed larval-pupal transition, and ultimately pupal lethality. Furthermore, active Wnt signaling amplified this adipocyte heterogeneity, while depletion of either Abd-A or Abd-B reduced the Wnt-activated gene expression and mitigated the adipocyte heterogeneity induced by active Wnt signaling. These findings highlight the intricate interplay between the BX-C proteins and Wnt signaling in defining adipocyte heterogeneity and regulating lipid homeostasis in *Drosophila*.

1431V **Utilizing Live Cell Imaging in Drosophila melanogaster Salivary Glands to Determine if Resveratrol Treatment Activates Heat Shock Factor DNA Binding** Martin Buckley[1], Tyra Skalos[1], Nichole Webb[1], Stacy Hrizo[2] [1]Slippery Rock University of Pennsylvania, [2]Biology, Slippery Rock University of Pennsylvania

One major stress response pathway is the heat shock response (HSR), which is mediated by the transcription factor, heat shock factor (HSF). The HSR is activated in cells exposed to conditions that induce protein misfolding, such as: high heat, oxidants, and other chemical stresses. Under such stressors, HSF activates expression of the Hsp70 chaperone, which helps cells deal with protein folding stress. However, HSR activation also leads to an increase in reactive oxygen species (ROS), which can damage cellular molecules. To combat this, cells are known to utilize endogenous antioxidants to scavenge free radicals through redox reactions. Therefore, we previously examined the effect of feeding an exogenous antioxidant, resveratrol, on the ability of wildtype Drosophila to withstand heat stress. Treatment with 100uM and 400uM resveratrol increased the ability of the flies to withstand heat stress-induced paralysis. We hypothesize that this result occurred because the flies had increased HSF activity due to the resveratrol treatment. To examine this hypothesis, Drosophila larvae expressing HSF-GFP were dissected to obtain salivary glands. These glands contain large polytene chromosomes that allow for visualization of HSF chromosomal binding using confocal microscopy. The most easily visible binding site is an HSF doublet binding at the Hsp70 loci. Salivary glands at room temperature function as a non-heat shock (NHS) control and exhibit no binding of HSF-GFP at the Hsp70 loci. Salivary glands heated to 37C for 10, 20, 40 minutes function as the positive control and exhibit the expected Hsp70 doublet from HSF-GFP binding of the DNA. We are testing variable concentrations (100uM, 200uM, and 400uM) of resveratrol dissolved in 0.5% DMSO to determine if it activates HSF-GFP binding of the DNA in salivary glands under non-heat shock conditions. Our preliminary data indicates resveratrol treatment does not lead to the recruitment of HSF at HSP70 loci in living polytene nuclei. Follow-up experiments are currently underway to examine the levels of Hsp70 protein in cells treated with resveratrol.

1432V **Neuroprotective Potential of Hydroalcoholic Extract of Centella asiatica Against 3-Nitropropionic Acid-Induced Huntington's Like Symptoms in Adult Zebrafish** Nitasha Rana Pharmacology, ISF College of Pharmacy, Moga

Huntington's disease (HD) is an inherited neurodegenerative disease. 3-Nitropropionic acid (3-NP) causes increased reactive oxygen species production and neuroinflammation. Centella asiatica (CA) is a strong antioxidant. The aim of this study is to investigate the effect of hydroalcoholic extract of C. asiatica (HA-CA) on 3-NP-induced HD in adult zebrafish. Adult zebrafish (*5–6 months old) weighing 470 to 530 mg was used and treated with 3-NP (5 mg/kg intraperitoneal [i.p.]). The animals received HA-CA (80 and 100 mg/L) daily for up to 28 days in water. Tetrabenazine (3 mg/kg i.p.) was used as a standard drug. We have done an open field test (for locomotor activity), a novel tank diving test (for anxiety), and a light and dark tank test (for memory), followed by biochemical analysis (acetyl-cholinesterase [AchEs], nitrite, lipid peroxidation [LPO], and glutathione [GSH]) and histopathology to further confirm memory dysfunctions. 3-NP-treated zebrafish exhibit reductions in body weight, progressive neuronal damage, cognition, and locomotor activity. The HA-CA group significantly reduced the 3-NP-induced increase in LPO, AchEs, and nitrite levels while decreasing GSH levels. Oral administration of HA-CA (80 or 100 mg/L) significantly reduces 3-NP-induced changes in body weight and behavior, in addition to neuroinflammation in the brain by lowering tumor necrosis factor-a and interleukin-1b levels. Moreover, HA-CA significantly decreases the 3-NP-induced neuronal damage in the brain. HA-CA ameliorates neurotoxicity and neurobehavioral deficits in 3-NP-induced HD-like symptoms in adult zebrafish.

1433V ***puf-9* promotes clearance of miR-35-41 microRNAs and somatic sex determination in *C. elegans*** Amelia F Alessi[1], Danny Yang[2], Mallory A Freeberg[2], Margaret R Starostik[1], John K Kim[1] [1]Biology, Johns Hopkins, [2]University of Michigan - Ann Arbor

MicroRNAs (miRNAs) are a conserved group of ~21nt RNAs that regulate post-transcriptional gene expression. MiRNA regulation is essential for diverse biological processes including differentiation and development, stress response, behavior and longevity. Dysregulation of the miRNA pathway has been linked to cancer and cardiovascular and metabolic disorders. Thus, understanding how miRNAs are regulated is critical to fully understanding their function. In *C. elegans,* the miR-35-42

family (miR-35Fam) is required for somatic sex determination (SSD), viability and fertility. miR-35Fam is highly expressed in the early embryo, where it regulates SSD by preventing precocious expression of *sup-26* and *nhl-2* (McJunkin 2014 *G3;* McJunkin 2017 *G&D).* Later in embryogenesis, the miR-35Fam is rapidly cleared by an incompletely understood mechanism. To explore regulation of miR-35Fam, we performed a targeted RNAi screen and assessed miR-35 levels in the 1st larval stage (L1d). We identified *puf-9* as a positive regulator of miR-35Fam clearance. Mutant analysis confirmed *puf-9(-)* have ~10-fold more miR-35 in L1d than wild-type. Additionally, *puf-9(-)* have enhanced SSD defects in *her-1(n695)* gain-of-function animals, indicating that *puf-9* promotes SSD. *her-1* mRNA is also ~2.5 fold upregulated in *puf-9(-)* in conjunction with ~8 fold upregulation of *mir-35-41*-dependent pseudomale genes. PUF-9 is part of the conserved Pumilio/FBF RBP family that regulates mRNAs by translational repression/degradation. To determine how *puf-9* promotes miR-35Fam clearance and SSD, we identified mRNAs bound by PUF-9 in embryo and L1d. Like other PUF proteins, PUF-9 preferentially binds the 3'UTR of mRNAs at UGUA-containing motifs, including *sup-26* and *nhl-2*. Thus far, we have established that *sup-26* and *nhl-2* are both required for *puf-9*-dependent miR-35 clearance and SSD genetic and molecular defects. Interestingly, *puf-9(-)* exhibit only modest upregulation of *sup-26* or *nhl-2* mRNA levels, suggesting that PUF-9 may regulate *sup-26* and/or *nhl-2* via translational repression. We are currently investigating if SUP-26 and NHL-2 protein levels are altered in *puf-9(-)* and whether PUF-9 directly regulates *sup-26* and *nhl-2* via our identified binding sites. Taken together, we propose that PUF-9 and the miR-35Fam co-regulate *sup-26* and *nhl-2* to ensure robust timing of an essential embryonic developmental program and that *puf-9* promotes miR-35Fam clearance through a target-dependent feedback mechanism.

1434V **The loss of SWI/SNF factor ARID1A leads to a cold tumor phenotype via suppression of IFN-g in neuroblastoma** Pamela Watson, Chelsea DeVaux, Kevin Freeman Genetics, Genomics, Informatics, University of Tennessee Health Science Center

Neuroblastoma (NB) is a highly aggressive, heterogeneous disease that arises from the sympathetic nervous system (SNS) and originates from neural crest cells (NCCs). NB is the most common extracranial cancer in pediatric patients, also accounting for 15% of the total number of pediatric cancer deaths. This high mortality rate is the result of the metastatic, immune evasive, and treatment resistant characteristics of the disease, as well as its heterogenous nature. It has been proposed that NB arises from blocks in differentiation during development, resulting in a mixture of two distinct cell types within the tumor: mesenchymal and adrenergic. The adrenergic cell type is more differentiated, and patients that exhibit more of this cell type have greater treatment success. The mesenchymal cell type is more stem like and is associated with the metastatic, immune evasive, and treatment resistant traits of NB. Because NB is considered a disease of development, many therapeutic strategies targeting differentiation exist for patients. Our work is currently focused on interrogating how the loss of ARID1A, a component of SWI/SNF, affects neuroblastoma's (NB) oncogenesis, its contribution to the heterogeneous cell populations in NB, and the immune evasive effects of the mesenchymal cell type.

Recent data reported that ARID1A has a role in initiating inflammatory signaling in adult cancers by opening areas of chromatin thereby enabling the transcription of Th1 signaling genes, but this immune impairment has not been sufficiently investigated in NB. NB is considered a cold tumor, a designation characterized by a lack of infiltrating CD8+ T cells in the tumor microenvironment, low MHC-I expression, and lack of tumor antigens. All the cold tumor characteristics further decrease therapeutic options for patients, and the few options that are available can lead to severe toxicities and adverse events. All of this suggests that differentiation of the immature, mesenchymal cell types could expand therapeutic options for treatment resistant cells including immunotherapy options in the future. Previously, the Freeman lab established that ARID1A loss, not MYCN amplification, is the root cause for immaturity in NB; we now want to establish ARID1A loss as a key factor for the cold tumor type in NB. Thus, we will interrogate the role of ARID1A in inflammatory signaling and immune infiltration as well as the effects of its loss within NB.

1435T **Identifying suppressors of stress-induced neurodegeneration in a *C. elegans* knock-in *sod-1 G85R* ALS model** Mika Gallati[1], Katherine S. Yanagi[2], Alexander T. Lin-Moore[2], Anne C. Hart[2] [1]Neuroscience, Brown University, [2]Brown University

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease mainly affecting cholinergic and glutamatergic motor neurons. Despite the discovery of several causal mutations in key genes, convergent cellular processes of ALS-associated neurodegeneration have still not been identified. Therefore, determining genetic modifiers of neurodegeneration in SOD1 ALS models can give insight into the mechanisms of ALS-associated neurodegeneration. Previously, the Hart lab generated a single-copy knock-in model of SOD1 G85R, a causative allele of ALS, in the model nematode *C. elegans*. Introduction of SOD1 G85R leads to specific degeneration of glutamatergic and cholinergic neurons following exposure to oxidative stress (PMID: 30296255). With this model, we performed a forward genetic screen to identify suppressors of neurodegeneration by exposing the *sod-1 G85R* model to ethyl methyl sulfonate (EMS). Lines were screened by assessing the suppression of neurodegeneration in glutamatergic tail neurons (12,586 haploid chromosomes screened). Lines showing suppression were isolated, ranging from slight decreases in degeneration to near-complete rescue. I have backcrossed the three lines with

the strongest suppression to diminish the number of background mutations caused by EMS and to create sibling lines that do not contain the causal mutation. I sent these lines for whole genome sequencing to identify causal mutations via the sibling subtraction method (PMID: 29237702). Through the use of MiModD, I garnered a list of possible causal mutations by subtracting mutations detected in sibling lines from those in the suppressor lines. This analysis pipeline is currently being implemented for additional suppressor lines identified from the screen. Identification of these suppressor genes may improve our understanding of the mechanisms underlying ALS and potentially inform the development of future treatments.

1436T **Inducible deletion of the *Caenorhabditis elegans* Alzheimer's-related gene *apl-1* demonstrates temporal restriction of essential functions** Megan J Moerdyk-Schauwecker, Christine Sedore, Zachary Munoz, Erik Segerdell, John Willis, Patrick Phillips University of Oregon

Aggregation of amyloid beta, a peptide derived from amyloid precursor protein (APP) is a diagnostic feature of Alzheimer's disease. However, while the role of the APP family of proteins - which is evolutionarily conserved across a number of vertebrates and invertebrates - is established in development, their non-pathogenic functions post-development are less clear. *Caenorhabditis elegans* has a single member of the APP family, *apl-1*. Since *apl-1* is developmentally required in *C. elegans*, we developed a conditional gene deletion system to study post-developmental function. The native *apl-1* gene was replaced with a cassette containing *apl-1* flanked by lox sites as well as a fluorescent reporter system that allowed *apl-1* removal - triggered by inducible expression of Cre - to be monitored at the level of individual cells based on a green-red fluorescent shift. We also took advantage of the ability of Cre fragments to self-assemble to delete *apl-1* in both a temporal and tissue specific manner, albeit with lower efficiency. A similar system could also be employed for the conditional deletion of other genes. While we were able to recapitulate the embryonic lethality phenotype in our system, early life deletion of *apl-1* did not reduce lifespan in *C. elegans*. Furthermore, while whole worm RNA-seq confirmed knock-down of *apl-1* transcripts, expression of all other genes was unchanged. Thus *apl-1* appears unnecessary, or at least required at much lower than typical physiological levels, for normal function in post-developmental *C. elegans*.

1437T **Mutation in F-actin polymerization factor suppresses Distal Arthrogryposis Type 5 (DA5) PIEZO2 pathogenic variant in *Caenorhabditis elegans*** Xiaofei Bai[1], Harold E. Smith[2], Valeria Vasquez[3], Luis O Romero[4], Briar Bell[4], Andy Golden[2] [1]Biology, University of Florida, [2]National Institutes of Health, [3]Biochemistry and Molecular Biology, Center for Membrane Biology, the University of Texas Health Science Center at Houston McGovern Medical School, [4]Center for Membrane Biology, the University of Texas Health Science Center at Houston McGovern Medical School

The mechanosensitive PIEZO channel family has been linked to over 26 disorders and diseases. Although progress has been made in understanding these channels at the structural and functional levels, the underlying mechanisms of PIEZO-associated diseases remain elusive. In this study, we engineered four PIEZO-based disease models using CRISPR/Cas9 gene editing. We performed an unbiased chemical mutagen-based genetic suppressor screen to identify putative suppressors of a conserved gain-of-function variant *pezo-1[R2405P]* that in human *PIEZO2* causes distal arthrogryposis type 5 (DA5; p. R2718P). Electrophysiological analyses indicate that *pezo-1(R2405P)* is a gain-of-function allele. Using genomic mapping and whole-genome sequencing approaches, we identified a candidate suppressor allele in the *C. elegans* gene *gex-3.* This gene is an ortholog of human *NCKAP1*(NCK-associated protein 1), a subunit of the Wiskott-Aldrich syndrome protein (WASP)-verprolin homologous protein (WAVE/SCAR) complex, which regulates F-actin polymerization. Depletion of *gex-3* by RNAi, or with the suppressor allele *gex-3(av259[L353F])*, significantly restored the small brood size and low ovulation rate, as well as alleviated the crushed oocyte phenotype of the *pezo-1(R2405P)* mutant. Auxin-inducible degradation of GEX-3 revealed that only somatic-specific degradation of GEX-3 restored the reduced brood size in the *pezo-1(R2405P)* mutants*.* Additionally, actin organization and orientation were disrupted and distorted in the *pezo-1* mutants. Mutation of *gex-3(L353F)* partially alleviated these defects. The identification of *gex-3* as a suppressor of the pathogenic variant *pezo-1(R2405P)* suggests that the cytoskeleton plays an important role in regulating PIEZO channel activity and provides insight into the molecular mechanisms of DA5 and other PIEZO-associated diseases.

1438T **Age-related changes in the morphology of a single-cell stem cell niche** Nilay Gupta[1], E. Jane Albert Hubbard[2] [1]Developmental Genetics, NYU Department of Biology, [2]Cell Biology, NYU Grossman School of Medicine

Morphological characteristics of cells often correspond to specific functions. Cells that participate in direct cell-cell contact and contact-dependent intercellular signaling may be especially reliant on their morphology. Age-dependent alterations in cell shape could conceivably lead to pathologies resulting from impaired function and/or signaling. How organismal age impacts cell morphology is not well understood. To understand how aging affects cell morphology, we are studying the distal tip cell (DTC) in the adult *C. elegans* hermaphrodite. The DTC produces membrane-bound ligands for the germline-expressed Notch receptor, GLP-1, the activity of which specifies germline stem cell fate. The adult hermaphrodite DTC has a complex cellular morphology that includes long proximally-extending processes (Byrd *et al.*, 2014). Previous work indicated that the germline

stem cell pool becomes depleted with age (Qin and Hubbard, 2015; Kocsisova *et al.*, 2019), and that *daf-2* (insulin/IGF-like receptor) mutants resist this depletion in a manner dependent on the DAF-16 (FOXO) transcription factor and on germline flux. Qin and Hubbard (2015) also showed that *daf-16* activity is required germ cell non-autonomously in the proximal somatic gonad to control the adult progenitor pool with age, distinct from its role in regulating lifespan. Here, using live imaging of the DTC, we show that three distinct DTC morphology parameters radically change with age. Surprisingly, we find that these parameters are differentially responsive to changes in *daf-2* and *daf-16* activity: nuclear displacement is independent of *daf-2*, the number of long processes is sensitive to *daf-2* but not to *daf-16*, and the length of processes is sensitive to both *daf-2* and to *daf-16*. Further, our results suggest that *daf-16* regulates DTC morphology non-autonomously from the muscle, a tissue requirement that is distinct from the influence of *daf-16* on the aging germline stem/progenitor pool and distinct from its influence on longevity. Our results offer a new model for the effects of aging on cell morphology, demonstrate *daf-2*-dependent and -independent aspects of aging cellular morphology, identify the muscle as a source of *daf-16*-dependent regulation of aging DTC morphology, and underscore the necessity to understand the regulation of age-dependent changes in cell morphology at the level of the whole organism.

1439T **Systematic creation and rapid phenotyping of Mendelian disease models in *C. elegans*: towards large-scale high-throughput drug repurposing** Thomas J O›Brien[1,2], Andre EX Brown[1,2] [1]Faculty of Medicine, Imperial College London, [2]MRC Laboratory of Medical Sciences

The goal of precision medicine is to tailor treatments for individuals based upon genomic sequencing data. Advancements in genome sequencing mean new Mendelian diseases are constantly discovered, however the majority of genetic disorders have no approved treatments. This is particularly true for rare disorders, where the identification of a genetic lesion may not lead to a candidate target because the cause is a complete loss of function of the causal gene or there is little understanding of the genetic pathways implicated. To address this need, we require scalable approaches that are relatively inexpensive compared to traditional drug development. In the absence of a validated drug target, phenotypic screening in model organisms provides a route for identifying candidate treatments. Success requires a screenable phenotype, however the right phenotype and assay may not be obvious for pleiotropic neuromuscular disorders.

We have developed tracking technologies capable of measuring changes in behaviour as the result of genetic mutation, or treatment with small molecules/metabolites. To test the power of our approach in treating human genetic disorders, we generated a panel of *C. elegans* strains containing mutations orthologous to those associated with rare human neuromuscular disorders. These strains represent patient-specific 'avatars' of rare genetic disease. Despite some mutations causing phenotypes imperceptible to the naked eye, they are captured by quantitative phenomics. The resulting 'behavioural fingerprints' provide a high-content view of multidimensional phenomic space for individual genetic disorders. With these, we have performed high-throughput screens of drug libraries and identified novel repurposing candidates with the potential to treat rare genetic disorders with no prior knowledge of the molecular basis of disease.

Our results show how a single assay, measuring multiple phenotypes, can be applied systematically to diverse Mendelian disease models. The relatively short time and low cost associated with creating and phenotyping multiple strains suggests that high-throughput worm tracking could provide a scalable approach to drug repurposing commensurate with large numbers of Mendelian diseases. Ultimately, this work will enable the development of a high-throughput precision medicine platform to identify candidate compounds for the treatment of many genetic disorders, using an individual's personalised *C. elegans* disease-model avatar.

1440T ***Stenotrophomonas indicatrix* promotes innate immune response against intracellular pathogens in *Caenorhabditis elegans*** Jordan D West, Samuel Li, Vladimir Lazetic Biological Sciences, The George Washington University

How do changes in intestinal microbiome affect innate immunity in *Caenorhabditis elegans*? To answer this question, we are studying the Intracellular Pathogen Response (IPR), which is a robust transcriptional response that protects *C. elegans* against obligate intracellular pathogens such as the Orsay virus and fungus *Nematocida parisii*. The IPR is activated upon infection and involves the upregulation of about 80 genes, some of which encode Cullin-RING ubiquitin ligase components. In this study, we performed a screen using different bacterial species isolated from the natural habitats of *C. elegans* and tested if any of them could induce the IPR in the absence of infection. We found that *Stenotrophomonas indicatrix* (JUb19) significantly enhanced the expression of the IPR reporter, *pals-5*p::GFP, when compared to the standard bacterial food source *Escherichia coli* (OP50). Our data indicate that the presence of alive JUb19 is necessary for IPR induction, as heat inactivation of bacteria suppressed the phenotype. Following JUb19 treatment, the expression of *pals-5*p::GFP reporter was observed in many tissues including the intestine, epidermis, and neurons, as well as several tissues where it had not been reported before – coelomocytes and somatic gonad. Our findings suggest that JUb19 treatment leads to a developmental delay which is a phenotype that has been previously associated with constitutive IPR activation. Animals fed with JUb19 also displayed lower infection levels than OP50-

fed animals, indicating that JUb19 protects against intracellular pathogens. In summary, our findings establish JUb19 as the first bacterial species that can induce the IPR in *C. elegans*.

1441T **Synthetic multivulva (SynMuv) genes and mes-4 antagonistically regulate the Intracellular Pathogen Response (IPR) in Caenorhabditis elegans** Samuel Li[1], Eillen Tecle[2], Theresa Bui[2], Michael J Blanchard[2], Emily R Troemel[2], Vladimir Lazetic[1,2] [1]Biological Sciences, The George Washington University, [2]Cell and Developmental Biology, University of California, San Diego

How do non-professional immune cells of the nematode Caenorhabditis elegans respond to natural intracellular pathogens? To answer this question, we are studying the Intracellular Pathogen Response (IPR) – a transcriptional response in C. elegans, that is activated by two molecularly distinct pathogens: Orsay virus and microsporidia Nematocida parisii. The IPR consists of 80 highly upregulated genes, including those encoding cullin-RING ubiquitin ligase components. Previous studies have shown that constitutive activation of the IPR protects against intracellular pathogens and improves proteostasis. Induction of the IPR also shares several similarities with the type-I interferon response in mammals. Through two independent forward genetic screens, we identified a member of the synthetic multivulva (SynMuv) family, lin-15b, as a negative regulator of the IPR. lin-15b, in conjunction with other SynMuv genes, are known regulators of development in C. elegans. Here, we found that loss of lin-15b causes constitutive expression of the fluorescent IPR reporter, upregulation of IPR genes, and resistance to N. parisii infection in the intestine. In a subsequent RNAi screen, we found that many other SynMuv genes, including components of DRM, NuRD, and SUMOylation complexes, control the IPR reporter expression. Finally, we found that IPR upregulation in lin-15b mutants is dependent on histone methyltransferase MES-4, which is a critical regulator of chromatin remodeling in embryonic and germline tissues. Previous studies have demonstrated opposing functions of some SynMuv genes and mes-4 in transcriptional regulation and chromatin remodeling during embryonic development. Our study suggests that antagonism between SynMuv genes and mes-4 is not restricted to embryonic development and that it plays an important role in regulating intestinal immune responses in C. elegans.

1442T **Impact of Stress on the Notch Signaling Pathway in *C. elegans*** Amy Hebert, Ismael Curiel Elmhurst University

At one point or another, we have all felt the strain that stems from stress, whether it be school, work, or other life stressors. There can be many physiological impacts such as long-term stress leading to neuron death in the hippocampus which could result in a decreased learning and memory. Utilizing *C. elegans* as a model organism, we assessed the impacts of temperature stress on learning and memory. Previous work in our lab has shown that temperature stress exposure (28°C) for 3 days during development leads to a significant reduction in learning and memory as measured by a chemotaxis assay. In this current work, we are aiming explore potential mechanisms for this reduction and are looking into the Notch signaling pathway that our previous work has shown is significantly impacted, along with learning and memory, in *C. elegans* when exposed to inflammatory cytokines. *C. elegans* that are GFP-tagged at adm-4, a key regulator of the Notch1 signaling pathway, were age matched and exposed to 28°C stress for 3 days before being analyzed for average fluorescence at the nerve ring. Change in average fluorescence allows us to gain an understanding of the impact that stress has on the regulation of the Notch signaling pathway and how this could be contributing to declines in learning and memory that are seen during neurodegenerative diseases such as Alzheimer's disease.

1443T ***Caenorhabditis* Intervention Testing Program: Updates on robust longevity effects of novel compounds in genetically diverse nematodes** Monica Driscoll[1], Christine Sedore[2], Anna Coleman-Hulbert[2], Erik Johnson[2], Erik Segerdell[2], Brian Onken[1], David Hall[3], Theresa FitzGibbon[3], Yuhua Song[1], Madhuri Achanta[1], Anna Foluger[3], Mustafa Sheikh[3], Stephen Banse[2], Gordon Lithgow[3], Partick Phillips[2] [1]Rutgers, The State University of New Jersey, [2]University of Oregon, [3]Buck Institute for Research on Aging

Many efficacious interventions that promote mouse longevity (sirtuins, TOR, insulin signaling) have identification roots in invertebrate genetics. The *Caenorhabditis* Intervention Testing Program (CITP) was charged by the National Institute on Aging to evaluate pharmacological interventions that promote healthy aging in a robust and reproducible manner across diverse genetic backgrounds of natural variant *Caenorhabditi*s strains. The central premise of the CITP effort is that compounds that have strong effects across diverse genetic backgrounds should have enhanced probability of translatability into pre-clinical research. Indeed, some CITP-verified compounds have been shown to promote healthspan and longevity in mouse models, in support of this fundamental premise.

Our current effort includes pursuing compound submissions from the larger scientific community of researchers on aging biology, as well as identification of candidates via high-throughput screening of chemical libraries and data mining of peer-reviewed publications. We now evaluate whole-organism RNA sequence data to estimate the mode of action for successful interventions, and conduct mortality analysis from a generalized family of distributions on high-resolution automated lifespan

data to determine whether a given intervention changes the rate or onset of aging. We are also creating multi-species “at risk” test sets, in which components of aging hallmarks (such as proteostasis, stress response circuits) are genetically compromised in diverse genetic backgrounds. Such genetic test sets might expand understanding of intervention action and help rank compounds for translational testing.

Recent promising CITP longevity interventions include a small molecule, a proprietary compound, an isothiocyanate and a vitamin derivative. In addition, we find that metabolic modulator Metformin and anti-amyloid Thioflavin T, which promote longevity and healthspan in multiple test CITP strains, can positively impact lifespan in diverse genetic backgrounds in which proteostasis is compromised, suggesting wide-ranging health benefits of these potent pro-longevity compounds. We will present on the breaking compound successes.

1444T **The impact of over-supplementation with folic acid after hypoxia in *Drosophila melanogaster*** Siddarth Gunnala[1], Alisha Harrison[2], Amber Juba[2], Paula Ashcraft[3], Teodoro Bottiglieri[3], Lori M Buhlman[2,2], Nafisa M Jadavji[1] [1]Biomedical Sciences, Midwestern University, [2]Midwestern University, [3]Baylor Scott and White Research Institute

Hypoxia is a major component of ischemic stroke, which is known for its disabling prognosis. Nutrition is a risk factor for the onset of ischemic stroke, as well as outcomes after a stroke. Our previous work, along with other published literature has shown the positive impact that folic acid supplementation can have after ischemic stroke. Folic acid is a water-soluble B-complex vitamin (B9) involved in nucleic acid synthesis, methylation, and DNA repair. It plays a central role in one-carbon (1C) metabolism, which is a metabolic network that integrates nutritional signals with biosynthesis, redox homeostasis, and epigenetics. Recently, over-supplementation of folic acid has become a problem in many countries with mandatory food fortification laws in place to reduce the prevalence of neural tube defects. However, the impact of over-supplementation of folic acid on brain injury is not well understood. The aim of our study was to investigate how folic acid over-supplementation impacts hypoxia outcome using *Drosophila melanogaste*r as a model. We maintained w1118 male and female flies on control and 100µM folic acid supplemented diets. Progeny from these parents were exposed to hypoxia (1% oxygen) for a period of two hours after which flies were returned to normoxic conditions to model reperfusion. Using liquid chromatography-tandem mass spectrometry, folic acid and tetrahydrofolate levels were elevated in supplemented flies. We confirmed that flies were exposed to hypoxia by measuring escape latency of larvae from food in vials. The survival rate of flies was recorded after hypoxia treatment for 90 days. In a separate group of flies 24 hours after hypoxia, fly climbing behavior was also measured. This data included the number of movements made and the motivation to climb. We observed that hypoxia treatment increased the number of dead flies over the span of their lifetime in both the control and folic acid supplemented diet (FASD) groups. Furthermore, we observed a reduction in the motivation to fly in control and FASD exposed to hypoxia. We are currently investigating apoptosis in brain tissue of flies to determine potential mechanisms. Preliminary data suggests that folic acid over-supplementation does not exacerbate negative health outcomes after hypoxia using the *Drosophila melanogaster* model.

1445T **Downregulation of Pten suppresses the Huntington’s disease in Drosophila model** Maynglambam Dhruba Singh[1], Nisha Vishwakarma[2], Bhavya Gohil[2] [1]National Brain Research Centre, [2]NBRC

Huntington’s disease (HD) is a dominantly inherited progressive neurodegenerative disorder that affects 3.92 per 100,000 individuals worldwide. The disease is caused by the expansion of CAG repeat in the coding region of Huntingtin gene (HTT). The expanded poly(Q) repeats have propensity to aggerate which induces neuronal cell death. The non-pathogenic CAG repeat length in normal people ranges from 10-35. However, repeats length above 40 is pathogenic and increase in repeat length is inversely correlated with the onset of the disease. Studies have shown that insulin signaling is altered and insulin resistance is induced by mutant Htt protein. We downregulated Downstream of Insulin receptor, Phosphatase and tensin homolog (Pten), in mutant Htt expressing fly model and observed that Pten significantly reduced the HD phenotypes. In the Drosophila eye, knockdown of Pten improved the rough eye phenotype caused by mutant Htt with 138 poly(Q) repeats. The retinal length and photoreceptor neurons were significantly improved. The degeneration of brain neuronal structure in the brain was improved by knockdown of Pten. Knockdown of Pten also improved the integrity of neuromuscular junction (NMJ) in dorso-lateral muscles. In addition, knockdown of Pten significantly improved the functional vision and climbing ability which are affected by mutant Htt138Q. Furthermore, we observed the Knockdown of Pten significantly reduced the number of poly(Q) aggregates in the larval eye disc and antennal lobe of the brain. Moreover, Pten knockdown reduced the level of apoptosis in the larval and pupal eye disc. Our study highlight that Pten is a genetic modifier of Huntington’s disease with potential therapeutic application.

1446T **The structure of human Orc6 protein – humanized Drosophila model of the Meyer-Gorlin syndrome** Maxim Balasov[1], Katarina Akhmetova[1], Guang Zhu[1], Igor Chesnokov[2] [1]University of Alabama at Birmingham, [2]Biochemistry and Molecular Genetics, University of Alabama at Birmingham

Orc6 is an important component of the Origin Recognition Complex (ORC) and has functions in both DNA replication and cytokinesis. We solved a solution structure of the full length human Orc6 alone and in a complex with DNA by NMR methods. We have shown that in eukaryotes, Orc6 has a homology with transcription factor TFIIB. The detailed analysis of the structure revealed amino acid clusters important for DNA binding. We further showed that human Orc6 is composed of three independent domains: N-terminal, middle and C-terminal. A mutation in the conserved C-terminal motif of Orc6 impedes the interaction of Orc6 with core ORC and results in Meier-Gorlin syndrome (MGS). MGS is a rare autosomal recessive disorder characterized by microtia, primordial dwarfism, small ears, and skeletal abnormalities. Patients with MGS often carry mutations in genes encoding the subunits of ORC, components of the pre-replicative complex (pre-RC) and replication machinery. Recently, additional MGS mutations in Orc6 were identified. One mutation is localized in the N-terminal domain of the protein. Another is a compound heterozygous mutation that includes a deletion of 20 amino acids from the N-terminus as well as a mutation within a splice site of the gene potentially resulting in a short deletion in the middle of the protein. Based on the structural information we created a hybrid human-*Drosophila* gene to rescue the *orc6* deletion in *Drosophila* and to study the functions of the protein in a living organism. Using this "humanized" *Drosophila* model of the Meier-Gorlin syndrome we discovered the molecular mechanisms underlying the observed MGS phenotypes. Our studies revealed the importance of evolutionarily conserved and variable domains of Orc6 protein and allowed the studies of human protein functions and the analysis of the critical amino acids in live animal heterologous system. We are expanding these studies to address the importance of Orc6 C-terminal motifs for its interaction with core ORC. We identified a structured motif in the Orc6 C-terminal domain which defines the dynamics of inter-subunit interactions within metazoan ORC. These studies suggest the molecular mechanism for the association of Orc6 with the core ORC in flies and humans.

1447T **An *in vivo* screen identifies small molecule modulators of the endoplasmic reticulum stress response** Emily Coelho, Katherine Beebe, Kevin A. Hope, Alexys R. Berman, Heather D. Evans, Clement Y. Chow University of Utah

Misfolded protein accumulation in the endoplasmic reticulum (ER) induces ER stress. Cells respond to ER stress by initiating the unfolded protein response (UPR) that upregulates chaperone protein expression, increases the degradation of misfolded proteins, and inhibits protein translation. Failure to effectively manage ER stress and restore homeostasis results in cellular dysfunction and ultimately apoptosis, a process implicated in numerous human diseases such as retinal degeneration, Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS), among others. Identifying small molecules that modulate ER stress may be effective therapeutics for human diseases caused by misfolded protein accumulation. Here, we used a *Drosophila* model of retinitis pigmentosa (RP) that expresses misfolded rhodopsin protein, $Rh1^{G69D}$, in the developing eye. $Rh1^{G69D}$ expression induces chronic ER stress and apoptosis, resulting in a degenerative eye phenotype. We took a drug repurposing approach and used the Prestwick Chemical Library, consisting of 1520 small molecules, the majority of which are FDA-approved, to identify compounds that modulate neuron cell death in $Rh1^{G69D}$ expressing flies. We identified multiple classes of drugs that enhance or suppress the degenerative eye phenotype, including compounds acting through monoamine neurotransmitters, folate metabolism, sodium channels, and the renin/angiotensin pathway. Degeneration-enhancing compounds may reveal novel ER stress pathways, while compounds that suppress degeneration are potential therapeutic candidates for RP. We are using an RNAi approach to identify the mechanism of action for the top enhancers and suppressors. Additionally, we will present data showing that compounds that rescue cell death in the RP model can also rescue disease-associated phenotypes in other *Drosophila* models of protein misfolding diseases, such as PD, HD, and ALS. This work identified potential therapeutic drugs for RP and possibly other human diseases that result from misfolded protein accumulation and ER stress.

1448T **Intake of Caffeine Containing Diet Remodels Gut Microbiota and Perturbs *Drosophila melanogaster* Immunity and Lifespan** Abeer Qush Department of Biomedical Sciences, Qatar University

The diet-microbiome-immunity axis is one among the many arms that draw up the "we are what we intake" proclamation. As such, studies on the effect of food and beverage intake on the gut environment and microbiome and on modulating immunological responses and the host's susceptibility to pathogens are on the rise. A typical accompaniment in different sustenance we consume on daily basis is the *trimethylxanthine* alkaloid caffeine. Being a chief component in our regular aliment, a better understanding of the effect of caffeine containing food and beverages on our gut-microbiome-immunity axis and henceforth on our health is much needed. In this study, we shed more light on the effect of oral consumption of caffeine supplemented sugar diet on the gut environment, specifically on the gut microbiota, innate immunity and host susceptibility to pathogens using the *Drosophila melanogaster* model organism. Our findings reveal that the oral intake of a dose-specific caffeine containing sucrose/agarose sugar diet causes a significant alteration within the fly gut milieu demarcated by microbial dysbiosis and an elevation in the production of *reactive oxygen species and* expression of immune-deficiency (Imd) pathway dependent *antimicrobial peptide* genes*. The oral intake of* caffeine containing sucrose/agarose sugar diet *also renders flies more susceptible to bacterial infection and shortens their lifespan in both infection and non-infection settings.* Our findings set

forth additional insight into the potentiality of diet to alter the gut milieu and highlight the importance of dietary control on health.

1449T **A comprehensive assessment of human huntingtin expression in the nervous system of larval and adult *Drosophila*** Tadros A Hana, Andrew H Michael, Veronika G Mousa, Rawan Haj-Hussein, Madona Aziz, Sabita Basnet, Kiel G. Ormerod Biology, Middle Tennessee State University

Huntington's Disease (HD) is an inherited, monogenic disease affecting ~1 / 10000 people yearly. Mutant Huntingtin protein contains a stretch of glutamine repeats that, when expanded, becomes unstable and forms inclusion bodies associated with the pathophysiology of the disease. Using *Drosophila* 3rd instar larvae as well as adults to model pathogenic huntingtin progression through development and into adulthood. We tracked huntingtin aggregate proliferation from eggs every 24 hours and determined a linear progression in the size and number of aggregates in the developing brain, motor axons, and at the neuromuscular junction. This trend of aggregate proliferation was also observed in the pathogenic huntingtin modeled in the adult wing. Interestingly, larval morphology and viability were not impacted. Using live imaging of fluorescently labeled huntingtin, we determined that axonal aggregates significantly impaired trafficking of organelles like synaptic vesicles, mitochondria, and dense core vesicles. To assess the downstream implications, we conducted electrophysiological recordings from muscles using intracellular voltage recordings and muscle force recordings and observed significant impacts on neuromuscular transduction. Larval crawling patterns were significantly impacted, showing impairments in movement speed and total distance traveled. These physiological deficits were also observed in adult flies, with impairments in motor function as well as behavioral manifestations. The lifespan of adults expressing pathogenic huntingtin was reduced by a third. Novel application of mTOR inhibitor Rapamycin shows a significant increase in lifespan, suggesting a mechanism by which autophagy can influence the pathology linked to huntingtin aggregates. Here we have shown significant molecular, cellular, physiological, and behavioral deficits associated with pathogenic human huntingtin expression in the nervous system of Drosophila. Our work serves as a robust model to assess the progression of HD, and as a rigorous tool for potential genetic and therapeutic treatments for HD disease progression.

1450T ***Prominin-like* regulates feeding behavior through the muscle-brain axis in *Drosophila*** Tae Hoon Ryu, Kweon Yu Disease Target Structure Research Center, Korea Institute of Bioscience and Biotechnology

Energy demands from peripheral tissue affects feeding behavior in animals. Although muscle is one of the most energy-consuming organ, less is known whether muscle-derived hormones regulate feeding behavior. Muscle-derived hormones, also known as myokines, are secreted from muscle in response to nutritional stress or exercise to regulate various physiological function. In this study, we found that *prominin-like* (*promL*), the homolog of Prominin-1, is a regulator of myokine in response to carbohydrates intake. Muscle-specific *promL* inhibition resulted in increased carbohydrate intake while protein intake was not changed. ATP level in the muscle of muscle-specific *promL* inhibition flies was reduced, indicating that *promL* regulates energy metabolism in the muscle. Next, we screened mRNA expression level of myokines in the muscle tissue and found PDGF- and VEGF-related factor 3 (Pvf3) as a feeding regulator. When we inhibited the receptor of Pvf3, PDGF- and VEGF-receptor related (Pvr), using various neuronal Gal4 drivers, Pvr inhibition in serotonergic neurons showed increased food intake. We further showed that the 5-HTP, a precursor of serotonin, rescued food intake and choice behavior, suggesting that Pvf3-Pvr signaling regulates food intake and choice by modulating serotonergic system. Taken together, these findings indicate that *promL* expressed in the muscle mediates feeding behavior by regulating myokine and neurotransmitter signaling.

1451T ***Wolbachia* enhances survival of *Drosophila* infected with fungal pathogens** Jessamyn I Perlmutter, Aylar Atadurdyyeva, Margaret E Schedl, Robert L Unckless University of Kansas

Often called "the world's greatest pandemic", *Wolbachia* bacteria of arthropods are the most widespread endosymbionts on the planet. They are found in over half of all insect species and exist on every continent except Antarctica. These bacteria are vertically transmitted from mother to offspring via the cytoplasm much like mitochondria. To ensure faithful inheritance of the symbiont, *Wolbachia* rely on a set of cunning host interactions to enhance the fitness of hosts carrying the symbiont. Crucially, one phenotype is the ability to inhibit viral pathogens when an arthropod host contains certain *Wolbachia* strains. Mosquitoes with the *w*Mel *Wolbachia* strain of *Drosophila melanogaster*, for example, exhibit significantly reduced transmission rates of viruses like dengue and chikungunya to new hosts. Global initiatives have thus far achieved great success in using *Wolbachia* in the wild to reduce mosquito-borne transmission of viral diseases to humans. However, very few studies have focused on *Wolbachia*'s interactions with other microbes such as fungi despite the prevalence of fungal pathogens in the wild. Here, we perform a comprehensive panel of fungal infection assays with *Drosophila melanogaster* flies with or without *Wolbachia* to fill this gap. We find that the symbiont protects hosts against a wide array of filamentous and yeast pathogens of agricultural and medical importance by increasing host longevity post-infection. Notably, the presence and strength of the phenotype is dependent on factors including host genotype, sex, and fungal species. Flies co-infected with *Wolbachia* and fungus have lower pathogen titers and exhibit higher egg-laying, indicating that the mechanism is likely host resistance and that the phenotype

confers a significant fitness benefit. Further, flies with the symbiont have increased expression of key immune genes post-fungal infection relative to flies without the symbiont, suggesting induction of host immunity may be key to *Wolbachia*'s ability to fight fungal pathogens. This study represents a major advancement in *Wolbachia* research and applications by demonstrating that its famous pathogen-blocking abilities can now be broadly extended to another major branch of microbial life. These results not only provide new information on how *Wolbachia* have achieved such a high global prevalence, but will also inform pathogen-blocking research and open up new possible applications of *Wolbachia* to areas like agriculture.

1452T **Regulation of *Drosophila* intestinal lipid metabolism by the gut microbiota** Joshua Derrick[1,2], Haolong Zhu[1], William B Ludington[3], Steve Farber[1] [1]Biology, Johns Hopkins University, [2]Biology, Carnegie Embryology, [3]Biology, Carnegie Institute of Embryology

Aims and Methods:

Microbiota species associated with western diets have been causally linked to worse health outcomes in humans, although both the mechanism and causal species are unclear. Work in both zebrafish and mice has shown that animals with a microbiome absorb more lipids into their enterocytes from a fatty meal than germ-free animals. In both animals, increased lipid absorption was linked to the presence of specific microbiome species. However, a mechanism has yet to be established: how exactly do microbes promote intestinal lipid absorption. Recent works including ours have developed a fly model with a natural and complete microbiome consisting of up to 5 to 10 members of the *Acetobacter* and *Lactobacilli* clades, which have analogs in the human gut. The goal of my project is to determine if members of this microbial community are linked to increased intestinal lipid absorption or whole animal lipid accumulation, and to establish a mechanistic link between microbial colonization and the altered lipid metabolism of the fruit fly host. Specifically, I used HPLC lipidomics to identify changes in whole animal lipids in the presence and absence of microbiota. To measure the postprandial response, we used the fluorescent lipid BODIPY-C12 as a metabolic tracer that was mixed into fly food containing a non-fluorescent non-absorbable dye to control for feeding rate. Two methods were developed to measure incorporation of this tracer: HPLC with a fluorescence detector was used to measure incorporation of the tracer into complex lipid species, and confocal microscopy was used to measure the spatial distribution and size of lipid droplets in the drosophila gut. Additionally, I developed a luminescent reporter line for the drosophila lipoprotein ApoLpp (a gene with significant homology to mammalian ApoB) to track lipids in circulation in the fly.

Results and Conclusions:

The HPLC approach revealed a significant (Mann-Whitney U test $p<0.05$) accumulation of a unique triglyceride peak at steady state in flies with a gut microbiota when fed a high fat diet. Remarkably, most of the 65 unique lipid peaks were not altered on a high-fat diet nor between germ-free and colonized animals, indicating a robust ability of flies to regulate their lipidome. Post–prandially unique lipid peaks were observed in the early time points after feeding that are significantly reduced in later time points. I hypothesize that these peaks may represent circulating lipids in the fly, which are different from storage lipids. Moreover, the colonization status of animals also appears to influence their postprandial response, affecting both the distribution of lipid species and the levels of ApoLpp post-prandially. Further work will investigate the specific mechanism through which microbiota act, examining the effects of specific microbiota and fly genes on post-prandial lipid absorption and processing.

1453T **The role of Yolk protein 3 (YP3) in aging and development in *Drosophila melanogaster*** Natania Kurien, Krystal Maya-Maldonado, Nichole A Broderick Department of Biology, Johns Hopkins University

YP3 is one of three yolk proteins in *Drosophila* involved in vitellogenesis; it is used as an energy source during embryogenesis. This project aims to evaluate non-canonical functions of YP3 in other host physiological processes. We focused on the effect of YP3 on aging and development. Additionally, since *YP3* expression is induced by the microbiome, we also assessed the impact of YP3 on the microbiome. To do so, we used a YP3 loss of function mutant (ΔYP3) to evaluate development and longevity compared to its background control, W1118. We evaluated pupal development in conventionally reared (CR) flies, and our results showed that there was a moderate decrease in the total number of pupae in ΔYP3 flies compared to the W1118 strain, as well as an increased time to pupation. Interestingly, when we compared pupal development in germ-free flies (axenic) we observed no difference between the mutant and W1118 strains. Our results indicate that loss of YP3 negatively impacts pupal development, and this effect is possibly mediated by the microbiome. In looking into longevity, we observed an increased lifespan in ΔYP3 females as compared to W1118 females. No significant difference was seen in males. This work highlights non-canonical roles of YP3, specifically those in aging and pupal development. Further work with gnotobiotic flies re-associated with specific microbial communities will help expand upon interactions between YP3 and the microbiome.

1454T **Enteric pathogens modulate metabolic homeostasis in the *Drosophila melanogaster* host** Hoda Najjar Biomedical

Sciences, Qatar University

On quotidian basis, living beings work out an armistice with their microbial flora and a scuffle with invading pathogens to maintain a normal state of health. Although producing virulence factors and escaping the host's immune machinery are the paramount tools used by pathogens in their "arm race" against the host; here, we provide insight into another facet of pathogenic embitterment by presenting evidence of the ability of enteric pathogens to exhibit pathogenicity through modulating metabolic homeostasis in *Drosophila melanogaster.* We report that *Escherichia coli* and *Shigella sonnei* orally infected flies exhibit lipid droplet deprivation from the fat body, irregular accumulation of lipid droplets in the midgut, and significant elevation of systemic glucose and triglyceride levels. Our findings indicate that these detected metabolic alterations in infected flies could be attributed to differential regulation of peptide hormones known to be crucial for lipid metabolism and insulin signaling. Gaining a proper understanding of infection-induced alterations succours in curbing the pathogenesis of enteric diseases and sets the stage for promising therapeutic approaches to quarry infection-induced metabolic disorders.

1455T **Effect of multiple exogenous fecal exposures on Parkinson's-like symptoms in *Drosophila melanogaster*** Sharon Shaju[1], Ariella Tamariz[1], Regina Lamendella[1,2], Kathryn A. Jewett[1] [1]Department of Biology, Juniata College, [2]Contamination Source Identification (CSI)

Parkinson's disease (PD) is characterized mainly by shaking and stiffness, but also by sleep challenges, gut dysbiosis, increased protein aggregation, and a shortened lifespan. Disruptions in the *GBA* gene, encoding the enzyme glucocerebrosidase, predispose humans to PD. *Drosophila melanogaster* lacking this gene serve as a well-characterized PD model. Previous studies on PD in both humans and flies have shown differential abundance in the gut microbiome of affected and non-affected individuals. This motivates investigation of the potential effects of manipulating and influencing changes in the gut microbiome.

In these experiments, we used external fecal inoculation to mimic fecal transplantation. In preliminary testing, we applied a single dose of fecal matter. Western blotting showed a significant decrease in protein aggregation in the heads of PD-like flies fed food inoculated with healthy fecal matter, but no change in the bodies. 16S rRNA gene sequencing of the flies' dissected gut hints at Alphaproteobacteria being a biomarker for PD-like flies. This may indicate that non-PD fecal matter could be beneficial for improving PD symptoms.

We have started to explore multiple external inoculations to characterize the long-term effects of healthy and PD-like fecal exposure. At day 10, (4-5 exposures) we are analyzing the 16S rRNA, protein aggregation, and sleep, as well as measuring the effect of adult lifetime exposure on lifespan. Due to changes in the microbiome composition, we predict PD flies exposed to healthy fecal matter will display better outcomes, and potentially, non-PD flies exposed to PD fecal matter will begin to show PD-like symptoms.

1456T **A novel antidiuretic hormone governs tumor-induced renal dysfunction** Wenhao Xu Wuhan University

Maintenance of renal function and fluid transport is essential for both vertebrates and invertebrates to adapt to physiological and pathological challenges. It has been observed that subjects bearing malignant tumors frequently develop detrimental renal dysfunction and oliguria, with previous studies suggesting the involvement of chemotherapeutic toxicity and tumor-associated inflammation. However, the direct modulation of renal functions by tumors remains largely unclear. In this study, using conserved tumor models in *Drosophila,* we characterized isoform F of ion transport peptide (ITP_F) as the first fly antidiuretic hormone that is secreted by a subset of yki^{3SA}-gut tumor cells to impair renal function and cause severe abdomen bloating and fluid accumulation. Mechanistically, tumor-derived ITP_F targets the GPCR TkR99D in stellate cells (SCs) of Malpighian tubules (MTs), an excretory organ equivalent to renal tubules, to activate NOS/cGMP signaling and inhibit fluid excretion. We further uncovered previously unrecognizedantidiuretic functions of mammalian neurokinin 3 receptor (NK3R), the homolog of fly TkR99D, as pharmaceutical blockade of NK3R efficientlyalleviates renal tubular dysfunction in mice bearing different malignant tumors. Altogether, our results demonstrated a novel antidiuretic pathway mediating tumor-renal crosstalk across species and offered therapeutic opportunities for the treatment of cancer-associated renal dysfunction.

1457T ***drop-dead* mutants show early neuronal apoptosis and subsequent glial hyperactivation of innate immune signaling** Unmila Jhuti[1], Edward Blumenthal[2] [1]Biological Sciences, Marquette University, [2]Department of Biological Sciences, Marquette University

Hyperactivation of innate immunity (HII) has been linked to neurodegeneration (ND) both in humans and *Drosophila*. The *drop-dead* (*drd*) mutant fly is an excellent tool to study the relationship between HII and ND. *drop-dead* (*drd*) encodes a protein of unknown function whose absence causes early ND in adult fly brains. *drd* mutant brains start to show cell

death right after eclosion and the flies die within the first week of adult life. We have previously reported that several cell death pathways are activated in mutant brains in the final days before organismal death. However, the primary and earliest mechanism of cell death in mutants is apoptosis. Immunostaining against the apoptotic marker death caspase-1 (Dcp-1) is widespread as early as the day of eclosion, whereas HII is a late phenotype observed in older 4 day old mutant brains. Co-localization analysis following double immunostaining shows that Dcp-1 localizes with neuron-specific ELAV but not with glia-specific REPO. Along with apoptosis, older *drd* mutants also show HII. The trend of HII upregulation is age-dependent. qPCR showed that both 2 day old and 4 day old adult flies exhibit upregulation of different antimicrobial peptides (AMPs). *attacin A1, cecropin C,* and *diptericin B* showed approximately 10-20 fold upregulation in 2 day old mutant brains, whereas upregulation of the same genes in 4 day old mutant brains was 1000-3000 fold. qPCR showed 10 to 17,000 fold upregulated expression of 15 different AMPs in 4 day old *drd* mutants- *diptericin(A-B)*, *cecropin(A-C)*, *attacin(A-D), baramicinA, defensin, drosocin, drosomycin and metchnikowin.* Immunostaining and co-localization analysis with 2 AMP reporters (*AttA-GFP* and *DptA-GFP*) and glia-specific REPO suggest that the site of AMP overexpression is in glial cells. Our work shows that the absence of *drd* causes early neuronal apoptosis and late glial HII and suggests a more complex causal relationship between HII and cell death than has been reported in other *Drosophila* models of ND. Thus studying *drd* mutants can help in understanding the roles of both neuronal and glial cells and the timeline of activation of cell death and innate immunity pathways that lead to ND and organismal death.

Supported by the Marquette University Department of Biological Sciences and Office of Research and Innovation.

Keywords: apoptosis, hyperactivation of innate immunity, cell death, aging, neurodegeneration.

1458T **Neurofibromin-dependent modulation of metabolic homeostasis via neuronal and molecular mechanisms** Valentina Botero[1], Seth M. Tomchik[1,1,2] [1]Neuroscience and Pharmacology, University of Iowa, [2]Iowa Neuroscience Institute, University of Iowa

Neurofibromatosis type 1 (NF1) is a multisystemic, monogenetic disorder arising from *NF1* gene loss-of-function mutations. *NF1* encodes neurofibromin (Nf1), a large protein containing a central GAP-related domain (GRD). Neurofibromin modulates diverse cellular and molecular mechanisms. Individuals with NF1 present with a wide spectrum of clinical manifestations, including peripheral nerve-associated tumors, brain tumors, skeletal and vascular abnormalities, and neurocognitive and behavioral deficits. Evidence suggests that Nf1 regulates cellular and organismal metabolism in humans: individuals with NF1 have overall reduced stature, reduced body mass index, pituitary growth hormone deficiencies, muscle weakness, and increased insulin sensitivity. Despite indications of Nf1's involvement in metabolic regulation, the critical molecular mechanisms underlying metabolic effects remain largely unknown.

Leveraging the *Drosophila* NF1 model and its highly conserved signaling pathways, we investigated the Nf1-metabolism connection. *In vivo* genetic analysis revealed that the loss of Nf1 disrupts metabolic homeostasis, resulting in increased metabolic and feeding rates, altered lipid dynamics, and increased susceptibility to starvation. These metabolic effects mapped to a distinct set of interneurons in the nervous system, which can be dynamically modulated to increase metabolic rate. Further investigation revealed that Nf1 regulates metabolic rate via neuronal mechanisms, with additional contributions from muscle cells.

Neurofibromin's Ras GAP activity is mediated by its central GRD. We found that Ras signaling is critical for mediating Nf1 effects on metabolism and further explored its downstream signaling through genetic approaches. Expression of a constitutively-active ERK (ERK^{SEM}) partially phenocopied the metabolic phenotype observed with Nf1 loss. Additionally, *in vivo* genetic experiments revealed the necessity of the Raf/MEK/ERK and PI3K/AKT/mTOR pathways, with Nf1 likely mediating metabolism via coordinated actions of both pathways. These data reveal a novel interaction between Nf1 and metabolism – identifying neural circuits and signaling mechanisms responsible for metabolic regulation by Nf1.

1459T **The impacts of increasing intestinal barrier function on protein aggregation in *Drosophila melanogaster*** Samantha Le, Latrell Fomby, Anna Salazar Christopher Newport University

The impact of gut health on aging and disease has become an emerging field of science. Intestinal barrier function is associated with changes in health and aging, with gut integrity linked to lifespan in numerous organisms, including humans. Recent studies have utilized *Drosophila melanogaster* as a model organism to study the effects of intestinal barrier permeability on several markers of aging. Snakeskin (Ssk) is expressed between adjacent gut epithelial cells and is a septate-specific occluding junction protein that ensures the integrity of the gut by maintaining the barrier between the intestines and the rest of the body. These junctional proteins between intestinal epithelial cells play a major role in controlling the ability of bacteria, and other inflammation-inducing molecules, to pass from inside the gut to outside the gut, thereby limiting microbial dysbiosis and preventing the 'leaky gut' phenotype. These investigations utilize the GeneSwitch Gal4/UAS system in order to

overexpress Ssk in *Drosophila*, in a tissue-specific manner, in order to examine its effects on markers of aging, such as protein aggregation and mitochondrial dysfunction. This research aims to investigate whether increasing intestinal barrier function can be a possible treatment for diseases associated with aging in humans.

1460T **Endogenous Retroviruses and TDP-43 Proteinopathy Form a Sustaining Feedback to Drive the Intercellular Spread of Neurodegeneration** Yung-Heng Chang[1], Josh Dubnau[1,2] [1]Department of Anesthesiology, Stony Brook School of Medicine, [2]Department of Neurobiology and Behavior, Stony Brook University

Neurodegenerative diseases initiate focally and spread through neural circuits over time. Most amyotrophic lateral sclerosis and about half of frontotemporal dementia cases are associated with abnormal hyperphosphorylated cytoplasmic inclusions of TAR DNA Binding protein 43 (TDP-43). TDP-43 proteinopathy has been proposed to spread between cells via transfer of aggregated protein that seeds re-initiation of pathology by a prion-like templating mechanism. While there is evidence for intercellular movement of TDP-43 protein, this mechanism has not been shown to be necessary or sufficient to propagate pathology of the endogenous protein through neural tissue or to underlie cellular degeneration of recipient cells. We have used a fly in vivo model to investigate cell-autonomous and non-autonomous effects of TDP-43 aggregation. We will show both recently published and unpublished findings demonstrating feedback amplification between TDP-43 aggregation and endogenous retrovirus (ERV) expression. Inter-cellular transmission of ERVs underlies propagation of disease phenotypes from cell-to-cell.

We utilized a “humanized” *Drosophila* model in which the endogenous fly TDP-43 ortholog is replaced with physiological levels of the human TDP-43 gene. This fully rescues loss of the fly gene, yielding no evidence of neurodegeneration. We initiated TDP-43 proteinopathy focally in adult surface glia, and observed the impact on neurons and glia that express physiological levels and normal localization of the human protein. We demonstrate that such focal onset of TDP-43 proteinopathy triggers TDP-43 proteinopathy in neurons at a distance from the initiating source. We detect DNA damage foci in neurons that are adjacent to the glial source, and at further distances over time. This is associated with neuronal loss and shortened lifespan. We observe no evidence that this involves movement of TDP-43 protein. Instead, we demonstrate that all of the intercellular effects require expression of the mdg4-(gypsy) ERV within the glia where we initiate TDP-43 proteinopathy. Expression of this ERV within glia triggers TDP-43 pathology in nearby neurons. Expression of either *Drosophila* mdg4-ERV or of the human ERV, HERV-K, also are sufficient to initiate TDP-43 pathology in cell culture. We demonstrate that intercellular viral ERV transmission is sufficient to initiate TDP-43 proteinopathy in the recipient cells, and anti-retroviral drugs are capable of reversing TDP-43 aggregation. These findings suggest that TDP-43 proteinopathy and ERV expression are mutually reinforcing. Intercellular viral transmission may underlie propagation TDP-43 aggregation through the nervous system.

1461T **Developmental Alcohol Exposure in Alzheimer’s Disease Models of *Drosophila melanogaster*** Desiree Filardo Biological Sciences, San Jose State University

Fetal Alcohol Spectrum Disorder (FASD) results from developmental exposure to alcohol in mammals. It is the leading non-genetic cause of intellectual disabilities worldwide, and causes a variety of other developmental deficits, including developmental delays, low body weight, behavioral changes, and reduced brain size. We have established a model for developmental alcohol exposure (DAE) in *Drosophila melanogaster* and find that many of the phenotypes seen in other animal models of FASD can be replicated in flies. To identify molecular targets of DAE, we carried out a large-scale genetic screen for mutations that alter the sensitivity of flies to developmental alcohol exposure. From this screen, we identified the gene Dementin (*Dmtn*), which encodes the Drosophila ortholog of the Alzheimer Disease associated protein TMCC2. TMCC2 is required for normal processing of amyloid precursor protein. Mutations in *Dmtn* cause sensitivity to DAE, and DAE alters *Dmtn* expression. Finally, adult flies, after developmental exposure to alcohol, show climbing defects indicative of central nervous system dysfunction. Similar climbing defects are also seen in fly models of neurodegenerative diseases, including Alzheimer’s Disease. These results led us to hypothesize that DAE interacts with pathways that, when mutated, lead to neurodegeneration. To test this hypothesis, we have been examining the effects of DAE in mutations that serve as fly models of neurogenerative diseases, specifically Alzheimer’s Disease. Here we will present the results of experiments testing the interaction between DAE and mutations in the genes tau, presenilin, and amyloid-beta precursor protein (APP). Mutations in tau, presenilin, and APP serve as fly models for Alzheimer’s Disease-related neurodegeneration. Our preliminary data indicate that tau mutations render flies sensitive to the developmental effects of ethanol. We will present both survival and behavioral data to examine the interaction between ethanol and Alzheimer’s Disease in flies.

1462T **Investigating the impacts of intestinal Snakeskin knockdown on protein aggregation in *Drosophila*** CeOnna Battle, Connor Auby, Tyler Hyun, Anna Salazar Christopher Newport University

Many neurodegenerative diseases, such as Parkinson’s Disease and Alzheimer’s Disease, increase with age and are associated

with elevated protein aggregate levels. Previous research in fruit flies has discovered a relationship between increasing age and a deterioration in gut health, with developing intestinal barrier dysfunction tightly linked to mortality. Because of this tight association between organismal health and gut function, several markers of aging have been investigated in order to determine the role of barrier integrity on aging phenotypes. The primary focus of this study is to investigate a specific aging phenotype associated with several diseases of aging, whether intestinal barrier deterioration can impact protein aggregation. This research utilizes a knockdown in the protein Snakeskin (Ssk) in the midgut of *Drosophila melanogaster*, which induces intestinal barrier permeability. Ssk is a septate junction protein, equivalent to mammalian tight junctions, important for maintaining the integrity of the connections between adjacent gut epithelial cells. Ssk mislocalizes in aging flies, perturbing these junctions and causing intestinal permeability. Knocking down its expression in the gut, using the GeneSwitch Gal4/UAS system, causes a decrease in barrier function and a severely reduced lifespan, in addition to other markers of aging such as dysbiosis and inflammation. These experiments are investigating protein aggregation in the Ssk knockdown model in order to investigate whether unhealthy or aging guts exhibiting barrier dysfunction may be associated with neurodegenerative diseases linked with protein aggregation. Ideally, these insights will fuel a focus on intestinal health in the studies of several diseases with accompanying protein aggregation.

1463T **Ptth regulates lifespan through temporal and spatial activation of STING/NF-κB signaling during *Drosophila* metamorphosis** Ping Kang[1], Peiduo Liu[1], Michael B O'Connor[2], Hua Bai[1] [1]Genetics, Development and Cell Biology, Iowa State University, [2]Department of Genetics, Cell Biology and Development, University of Minnesota

The prothoracicotropic hormone (Ptth) is well-known for its role in controlling insect developmental timing and body size by promoting the biosynthesis and release of ecdysone. However, the role of Ptth in adult physiology is largely unexplored. Here, we show that Ptth null mutants (both males and females) are long-lived and increase resistance to oxidative stress. Transcriptomic analysis reveals that age-dependent upregulation of the innate immunity pathway is attenuated by Ptth mutants. Intriguingly, we find that Ptth regulates the innate immunity pathway specifically in fly oenocytes, the homology of mammalian hepatocytes. We further show that oenocyte-specific knockdown of NF-κB/Relish extends lifespan, while oenocyte-specific overexpression of NF-κB/Relish attenuates the lifespan extension of Ptth mutant. In addition to the oenocyte-specific regulation of the innate immunity pathway, we find that Ptth mutants exhibit reduced STING and NF-κB/Relish signaling during pupal development. Surprisingly, knockdown of either STING or NF-κB/Relish in pupal oenocytes significantly prolongs lifespan of adult flies. Thus, our findings reveal an unexpected longevity regulation mediated by Ptth hormonal factor and STING/NF-κB signaling in developing hepatocytes.

1464T **Intestinal serotonin promotes immunity and immune-related metabolism** Xiang Ding, Paula Watnick Division of Infectious Diseases, Boston Children›s Hospital, Harvard Medical School

Vibrio cholerae quorum sensing regulates the host survival during intestinal colonization in a *Drosophila melanogaster* oral infection model. We previously showed that the high cell density quorum-sensing regulator HapR represses pathogen anabolic metabolism and tryptophan uptake to activate host intestinal serotonin synthesis and innate immune signaling via an unknown pathway. Here, we show that, in uninfected flies, tryptophan is converted to serotonin in enterocytes. Serotonin released from these enterocytes activates receptors in enteroendocrine cells (EECs) of anterior midgut. Protein kinase C acts downstream of the serotonin receptor to activate ecdysone signaling, which promotes the transcription of *PGRP-LC*, signaling through the IMD pathway, and transcription of the enteroendocrine peptide Tachykinin, a repressor of lipid synthesis, and anti-microbial peptides (AMPs). Thus, we show that tryptophan, a microbe-impacted intestinal metabolite, regulates the ecdysone signaling and the intestinal innate immune response via serotonin.

1465T **A large-scale *in vivo* screen to investigate the roles of human genes in *Drosophila melanogaster*** Ashley Avila[1], Lily Paculis[1], Roxana Gonzalez Tascon[1], Belen Ramos[1], Dongyu Jia[2] [1]Georgia Southern University, [2]Kennesaw State University

Understanding the signaling pathways in which genes participate is essential for discovering the etiology of diseases in humans. The model organism, *Drosophila melanogaster*, has been crucial in understanding the signaling pathways in humans, given the evolutionary conservation of a significant number of genes between the two species. Genetic screens using *Drosophila* are a useful way of testing large quantities of genes to study their function and roles within signaling pathways. We conducted a large-scale genetic screen to identify which human genes cause an alteration in the morphology of the *Drosophila* eye. The *GMR-Gal4* was employed to activate a single *UAS*-human gene within each individual fly. In total, 802 *UAS*-human stocks corresponding to 787 human protein-coding genes underwent screening. Among these, changes in eye phenotypic characteristics such as texture, size, shape, bristles, and ommatidia were observed in 64 genes. Upon completion of the screen, bioinformatic databases were used to acquire biological information about the 64 genes such as up-regulated gene functions, cancer associations, and protein product homology between *Drosophila* and humans.

1466T **Interplay between intestinal barrier function, aging, and neurodegeneration** David Grace, Kayla Pauley, Stuart Saba,

Anna Salazar Christopher Newport University

The world population is aging, with the number of people over 65 more than doubling to 1.57 billion by 2050, making a concomitant elevation in numerous age-related pathologies, including neurodegenerative diseases such as Alzheimer's Disease, highly likely. Because of this, a clearer understanding of the pathophysiological changes accompanying aging, and the discovery of novel therapeutics to assist in aging phenotypes, are absolutely essential. Aging is a process marked by a continuous decline in multiple physiological functions, including the intestinal barrier function, which is tightly linked to longevity in *Drosophila melanogaster* and other organisms. We have previously shown that altered expression of occluding junctions in the guts of fruit flies can lead to various hallmarks of aging, including modulation of intestinal homeostasis, variations in microbial dynamics, changes in immune activity, and alterations in lifespan. Loss of a specific occluding junction, Snakeskin (Ssk), leads to rapid and reversible intestinal barrier dysfunction, altered gut morphology, dysbiosis, and a dramatically reduced lifespan. Remarkably, restoration of Ssk expression in flies showing intestinal barrier dysfunction rescues each of these phenotypes previously linked to aging. Intestinal up-regulation of Ssk protects against microbial translocation following oral infection with pathogenic bacteria. Furthermore, intestinal up-regulation of Ssk improves intestinal barrier function during aging, limits dysbiosis, and extends lifespan. Additionally, perturbing barrier function in the gut has non-cell-autonomous impacts, including alterations in the brain and muscle. These investigations add more information about the impact of the gut on tissue outside the gut and begin to address communication between the gut and the brain and muscles in disease models. These findings indicate that intestinal occluding junctions may represent prolongevity targets in mammals, in addition to their possible roles in intestinal dysfunction, aging, and disease. Current work utilizes cellular and molecular biological methodologies to build upon current knowledge to address crucial questions at the intersection between microbial dysbiosis, epithelial integrity, inflammation, protein aggregation, neurodegeneration, and disease, with the ultimate goal of discovering novel therapies that may enhance barrier function, healthspan, and lifespan.

1467T **Establish a *Drosophila* model to investigate Epidermolysis Bullosa** Yan-Yan Lin[1], Anna C.-C. Jang[1], Yu-Chiuan Chang[2], Chao Kai Hsu[3] [1]Department of Biotechnology and Bioindustry Sciences, National Cheng Kung University, [2]Institute of Biomedical Sciences, National Sun Yat-sen University, [3]Department of Dermatology, National Cheng Kung University Hospital

Epidermolysis Bullosa (EB) is a rare genetic disorder characterized by an extreme fragility of the patients' skin. Currently, there is no cure for individuals afflicted by this condition, and despite the identification of common mutations responsible for EB, the underlying pathogenic mechanism has not yet been fully understood. In this study, by expressing the pathogenic variants found in patients with epidermolysis bullosa simplex, Dowling-Meara type (EBS-DM) in *Drosophila*, we establish an EBS-DM disease model which shows disrupted epidermal phenotype corresponding to the patients. This disease model not only serves as a tool for further exploring the pathogenic mechanism of EB but also provides a platform for expediting the screening of potential therapeutic drugs.

1468T **Building a Prostate Cancer Model: Aging Reduces the Nuclear Size of Virgin Flies and Glycolysis Levels of Mated Flies in *Drosophila melanogaster* Secondary Cells** Mischa Emery[1], Christian Massino[2], Susanne Broschk[2], Daimark Bennett[3], Klaus Reinhardt[2], Marko Brankatschk[2], Mirre Simons[4], Clive Wilson[5], Stuart Wigby[1] [1]Evolution, Ecology and Behaviour, University of Liverpool, [2]Technische Universität Dresden, [3]University of Manchester, [4]University of Sheffield, [5]University of Oxford

Introduction: Prostate cancer (PCa) is the most prevalent cancer of aging men, with a 1/3 of cases in the UK affecting those over 75. PCa cells differ from healthy prostate cells; they have elevated levels of glycolysis and cell division. The accessory gland of male *Drosophila melanogaster* contains secondary cells (SC) that share many characteristics with the human prostate. SC, unlike PCa cells, do not divide but instead, their nuclei grow in early adult life, with endoreplication occurring only in mated flies. The metabolic state of SC in young or aged flies is currently unknown. Based on previous work, we expected the nuclear size to increase with age, with accelerated growth in mated flies. In addition, we expected higher levels of glycolysis in the SC of flies allowed to mate, a phenotype that would be useful in a PCa model.

Methods: We housed male *D. melanogaster* as virgins, or in mixed-sex groups in which flies were allowed to mate freely ("mated"). Initial nuclear size experiment used 1 and 3 day old virgin males and aging experiments used 1, 3 and 5 week old virgin and mated flies. Flies were imaged with immunohistochemistry for nuclear size and fluorescence-lifetime imaging microscopy for metabolic status.

Results: We found, as previously reported, that in early adult life (day 1 to 3 following eclosion), there is a significant increase in SC nuclear size. However, at weeks 1 and 3 there are no differences in nuclear size between virgin and mated flies, while at week 5 there is a significant reduction nuclear size of virgin flies. At weeks 1 and 3 glycolysis is higher in mated flies however, at week 5 there is no difference in glycolysis level between virgin and mated flies.

Conclusions: We investigated SC cell characteristics that are important for building a PCa model. Flies aged to 5 weeks

did not exhibit nuclear size changes nor glycolysis levels that would mimic a PCa cell phenotype. Further tests can show if endoreplication is occurring in the older flies, which may reveal DNA replication without an increase in nuclear size. Further work is required to establish whether aged flies have a phenotype that mirrors normal, aged prostate cells rather than PCa cells. This study provides a background for the application of age-extending treatments such as pharmaceuticals or dietary changes to further characterise SC as a PCa model.

1469T **Nazo, the *Drosophila* homolog of the NBIA-mutated protein – c19orf12, is required for triglyceride homeostasis in *Drosophila* Gut** Sreejith Perinthottathil, Rajnish Bharadwaj Pathology and Lab Medicine, University of Rochester Medical Center

Lipid dyshomeostasis has been implicated in a variety of diseases ranging from obesity to neurodegenerative disorders such as NBIA. Here, we uncover the physiological role of Nazo, the *Drosophila* homolog of the NBIA-mutated protein – c19orf12, whose function has been elusive. Ablation of *Drosophila* c19orf12 homologs leads to dysregulation of multiple lipid metabolism genes. *nazo* mutants exhibit markedly reduced gut lipid droplet and whole-body triglyceride contents. Consequently, they are sensitive to starvation and oxidative stress. Nazo localizes to ER-lipid droplet contact sites and is required for maintaining normal levels of Perilipin2, an inhibitor of the lipase – Brummer. Concurrent knockdown of Brummer or overexpression of Perilipin2 rescues the *nazo* phenotype, suggesting that this defect, at least in part, may arise from diminished Perilipin2 on lipid droplets leading to aberrant Brummer-mediated lipolysis. Our findings provide novel insights into the role of c19orf12 as a possible link between lipid dyshomeostasis and neurodegeneration, particularly in the context of NBIA.

1470T **Dihydromotuporamine C acts through Rho1 and diaphanous to inhibit cell migration.** Laurie von Kalm, Corey Seavey Biology, University of Central Florida

The motuporamines are a promising class of anti-metastatic compounds. In mammals, Dihydromotuporamine C (Motu33) has been shown to activate the small GTPase RhoA, however, little is known about subsequent downstream events leading to cell migration inhibition. In the present study, we investigated the mechanism of action of Motu33 and a synthetic derivative, Motu-(CH_2)-33, in Drosophila by manipulating the gene dose of positive and negative regulators of actin dynamics. Consistent with previous findings, reduced gene dose of Rho1 (the Drosophila RhoA ortholog) attenuates motuporamine activity, confirming that RhoA/Rho1 is targeted by these compounds. Actin-myosin contraction is controlled by the Rho1-ROCK-myosin regulatory light chain (MRLC) pathway. Reduced gene dose of the myosin binding subunit of myosin phosphatase, a negative regulator of the Rho1-ROCK-MRLC pathway, enhances motuporamine activity indicating that the motuporamines stimulate actin-myosin contraction through activation of the myosin regulatory light chain. Rho1 also activates diaphanous (dia) to control actin polymerization. Surprisingly, reduced gene dose of dia enhances motuporamine activity, suggesting that the motuporamines act on dia in a Rho1-independent manner. Reduction in gene dose of the Drosophila Rac orthologs also enhances motuporamine activity. In contrast, motuporamine activity is unaltered by reduced gene dose of slingshot (ssh) which acts to trigger actin severing and depolymerization. Since ssh is directly regulated by Rac, the enhanced activity of motuporamines observed when Rac gene dose is reduced may reflect an indirect mode of action on the Rac GTPases leading to increased Rho1 activity. In summary, these findings demonstrate that motuporamines act through RhoA/Rho1 and diaphanous to regulate actin-myosin contractility and actin polymerization.

1471T **Characterization of seizure susceptibility in a *Drosophila* model of KDM5C-associated X-linked intellectual disability disorder** Bethany K Terry[1], Matanel Yheskel[1], Hayden AM Hatch[1,2], Julie Secombe[1,2] [1]Department of Genetics, Albert Einstein College of Medicine, [2]Dominick P. Purpura Department of Neuroscience, Albert Einstein College of Medicine

KDM5C-associated X-linked intellectual disability disorder (XLIDD), also known as Claes-Jensen syndrome, is a rare neurodevelopmental disorder caused by variants in the Lysine (K)-specific demethylase 5C (*KDM5C*) gene. In addition to physical growth challenges, individuals with KDM5C-associated XLIDD have been reported display a spectrum of different neurological changes, which include intellectual disability, gross and fine motor delays, emotional and behavioral changes, and epilepsy. However, although seizures have been reported in up to a third of individuals with this disorder, how alterations in KDM5C activity result in the promotion of seizures is not well understood.

Previous work in our lab has demonstrated that perturbation of KDM5, *Drosophila*'s KDM5C ortholog, can impact neurodevelopment and cognitive functioning. In this study, we utilized our *Drosophila* models to investigate the role of KDM5 in seizure susceptibility. To do this, groups of adult flies were exposed to heat or mechanical stress and then recorded for several minutes. Video recordings were then assessed to determine the number of flies that seized and the time that each fly seized for. Interestingly, we found that expression of patient-related variants of *Kdm5* increases the proportion of flies that seize in response to mechanical stress in comparison to control animals. Furthermore, we found increased seizure

susceptibility and duration following neuron-specific knockdown of *Kdm5* in comparison to controls. Having established the increased propensity of our *Drosophila* model to seize, ongoing work will aim to identify the mechanisms underlying the seizures that occur following KDM5 perturbation.

1472T **A *Drosophila* model for infection-induced loss of intestinal barrier function and homeostasis** Madison Clark[1], Nichole Broderick[2] [1]Johns Hopkins University, [2]Biology, Johns Hopkins University

Gastrointestinal diseases, such as inflammatory bowel disease and antibiotic-induced colitis are major concerns worldwide. While the underlying causes of gut disease are not completely understood, innate immune responses and a healthy gut microbiome have been suggested as key to the maintenance of intestinal homeostasis. *Drosophila* is an ideal host to study host-microbe interactions as it has a low complexity microbiome that is easily manipulated to study the contributions of individual microbes on gut health. This study characterizes the response of *D. melanogaster* to a novel pathogen, *Chromobacterium subtsugae,* a Gram-negative environmental bacterium known for its quorum sensing production of the purple-pigment violacein. We fed *C. subtsugae* to adult *D. melanogaster* and found flies are significantly more susceptible to a purple pigmented strain that over produces violacein (ΔvioS), compared to the wild-type non-pigmented strain. Initially after infection, pathogen load is high, but gradually decreases as the infection progresses. By day 4, almost no pathogen can be detected in flies infected with either strain. Interestingly, most death post infection occurs 7-10 days after ingestion. This suggests flies can clear the pathogen early in the course of the infection and that constant association of the pathogen with the host is not necessary for death. In examining the early events in the course of infection that contribute to death, we found that ingestion of the ΔvioS strain disrupted barrier integrity, leading to gut leakiness. Initially, immune and homeostatic mechanisms to repair intestinal damage are induced. However, around day 6 post-ingestion, we observed that total gut length was reduced by about 30% and this was associated with an increase in undifferentiated cells in the gut. We will discuss our exploration of signaling pathways contributing to this response as well as the role of the microbiome to host survival. We propose that the *D. melanogaster-C. substugae* infection model provides a useful new tool to study the dynamics of gut disease that lead to the loss of whole-organism homeostasis, such as in mammalian sepsis. Understanding how microbes interact with a host to cause such diseases will allow us to identify innovative mechanisms to limit the damage microbes cause during infection.

1473T **Trigger warning: Do psychological stressors trigger neurodegeneration in a *Drosophila* TDP-43 model?** Narmin H Mekawy[1,2], Swetha BM Gowda[3], Joshua Dubnau[1,2,3] [1]Department of Neurobiology and Behavior, Stony Brook University, [2]Program in Neuroscience, Stony Brook University, [3]Department of Anesthesiology, Stony Brook Medicine

Aging is a major risk factor of onset of neurodegeneration, however the rate of progression is not impacted by the age of onset. Other risk factors include post-traumatic stress disorder, emotional stress, obesity, and environmental toxins. It is not clear whether and to what extent biological aging, cumulative effects of lifelong stress, or early life stresses act to trigger onset of neurodegeneration. The mechanisms by which psychological stress may drive disease are also not known. Genetically inducing TDP-43 pathology animal models is sufficient to trigger progression of neurodegenerative phenotypes. For example, in *Drosophila*, inducing TDP-43 over-expression in glial cells is known to trigger spread of neurodegeneration to other glia and to neurons in. This is also associated with loss of nuclear TDP-43 and accumulation of cytoplasmic inclusions. To investigate the upstream triggers of neurodegeneration, we are testing the effects of “psychological stressors” by providing stressful perceptual experiences to the flies that have or are genetically sensitized towards TDP-43 neurodegeneration. We are testing the impacts of these manipulations on TDP-43 protein pathology and effects on neurodegenerative phenotypes as well as on lifespan. In this poster, we will describe the experimental strategies used to test the impacts of perception of predation risk, frustration of mating potential and restraint stress.

1474T **Gene-by-Environment Analysis of Sleep Deprivation on Diet Choice in *Drosophila*** Jhilam Dasgupta, Gabbie Bicanovsky, Miled Maisonet-Nieves Biological Sciences, University of Alabama

More than 30% of individuals in the United States suffer from metabolic syndrome, which is a risk factor for diseases including cardiovascular disease, diabetes, and hypertension. Disruptions to sleep can increase risk of obesity in humans. *Drosophila melanogaster* is an established model organism that can be used to illustrate the effects of sleep deprivation on metabolism. Sleep varies between individuals, and it is important to understand how genetics impact metabolic health across wild type lines with differing sleep phenotypes. To study these effects, *Drosophila Genetics Reference Panel* (DGRP) short-sleeping and long-sleeping strains were placed in a *Drosophila* sleep deprivation apparatus, which shakes the flies for five seconds in one-minute intervals over a three-day period. Fly activity was monitored to compare daytime and nighttime activity between short-sleeping and long-sleeping DGRP strains. Following the sleep deprivation period, a choice capillary feeding (CaFe) assay was performed to measure consumption of high sugar (30%) sucrose, high fat (coconut oil derived ketogenic mix) and normal diet (10% sucrose). We have chosen these diets to better represent the most common westernized diets that are correlated with reduced metabolic health. This experiment seeks to identify the extent to which sleep deprivation affects dietary choice

in sleep mutant strains. In the future, by replicating these experiments across multiple DGRP lines, we will be able to identify gene polymorphisms that may increase or decrease diabetic risk factors due to sleep deprivation. Due to conservation of gene function between *Drosophila* and humans, results will likely be useful in determining the relationship between sleep and metabolic health in humans.

1475T **Rescue effects of the antimicrobial peptide LL-37 on beta amyloid-induced pathology in a Drosophila model of Alzheimer's disease** MaiLan Kasch[1], Belal Alatasi[1], Kenneth Owyang[1], Julia Aguiar[1], Alison Swick[1], Miles Maybrun[1], Kayla Azad[1], Waleed Alsibai[1], Morgan Wong[1], Annelise Barron[2], Jeremy Lee[1] [1]Department of Molecular, Cell, and Developmental Biology, University of California, Santa Cruz, CA 95064, UC Santa Cruz, [2]Department of Bioengineering, Stanford University School of Medicine, Stanford, CA 94305, Stanford University

Alzheimer's disease (AD) is characterized by the aggregation of neurotoxic amyloid plaques, largely composed of the peptide amyloid beta (Aβ). Research has shown that when bound in vitro with Aβ, the human antimicrobial peptide LL-37 decreases amyloid aggregation (De Lorenzi, et al., 2017). Based on these findings, we hypothesized that the expression of LL-37 ameliorates the effects of Aβ's neurotoxicity. To test this hypothesis in vivo, we generated four transgenic fly lines that pan-neuronally express the human peptides LL-37 and Aβ individually or together and compared these genotypes with non-expressing controls.

When expressed alone, Aβ had detrimental effects on fly lifespan and survivorship, but co-expression with LL-37 resulted in a significant rescue of adult lifespan and full rescue of survivorship to adult. This suggests that co-expression of LL-37 with Aβ partially alleviates the effects of Aβ. We then used RNA sequencing to examine the gene expression profiles of the different genotypes. We discovered that the largest category of genes that were upregulated in Aβ-expressing flies were genes encoding proteins involved in proteolysis. We also found that in flies co-expressing LL-37 with Aβ, many of these proteolytic genes were subsequently downregulated in comparison to Aβ-expressing flies. Similarly, proteolytic genes that were downregulated in Aβ-expressing flies as compared to controls were subsequently upregulated when LL-37 was coexpressed with Aβ. This evidence indicates that the proteolytic genes that were misregulated in Aβ-expressing flies were at least partially rescued by expression of LL-37. Additionally, there were no misregulated genes for which misexpression was exacerbated by co-expression of LL-37, which suggests that the attenuation of the misregulation is not random.

To further investigate the mechanisms of LL-37's effects on AD-like pathology, we are performing rapid iterative negative geotaxis and olfactory learning assays to investigate the neurodegenerative effects of Aβ with and without expression of LL-37 on motor function and memory. We are also exploring the phenotypic effects of Aβ through expression with a GMR-Gal4 driver, which limits expression to the eyes. The results from these experiments could further shed light on whether LL-37, and/or factors that increase its expression, could serve as promising targets for the future development of Alzheimer's disease therapeutics.

1476T **Illuminating the non-genetic factors of immune activation** Yu Yang Boston University

Immune activation is a tightly controlled process, as over-activation leads to autoimmunity, while under-activation lets bacteria proliferate unchecked. However, even genetically identical *D. melanogaster* infected with the same number of bacteria will die at different time points. Since many non-genetic factors including sex, age, past infections, and the environment can change immune response, two flies with similar life histories can have different immune recognition speeds and therefore a different pathogen growth trajectory. A fly's ability to survive an infection depends on rapid immune activation controlling the bacterial load in the first few hours of infection. However, the exact interplay between bacteria growth and immune response in individual animals has yet to be observed. By observing and modeling the individual variation in immune response, we can discover new targets that control immune activation. I will approach this question using bioluminescent bacteria, allowing me to continuously track infection progress in individual flies in a high throughput manner. To make the bacteria, I transform them with the iLUX plasmid, which generates bioluminescence without the need for any additional substrate. The signal is closely correlated with bacterial load in the fly. I will use both gram-positive and gram-negative bacteria (*E. faecalis, E. coli, and S. marcescens*) to probe the activation speed and variability of the two major innate immune pathways: Toll and IMD. At the same time, I will track fly immune response using flies that produce mCherry when producing antimicrobial peptides (AMP) such as diptericin and drosomycin. I will image the Dpt-mCherry and Drs-mCherry enhancer reporter flies injected with bioluminescent bacteria in a microplate reader for two days after injection, tracking how the iLUX signal changes in response to immune activation. Using these data, I will create a computational model of resistance and death. From this, we can study the random variations between individuals and model non-genetic drivers of resistance and tolerance.

1477T **The impact of timing on the protective effect of chronic infection in *Drosophila melanogaster*** Grace Ginder, Moria C. Chambers Biology, Bucknell University

One potentially influential category of microbes are ones that initially cause an acute infection and persist as a chronic infection if they don't kill their host. These chronic infections can influence many elements of host biology including metabolism, behavior, and immunity to future infection. Our lab has found that in the fruit fly, *Drosophila melanogaster*, chronic bacterial infection confers non-specific protection against more lethal bacterial infections given a week later. However, it is unclear how time between initial infection and secondary infection impacts this protective effect. We hypothesized that there is an optimal window for protection, as longer times between infections may allow the host to recover from the first infection but may also result in lower immune gene expression as well. To test how the time between the two infections impacts protection, three commonly used fly lines – w1118, Canton S, and Oregon R – were injected with a sub-lethal dose of *Serratia marcescens* that causes chronic infection and promotes continued expression of antimicrobial peptide genes at seven days post-infection. Then, 3, 7, or 14 days later, the flies were injected again with a lethal infection of *Providencia rettgeri*. To assess overall protection, survival was tracked for 8 days post-infection. To specifically determine the impact of chronic infection on resistance, bacterial load was measured 12 hours post-infection. The protective effect was strongest in w1118 flies, which showed significant protection at all times tested. Similar to previous results in the lab, our bacterial load assays indicated that protection is likely due to changes in resistance. We are currently testing how the strength of protection correlates with both antimicrobial peptide gene expression and phagocytic index. To functionally test the role of phagocytes in this protection, in the future we will assess whether fly lines missing key phagocytic genes can be protected by chronic infection.

1478T **Identifying novel links between cardiovascular disease and insomnia by *Drosophila* modeling of genes from a pleiotropic GWAS locus** Farah Abou Daya[1], Torrey Mandigo[2], Lily Ober[1], Dev Patel[1], Matthew Maher[2], James Walker[2], Richa Saxena[2], Girish Melkani[1] [1]Pathology, University of Alabama at Birmingham, [2]Massachusetts General Hospital

Cardiovascular disease (CVD) is the leading cause of death worldwide. CVD is associated with insomnia such that insomnia symptoms double the risk of incident CVD. However, how they are related is unknown. Two recent genome-wide association studies (GWAS) identified genetic loci significantly associated with insomnia, including one locus with five nearby genes that are associated with CVD in an independent GWAS. Therefore, we hypothesized that genetic predisposition to insomnia contributes to the development of CVD. To test this and identify causal genes at this locus, we used Drosophila melanogaster, which are well- established model systems for sleep and cardiac studies. To assess the role of these genes on cardiac physiology, we used the cardiac-specific Hand-Gal4 driver to perform genetic knockdown (KD). One-week-old Drosophila progeny were then used for semi-intact microscopic heart preparation followed by high-speed videography to assess cardiac physiology. Similarly, to assess their role in sleep, we used the neuronal-specific Elav-Gal4 driver to perform KD of these genes. Sleep and locomotor activity of one-week-old flies were monitored using the Drosophila Activity Monitoring System. We found that neuronal and cardiac-specific RNAi KD of four genes conserved in Drosophila: Lsn, ATPSynC, Bruce, and Imp, contributes to compromised sleep and cardiac performance, respectively. Cardiac-specific KD of Lsn led to significant cardiac dilation and reduced fractional shortening, a measure of cardiac performance. KD of ATPSynC led to significantly reduced fractional shortening without dilations. Furthermore, Lsn and ATPSynC KD hearts had disrupted actin- containing myofibrillar organization. Suppression of Lsn increased Pericardin deposition, indicative of fibrosis. Also, the cardiac suppression of ATPSynC and Lsn significantly shortened lifespan. Neuronal-specific KD of three genes significantly disrupted sleep. Furthermore, KD of ATPSynC and Lsn in the heart disrupted sleep in a non-cell-autonomous manner. This work provides novel insights into genetic mechanisms linking CVD and insomnia, highlighting the potential importance of these four genes in the development of both diseases.

1479T **Hedgehog signaling converges with HAP40 to control intestinal aging and disease** Jennifer I Alexander[1,2], Alana M O'Reilly[3], Christopher J Lengner[1] [1]Biomedical Sciences, University of Pennsylvania, [2]Cancer Signaling and Microenvironment, Fox Chase Cancer Center, [3]Cancer Signaling and Micronenvironment, Fox Chase Cancer Center

Alarmingly, Colorectal Cancer (CRC) incidence is disproportionately rising in young patients (EAO-CRC) without known cause. However, the underlying mechanisms at the intersection of aging biology and EAO-CRC pathogenesis remain elusive. By leveraging the powerful molecular genetics of the fly-to-human intestinal organoid pipeline, our goal is to delineate the mechanisms of aging that drive EAO-CRC. We discovered a novel Hedgehog (Hh)-dependent mechanism that balances autophagy-based cellular repair and proliferative regeneration to sustain healthy tissue aging. Specifically, we identified the Hh effector Patched (Ptc) as the critical switch for regulating both processes. We also found that the autophagy-associated transcript, HAP40, was reduced in Ptc hypomorphs. We then determined the impact of gain or loss of HAP40 in intestinal cells and observed evidence of increased cellular aging coupled with decreased survival and proliferation. We then queried human-derived transcriptomic data to assess HAP40 status in Hh-dependent cancers and found that 7% of patients displayed either gene amplification or deep deletion. We next compared the diagnosis age of patients, finding that patients bearing mutations in the HAP40 gene were diagnosed younger than those without mutations. Moreover, survival probability of patients with

normal HAP40 and Hh pathway signaling was significantly better than patients with mutant HAP40 or Hh effectors. The phenotypic similarities and dependency of HAP40 expression on Ptc suggests a new link between Hh and HAP40 signaling that is critical for intestinal tissue maintenance and aging regulation in flies. Taken together, this suggests a model in which Hh pathway components intersect with an understudied gene as a dual signaling cassette that impacts patient outcomes. Our next goal is to generate isogenic patient-derived CRC organoids to validate our experimental and transcriptomic data. Delineation of the sequential activation steps of this novel pathway will establish a new paradigm for the biological impact of Hh signaling driving EAO-CRC.

1480T **A Drosophila model of a rare Congenital Disorder of Glycosylation associated with ALG10** Suraj R Math[1], Juan Miguel M Guerra Solano[1], Athena Q Ye[1], Brittany S Leger[1], Torrey R Mandigo[1], Christina M Woo[2], Richa Saxena[1], James A Walker[1] [1]Center for Genomic Medicine, Massachusetts General Hospital, [2]Department of Chemistry and Chemical Biology, Harvard University

Congenital disorders of glycosylation (CDGs) are a group of rare multifaceted genetic disorders resulting in severe development problems, neurological deficits, seizures, and metabolic issues. They affect the post-translational addition of *N*-glycans to proteins which can alter their cellular processes including solubility, stability, cellular localization, and molecular trafficking. The *N*-glycosylation pathway relies on the activity of transmembrane asparagine-linked glycosylation (ALG) enzymes functioning in the endoplasmic reticulum (ER). Most enzymes involved in the *N*-glycosylation pathway have an associated CDG; however, to date no CDG has been described for ALG10, which catalyzes the terminal step of lipid-linked oligosaccharide (LLO) biosynthesis. We have found that the human genome encodes two paralogs *ALG10* and *ALG10B* arising from a recent duplication in primate evolutionary history. We subsequently identified a human subject with homozygous variants in both *ALG10* and *ALG10B*, suffering from progressive myoclonic epilepsy. In contrast to humans, *Drosophila* possesses a single *Alg10* gene. Neuronal RNAi knockdown of Alg10 in flies led to bang-sensitive seizures indicating a CDG-like phenotype in flies. Glycoproteomic analysis of *Alg10* knockdown was used to identify key target genes of the *N*-glycosylation pathway in the brain. We are utilizing our fly model to screen potential therapeutics for ALG10-CDGs. We are also conducting a structure-function analysis using CRISPR-Cas9 to introduce mutations into specific highly conserved regions of *Alg10*, to identify key residues and domains for its catalytic activity, transmembrane domains and potential signal peptide sequences required for localization to the ER.

1481T **Metabolomics and lipidomics studies reveal altered metabolism in a *Drosophila melanogaster* disease model of *PLA2G6*-associated Neurodegenerative disease (PLAN)** Shahira Helal Arzoo[1], Rubaia Tasmin[2], Eliezer Heller[3], Jeremy Purow[3], Josefa Steinhauer[3], Surya Jyoti Banerjee[4] [1]BIOLOGY, Texas Tech University, [2]Biology, Texas Tech University, [3]Biology, Yeshiva University, [4]Biological Sciences, Texas Tech University

The recently described *Drosophila melanogaster* models of *PLA2G6*-associated neurodegeneration (PLAN), which carry loss of function mutations in the calcium-independent phospholipase A2 (iPLA$_2$) VIA gene, exhibit age dependent locomotor defects, reduced life-span, and female specific fertility defects. We previously showed that wild-type *iPLA$_2$-VIA-PB* localizes to mitochondria in female germ cells, and that in aged *iPLA$_2$-VIA* null mutant female flies, the germ cells show abnormal mitochondrial aggregation and elevated apoptosis. These observations, along with data from other systems suggesting important roles of *iPLA2-VIA* at mitochondria, led us to investigate whether systemic mitochondrial functions are perturbed in *iPLA2-VIA* null mutants. We hypothesized that age-dependent and sex-specific metabolic abnormalities would be observed in *iPLA2-VIA* mutant flies. Therefore, we performed mass-spectrometry of small metabolites and of lipids isolated from young (< 1 week) and aged (1 month) *iPLA2-VIA* null mutant and isogenic control, adult male and female flies, and we analyzed the data with SIMCA and MetaboAnalyst software. We identified 195 small metabolites and 379 lipids that passed the quality control. We identified the metabolites and lipids that are significantly up- or down-regulated by at least 1.5-fold in the aged control flies compared to the aged *iPLA2-VIA* null mutant flies. In the aged male mutant flies, 27 metabolites are upregulated and 55 metabolites are downregulated; furthermore, 3 lipids are upregulated and 303 lipids are downregulated. In the aged female mutant flies, 46 metabolites are upregulated and 36 metabolites are downregulated; further, 130 lipids are upregulated and 102 lipids are downregulated. The Principal Component Analysis (PCA) reveals that there is almost complete overlap of the metabolic profiles between young *iPLA2-VIA* null mutant and control male flies, and partial overlap of those in the aged mutant and control male flies. The PCA analysis of lipidomics data shows that the lipid profiles of only the young mutant and old control male flies are very different. Conversely, complete separation of the metabolites is observed in the young and aged mutant females, and in the young and aged control females. Interestingly, the profile of metabolites in the young *iPLA2-VIA* null mutant female flies has close similarity with that of the old control female flies, suggesting that *iPLA2-VIA* mutant females experience premature aging. This raises the possibility that the female fertility defect and associated ovarian phenotypes derive from the somatic metabolic environment, consistent with our data showing that *iPLA2-VIA* knockdown in somatic tissues only can phenocopy the ovary defects of the null mutant.

1482T **Toward identification of protective modifiers of perinatal lethality in genetically divergent mice with Cornelia de Lange Syndrome.** Catherine J. Brunton, Steven C Munger The Jackson Laboratory

Cornelia de Lange Syndrome (CdLS) is a rare multisystem malformation syndrome that presents at birth with a spectrum of deficits, including limb truncations, craniofacial defects, heart defects, developmental delays, and early lethality. Mutations in cohesin complex associated genes, predominantly in NIPBL, are implicated in most cases of CdLS, yet 30% of affected humans lack mutations in canonical genes. Furthermore, a wide range of disease manifestation from mild to severe cases suggests that other gene variants could play a protective or sensitizing role. While the low incidence of CdLS (1:10,000 live births) prohibits large genome-wide association studies in the human population, emerging genetic resources in mice hold promise for finding genetic modifiers of CdLS-associated phenotypes.

The common C57BL/6J (B6) laboratory strain is particularly sensitive to a hypomorphic gene trap allele of *Nipbl*, with few heterozygous mice surviving to one week of age. In contrast, F1 hybrid progeny from reciprocal crosses of B6 with the evolutionarily divergent CAST/EiJ (CAST) strain are largely protected from effects of the *Nipbl* gene trap allele, with most heterozygous CASTB6F1 progeny living to adulthood and maintaining fertility. These observations suggest that the CAST genetic background harbors at least one dominant, protective modifier allele.

To profile genomic differences between our two CdLS-affected mouse strains, we will perform allele-specific expression analysis on RNA-seq data obtained from developing cerebral cortex and kidney of female *Nipbl*+/- and *Nipbl*+/+ embryos harvested from both the CdLS-sensitive B6 and CdLS-protective CASTB6F1 strains. Within CASTB6F1 *Nipbl*+/- individuals, we will apply EMASE software to map genes that exhibit unequal transcript abundance between the CAST and B6 alleles (i.e., allelic imbalance). Transcript abundance estimates in CASTB6F1 *Nipbl*+/+ and B6-derived heterozygous and wild-type tissues will serve as controls. Cis-acting strain variation likely underlies allelic differences in gene expression, and one or more genes exhibiting differential allelic expression in tissues harvested from affected individuals may be associated with the observed strain differences in viability and other defining features of the CdLS phenotype. Ultimately, identification of protective allele(s) could provide a genetic marker for enhanced diagnosis or potentially a novel gene target for therapeutic interventions in CdLS patients.

1483T **Multiple genetic loci influence vaccine-induced protection against *Mycobacterium tuberculosis* in genetically diverse mice** Sherry Kurtz[1], Richard Baker[2], Daniel Gatti[3], Karen Elkins[4] [1]CBER/OVRR, US Food and Drug Administration, [2]University of Massachusetts, [3]Jackson Laboratories, [4]US Food and Drug Administration

Diversity Outbred (DO) mice are a genetically and phenotypically diverse small animal population uniquely suited for performing genetic mapping studies. We used DO mice to study vaccine-induced responses to *Mycobacterium tuberculosis* (Mtb) challenge. Over 1000 DO mice were vaccinated with BCG, challenged with Mtb 8 weeks later, then followed for 14 weeks before euthanasia and sample collection. Compared to naïve DO mice, BCG-vaccinated animals were largely protected from early morbidity, and across the population lung and spleen Mtb burdens were reduced in vaccinated mice. Some vaccinated mice contained high levels of *M.tb*. in lungs and spleens, while others apparently cleared *M.tb*. from spleens. Evaluation of lung tissues revealed diverse disease pathologies in terms of the proportion of inflamed lung tissue as well diverse pathologies. From a subset of 300 DO mice, levels of 37 cytokines were quantified in lung tissue samples collected necropsy. Cytokine expression patterns across the DO population were heterogenous, and several cytokines significantly correlated with lung or spleen bacterial burdens. Infection outcomes, such as lung and spleen Mtb CFU and cytokine data, were used to perform Quantitative Trait Locus (QTL) mapping. Mapping revealed novel QTL associated with disease traits such as weight loss and lung and spleen Mtb burdens. Similar to observations in humans, BCG vaccination provided greater protection in DO mice against systemic versus pulmonary Mtb, and QTL analyses revealed 2 loci associated with the ratio of lung/spleen Mtb. Genetic mapping also revealed several novel QTL associated with lung cytokines including lung IL1a, CXCL1 and IL13. These cytokine-associated loci are largely independent of infection trait QTL and may reveal novel regulatory pathways for these cytokines and novel associations with protection. Taken together, our analyses revealed novel genetic loci associated with vaccine-induced protection against Mtb and point to genes associated with these loci. Importantly, results imply that protection is multigenic, influencing various aspects of immunity that collectively are critical for protection.

1484T **Generation, Genetic Characterization and Phenotypic Analysis of a Novel *Serpina1* Rat Model** Brooke Bowman, Daniel Davis, Elizabeth Bryda University of Missouri

SERPINA1 is a gene that codes for the alpha-1 antitrypsin protein, a serine protease inhibitor produced primarily in the liver. Alpha-1 antitrypsin plays a key role in the inactivation of proteolytic enzymes in lung tissue, especially neutrophil elastase. Excess neutrophil elastase can cause lung damage. Mutations in *SERPINA1* can result in a genetic disorder known as alpha-1 antitrypsin deficiency. Over one hundred *SERPINA1* variants have been associated with this disorder which leads

to adverse health effects, particularly liver and lung disease. One variant is the S allele (p.Glu264Val). The S allele produces an atypical type of alpha-1 antitrypsin that results in reduced serum alpha-1 antitrypsin concentration. Inheritance of this allele is associated with a small risk for lung disease. Using CRISPR-Cas9 genome editing, we generated a novel rat model carrying the *Serpina1* S allele. This is the first reported rat model with a genetic alteration in the *Serpina1* gene. As part of the phenotypic characterization of the model, we have optimized salivary chloride assays to test the hypothesis that the *Serpina1* mutant rats have reduced chloride levels. This new rat line will provide an animal model for researchers interested in studying *Serpina1* and understanding the biological consequences of mutating the gene. (Funded by NIH grant P40 OD011062 to ECB).

1485T **Mitochondrial phenotypes in BXD models of aging and Alzheimer's disease** Mikhail Tiumentsev[1], Stephen E. Alway[2], Richard Cushing[2], Malik Hullette[2], Jesse Ingels[2], John T. Killmar[1], Melinda McCarty[2], Hector G. Paez[2], David Ashbrook[1] [1]Genetics, Genomics and Informatics, The University of Tennessee Health Science Center, [2]The University of Tennessee Health Science Center

The connection between mitochondrial dysfunction and aging is well-established, and mitochondrial dysfunction seems to contribute to the pathogenesis of Alzheimer's disease (AD). However, the exact mechanistic nature of this connection is not fully understood. One of the main scientific gaps is that the interactions between mitochondrial function, multiple genetic variants, and health outcomes are not known. Many animal models use a single genome in a single environment to address this problem, but this approach does not accurately represent the highly genetically and environmentally diverse human population found in a clinical setting. These studies are further complicated by the many variables that define mitochondrial function.

The ongoing study aims to identify a link between genotype, environment, and mitochondrial function, gaining an insight into their interaction. Here we present the preliminary data for a project investigating mitochondria in the BXD and the AD-BXD isogenic strains. Our experiment is intended to provide detailed, tissue-specific data on the activity of the mitochondrial respiratory chain, reactive oxygen species (ROS) production, and mitochondrial DNA (mtDNA) copy number in mice described by the combination of age, sex, genetic background, and 5XFAD transgene status. We analyze data obtained in our experiment in two ways: on the group level: to identify sex, age or transgene effects on mitochondrial function; and on the strain level: to look for associations with other phenotypes collected in the population, including behavior and neuroanatomy.

Our preliminary data show connection between mtDNA copy number, respiratory activity and BXD strain longevity in 6-month-old animals with the 14-month-old group to be assessed next. We combine the data on mtDNA copy number obtained with a high throughput method of qPCR from many samples and data from a low-throughput method of high-resolution respirometry (HRR). HRR experiments are usually restricted to a small number of experimental groups to process enough samples. In our experiment, in order to be able to compare the HRR against the mtDNA copy number data from all experimental groups we use an incomplete nested design and linear mixed models. Subsequent measurements of ROS production following the same design as in HRR will be added to the respirometry data. This approach allows us to obtain important bioenergetic data and draw conclusions for each grouping factor, addressing a significant limitation within the field of bioenergetics, while capitalizing on the well-defined genetics of the BXD and AD-BXD strains.

In summary, our findings elucidate the mechanisms behind the interactions of genetic makeup, mtDNA copy number, and mitochondrial function in aging and AD, thus paving the road to the development of translatable interventions.

1486T **Elucidating candidate genetic mechanisms and underlying modifier genes leading to background-dependent tumor growth in the absence of ERBB3 in colorectal cancer** Kaitlyn E Carter, Michael P McGill, David W Threadgill Cell Biology and Genetics, Texas A&M University

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths in the United States. Significant progress has been made in early detection, diagnosis, and treatment through the developments in precision medicine and increased understanding of the molecular mechanisms governing CRC progression. Overall mortality rates have trended downward over the last five decades but have increased for those under fifty-nine. This study focuses on the need to improve targeted therapeutic approaches based on the genetic alterations of the host and tumor molecular signatures. The ERBB receptor tyrosine kinase family activates genetic mutations and aberrant signaling in pathways. These receptors govern various complex biological functions associated with dysregulated cell proliferation and survival. ERBB3, a pseudo-kinase, lacks intrinsic kinase activity and relies on transactivation of other ERBB receptors. Due to their prominent role in these pathways, the ERBB family

has been investigated as therapeutic targets and seemed promising in preclinical studies. It was shown that intestinal-specific deletion of ERBB3 leads to a significant reduction in colon and intestinal tumor multiplicities. However, the ERBB family performed with little to no efficacy and even promoted tumor growth in some cases during clinical trials. Our group performed additional experiments suggesting that intestinal-specific ERBB3 ablation was genetic background dependent, and that this tumor growth response could be mediated by EGFR (Mantilla-Rojas et al, 2021). This study aims to use novel mouse models to understand the background-dependent tumor growth in the absence of ERBB3 in CRC. By leveraging an F2 population and polyp count distribution, we capture the total phenotypic variance of the 129S1/SvlmJ (129) and C57BL/6J (B6) mouse populations through quantitative trait loci. In doing so, we can better identify molecular signatures or modifier genes and corresponding biomarkers contributing to this effect. We further characterize ERBB3 and EGFR transcript, protein, and protein localization differences in backgrounds using mouse intestinal organoids. ERBB3 and EGFR inhibitor resistance is investigated using mouse intestinal organoids and patient-derived organoids (PDO). We will use these findings to elucidate pathways contributing to tumor progression in the absence of CRC. These studies will broaden our mouse study and better address translational gaps seen in cancer research.

1487T **Machine learning for quantification of behavior in rodent models of aging and Alzheimer's disease.** Joy Afolabi[1], John T Killmar[1], Michael P McDonald[2], Allan G Johnson[3], Robert W Williams[1], David G Ashbrook[1] [1]Genetics, Genomics, and Informatics, University of Tennessee Health Science Center, [2]University of Tennessee Health Science Center, [3]Duke University

Background:

Aging is a major risk factor for many diseases, including Alzheimer's disease (AD). The prevalence of AD continues to be positively correlated with longevity. Alzheimer's disease (AD) is a complex disease, that destroys neurons and brain cells involved in memory and eventually affects reasoning and social behavior. Accurate quantification of behavior is vital for exploring the genetics of these different aspects of AD. Machine learning tools are recently being used to quantify these behaviors.

Research aim:

Mouse models have traditionally been used for behavior assays to test phenotypes including memory, gait and frailty. However, these models have traditionally involved the manual analysis of a limited number of pre-defined behaviors. We aim to use 'computerized' behavior quantification to explain genetic predisposition to aspects of AD and to identify new phenotypes that may be associated with AD and aging in mouse models.

Methods:

We will identify novel behavioral phenotypes associated with aging and Alzheimer's disease within traditional assays, using AD-BXD model mice. We will then use QTL mapping to determine regions of the genome associated with variation in any phenotype measured. Following, we will search for genes within the QTL to identify candidate genes that may influence our trait of interest. We have previously collected videos of mice exploring a snowflake maze. We will use DeepLabCut and a modified version of High-Resolution Net (HRNet) software (supervised learning) as well as Motion Sequencing (MoSeq) or DeepOf (unsupervised learning) in conjunction with Simple Behavioral Analysis (SimBA) software to test if machine learning tools can accurately quantify these behavioral phenotypes of aging and Alzheimer's disease.

Expected Findings:

Alzheimer's disease and aging both lead to a range of linked phenotypes. We aim to identify phenotypes which may be unique to one or shared by both and identify genetic loci underlying these phenotypes.

1488T **CCR6 is required to generate an effective host immune response during *Mycobacterium tuberculosis* infection in mice** Summer Harris[1], Rachel K. Meade[1], Kaley M. Wilburn[1], Alwyn Ecker[1], Oyindamola Adefisayo[1], Ashley Moseman[2], Clare Smith[1] [1]Molecular Genetics and Microbiology, Duke University, [2]Integrative Immunobiology, Duke University

Tuberculosis (TB) remains among the most prevalent infectious diseases in human history and is caused by infection with *Mycobacterium tuberculosis* (Mtb). Mtb is highly successful at infecting and surviving in humans, resulting from a long history of host-pathogen coevolution. TB disease progression is heterogeneous within and between individuals and is impacted by a variety of genetic and environmental risk factors. During Mtb infection, cytokines and chemokines must be carefully balanced to promote bacterial killing or containment without causing excessive inflammation and damage. CCR6 is a chemokine receptor that is expressed by myeloid dendritic cells (DCs), effector and memory T cells, and B cells. CCL20, the only known ligand for CCR6, functions as a chemoattractant that recruits CCR6-expressing immune cells. It has been proposed that CCR6/CCL20 may play a protective role in TB immunity. Here, we sought to establish whether $CCR6^{-/-}$ mice (B6.129P2-

Ccr6^{tm1Dgen}/J) are able to maintain control of Mtb infection. We aerosol infected CCR6$^{-/-}$ mice with Mtb and profiled them at 2, 3 and 4 weeks post-infection. We quantified survival, weight change, bacterial burden and cytokines from the lung, and bacterial dissemination in the spleen. CCR6$^{-/-}$ mice had higher bacterial burden in both the lung and spleen relative to CCR6$^{+/+}$ controls. Additionally, CCR6$^{-/-}$ mice had an increased risk of early death. Overall, this study establishes the functional importance of CCR6 in generating a protective immune response to Mtb.

1489T **Killer toxin K62 of *S. paradoxus* is a novel aerolysin toxin** Jack Creagh Biological Sciences, University of Idaho

Pore-forming proteins are found across the tree of life in various roles, including toxins that kill cells by creating pores, causing uncontrolled ion leakage. Aerolysin toxins are a family of pore-forming toxins commonly found in bacteria, where they function as virulence factors that cause hemorrhagic diseases in animals. Although diverse aerolysins share similar mechanisms of cytotoxicity, they have little to no amino acid sequence conservation. Therefore, the aerolysin family is defined by a five beta-sheet domain, which positions an amphipathic loop in the membrane responsible for membrane pore formation. Using the protein structure prediction software AlphaFold2, we have identified a putative aerolysin toxin named K62, produced by the yeast *Saccharomyces paradoxus*. Our model of K62 has high structural similarity to the bacterial aerolysin-family toxin parasporin-2 with an LDDT over 90 and a root mean squared deviation (RMSD) of 5.5 Å. K62 was first identified as an antifungal "killer" toxin, thought to play a role in niche competition between wild yeasts. K62 is similar to many canonical killer toxins in that it is most active at inhibiting the growth of other fungi at an acidic pH and temperatures less than 30°C. To test our modeling predictions that define K62 as an aerolysin-family toxin, we have developed ectopic expression systems for K62 that recapitulate the antifungal activities of K62. Recombinant K62 forms SDS and heat-resistant complexes with apparent molecular weights of 55 kDa and >250 kDa. These oligomers are considerably larger than the predicted K62 monomer (27.5 kDa) and likely represent stable dimers and possible oligomeric pores. Oligomerization is a crucial step in aerolysin pore formation that is also heat and SDS-resistant due to the prion-like oligomerization of the five-beta sheet domain. Although K62 is an antifungal killer toxin, we have found K62 like sequences in plant pathogenic fungi such as *Fusarium sp.* and the emerging human pathogen *Candida auris*. Given the known role of aerolysins in bacterial pathogenicity, we speculate that K62-like proteins could also be relevant in fungal disease. Using computational, genetic, and biochemical techniques, we have characterized a novel aerolysin family toxin in *Saccharomyces* yeasts that will serve as a powerful model for the future discovery and characterization of diverse aerolysin-family pore-forming toxins.

1490T **Characterization of novel disease-linked mutations in the RNA exosome in *Saccharomyces cerevisiae*** Milo B. Fasken[1], Sara W. Leung[2], Anita H. Corbett[2] [1]Biology, Emory University, [2]Emory University

The RNA exosome is an essential, evolutionarily conserved ribonuclease complex that processes and/or degrades multiple classes of RNA. The 10-subunit complex is composed of an upper ring of three structural 'cap' subunits (Human EXOSC1-3; *S. cerevisiae* Csl4/Rrp4/Rrp40), a lower ring of six structural 'core' subunits (EXOSC4-9; Rrp41/Rrp46/Mtr3/Rrp42/Rrp43/Rrp45), and a catalytic ribonuclease (DIS3/Dis3) at the bottom of the complex. With the assistance of exosome cofactors, RNA substrates are fed through the central channel of the complex to DIS3/Dis3 for processing/decay. Recently, missense mutations in RNA exosome genes *EXOSC1/3/8/9* have been linked to pontocerebellar hypoplasia type 1 (PCH1) and missense mutations in *EXOSC4/5* have been linked to neurodevelopmental disorders. In addition, missense mutations in *EXOSC2*have been linked to a novel syndrome characterized by short stature, hearing loss, retinitis pigmentosa, and distinctive facies (SHRF). To determine the molecular defects associated with missense variants of the human RNA exosome subunits, we and others have developed budding yeast models that express the disease-linked missense variants of the *S. cerevisiae* RNA exosome subunits. To date, these yeast models have shown that several disease-linked subunit variants of the RNA exosome impair yeast growth, reduce RNA processing, decrease subunit levels, and disturb translation. Here, we characterize a novel set of *EXOSC/rrp* mutations in *S. cerevisiae* and compare these to the previously studied *EXOSC2/3/5-rrp4/40/46* yeast models. These studies shed further light on how missense subunit variants of the RNA exosome can alter the function of the complex, potentially in mechanistically distinct ways, and provide insights into the molecular defects that could occur in the cells of affected individuals.

1491T **Human disease modeling in *Xenopus laevis* and *Xenopus tropicalis* at the *Xenopus* Mutant Resource** Zoë T Reynolds[1], Kelsey Coppenrath[1], Sarah Porter[1], Ben Evans[2], Artur Llobet[3], Helen Willsey[4], Gerald Thomsen[5], Richard Behringer[6], Marko Horb[1] [1]Eugene Bell Center for Regenerative Biology and Tissue Engineering, Marine Biological Laboratory, [2]Biology, McMaster University, [3]3Laboratory of Neurobiology, Bellvitge Biomedical Research Institute, [4]Department of Psychiatry, University of California San Francisco, [5]Department of Biochemistry and Cell Biology, Stony Brook University, [6]7Department of Molecular Genetics and Program in Genes and Development, University of Texas Houston

At the *Xenopus* Mutant Resource (XMR), we have closely collaborated with the *Xenopus* community to prioritize the generation of null knockout mutants in both *Xenopus tropicalis* and *Xenopus laevis* genes of interest. Generating these

lines at the XMR allows the community to take advantage of our efficient CRISPR pipeline, in addition to the husbandry and lab resources available to help expedite your research project. To date we have generated over 250 mutant lines spanning many research disciplines. My work consists of managing and establishing over 40 mutant gene lines. Specific genes I have targeted have resulted in striking phenotypes. In F0 *X. tropicalis edn3* mutants present we find loss of pigment. *Pax7* null *X. laevis* froglets feature severe bloating around stage 54 of development. We have also created several mutants in genes involved in sex determination, including *dm-w* and *dmrt1*, both of which display a striking phenotype. We have also created *X. tropicalis* mutants *naglu* and *lamp2* are actively being examined for a phenotype due to their role in lysosomal storage and regulation. In this poster, I will present our methodology and progress in generating these various CRISPR knockouts and how the resources at the XMR can help streamline research on these human disease models.

1492T **Functional characterization of the chr1p36.33 *KLHL17*/*NOC2L* pancreatic cancer risk locus suggests effects on the unfolded protein response pathway** Katherine Hullin[1], Ehssan Abdolalizadeh[1], Jun Zhong[1], Jason Hoskins[1], Daina Eiser[1], Michael Mobaraki[1], Aidan O'Brien[1], Ashley Jermusyk[1], Irene Collins[1], Sudipto Das[2], Thorkell Andresson[2], Pancreatic Cancer Cohort Consortium (PanScan)[1], Pancreatic Cancer Case-Control Consortium (PanC4)[1], Rachael Z. Stolzenber-Solomon[1], Allison P. Klein[3,4,5], Jianxin Shi[1], Brian M. Wolpin[6], Jill P. Smith[7], Samuel O. Antwi[8,9], Katelyn E. Connelly *[1], Laufey T. Amundadottir *[1] [1]Division of Cancer Epidemiology and Genetics, National Cancer Institute, [2]Frederick National Laboratory for Cancer Research, [3]Department of Epidemiology, Johns Hopkins School of Public Health, [4]Department of Oncology, Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins School of Medicine, [5]Department of Pathology, Sol Goldman Pancreatic Cancer Research Center, Johns Hopkins School of Medicine, [6]Department of Medical Oncology, Dana-Farber Cancer Institute, [7]Department of Medicine, Georgetown University, [8]Division of Epidemiology, Department of Quantitative Health Sciences, Mayo Clinic, [9]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Mayo Clinic

Pancreatic ductal adenocarcinoma (PDAC) is predicted to become the second leading cause of cancer-related deaths in the US by 2030. Genome wide association studies (GWAS) for PDAC identified chr1p36.33, tagged by rs13303010 (P=7.3x10^{-7}), as a risk locus. Two nearby candidate target genes were implicated by expression quantitative trait locus (eQTL) analysis: *KLHL17* and *NOC2L*. Initial *in vitro* assays to identify variants with allele-specific activity demonstrated enhanced binding and transcriptional regulatory activity for the protective allele. This aligns with an eQTL for *KLHL17* in the Genotype-Tissue Expression (GTEx) v8 dataset, where higher *KLHL17* expression is linearly associated with protective allele dosage (P=4.9x10^{-9}, β = 0.35).

In silico knockdown of *KLHL17* in the pancreas GTEx data reveals lower *KLHL17* is associated with lower expression of heat shock protein genes. We hypothesize that decreased expression of *KLHL17* leads to a reduction in the level of heat shock proteins available to facilitate newly synthesized protein folding leading to increased un/misfolded proteins in the endoplasmic reticulum (ER), ER stress, and dysregulation of the unfolded protein response (UPR). This could result in increased apoptosis, inflammation, and pancreatic cell regeneration, which may promote tumorigenesis.

Under normal conditions, overexpression of *KLHL17* does not confer a growth phenotype, but knockdown of *KLHL17* results in decreased proliferation and increased apoptosis. Under ER stress conditions, this apoptosis phenotype is exacerbated, revealing an interaction effect between *KLHL17* knockdown and ER stress (P=1.16x10^{-6}). We then assessed if the reduction of *KLHL17* expression alters cellular response to ER stress in the normal-derived pancreatic ductal epithelial cell line HPDE. Under ER stress conditions, there is an approximate two-fold increase in spliced *XBP1, HSP5A* and *PERK* mRNA expression when *KLHL17*expression is reduced, suggesting an increased activation of the UPR with reduced *KLHL17* expression.

To determine what role *KLHL17* might be playing in the UPR, we performed KLHL17-FLAG immunoprecipitation followed by mass-spectrometry. This revealed Cullin-3, an E3 ubiquitin ligase, is enriched upon *KLHL17* overexpression and pull-down. Work is ongoing to further elucidate KLHL17's role in pancreatic cells. Understanding how KLHL17 interacts with underlying processes and promotes tumorigenesis may provide insight into potential preventative or therapeutic approaches for patients with a predisposition towards UPR-driven pancreatitis.

1493T **A Yeast Phenomic Model for Mitochondrial DNA Release** Tapasya Katta[1], Ryan Mancinone[2], Keshav K Singh[2], John L Hartman[2] [1]University of Alabama at Birmingham, [2]Department of Genetics, University of Alabama at Birmingham

Release of mitochondrial DNA from the mitochondrial compartment is implicated in the initiation of innate inflammatory responses, mutagenic integration into the nuclear genome, cancer, and related pathologic processes. The first genes to be involved in regulating escape of mitochondrial DNA were identified in *S. cerevisiae*. In particular, *YME1* is an evolutionarily conserved gene that has also been strongly implicated in cancer and is also studied with increasing interest for its role in triggering innate immunity. Other factors in maintaining the mitochondrial outer membrane barrier and in regulating mitochondrial DNA transport across it are highly conserved. We are attempting to more fully characterize evolutionarily

conserved aspects of this gene network, leveraging the mitochondrial escape reporter, together with the *S. cerevisiae* gene deletion strain collection, synthetic genetic array methodology and custom high throughput cell array phenotyping technology developed in our laboratory. The yeast mitochondrial escape (YME) reporter has a CEN element and the TRP1 gene integrated into mitochondrial DNA, so that presence of this modified mitochondrial genome in the nucleus can be detected in a *trp1* auxotroph plated on tryptophan dropout media. We confirmed that the mitochondrial DNA escape phenotype of the *yme1-1* allele segregates as a single gene trait. Other preliminary work on the model has revealed that a point mutation in *YME1* has much greater influence on mitochondrial DNA release than the knockout and ways to enhance the sensitivity of the screen include adding low dose HU and early entry into stationary phase. Our SGA strategy is to first deplete mitochondrial DNA in the yeast gene deletion strain (YGDS) library, and then to introduce the *TRP1*-containing mitochondrial DNA reporter and *trp1* auxotrophy, recovering the haploid YGDS library competent for screening by quantitative high throughput cell array phenotyping. The screen optimization is nearly complete, and we intend to report the results along with consequent hypothesis generation and testing of related hypotheses and other progress during the meeting.

1494T **Genome-wide association study of extended replicative lifespan in outbred populations of *Saccharomyces cerevisiae*** Katie M McHugh, Felipe Barreto, Molly Burke Oregon State University

Longevity varies substantially within and among species, as do heritability estimates for this trait. While molecular genetic techniques have identified many conserved genes and gene regulatory pathways involved in aging and longevity, it is unclear which of these are the most important in regulating observed variation in lifespan within populations. Genome-wide association studies (GWAS) are powerful tools for parsing the relationships between phenotypic and genomic variation, and have been used to investigate the genetic basis of longevity across a number of species, including humans. However, it can be challenging to achieve sufficiently large, unbiased cohorts of long-lived individuals for this approach to be successful in natural populations. Thus, applying GWAS methods to controlled laboratory populations of model organisms can strengthen and supplement the conclusions made in other systems. In this study, we use outcrossed populations of the yeast *Saccharomyces cerevisiae* that harbor extensive standing genetic variation as a GWAS model. Using pooled-population methods, we sequence the genomes and transcriptomes of age-sorted cohorts to investigate the genetic basis of replicative lifespan - the number of times a yeast cell is capable of dividing before death. We show that fluorescence-activated cell sorting (FACS) produces cohorts of cells with significantly differentiated replicative ages, and we use this technique to isolate young and old age cohorts in 12 replicate populations. In each replicate, we compare the genome-wide allele frequencies and global gene expression patterns between the descendants of the young and old cells. We identify candidate alleles that are overrepresented in populations capable of achieving increased replicative ages. We also make connections between observed differences in allele frequencies and observed differences in gene expression to investigate the potential functional consequences of these candidate alleles for replicative lifespan.

1495T **Mutational mapping using dominant synthetic lethal screening to uncover cohesin structure-function relationships** Elizabeth Stephens[1], Nigel O'Neil[2], Peter Stirling[3], Philip Hieter[1] [1]Medical Genetics, Michael Smith Laboratories, University of British Columbia, [2]Michael Smith Laboratories, University of British Columbia, [3]Medical Genetics, BC Cancer Research Center, University of British Columbia

Background: Cancer remains a leading cause of mortality worldwide. Understanding the underlying genetics of a tumour can allow for a personalized approach to exploit genetic vulnerabilities, leading to outcomes with increased effectiveness. One strategy of genetically targeting tumour cells is through synthetic lethal (SL) interactions. A SL interaction between two genes occurs when the disruption of either gene alone is viable, but the disruption of both genes simultaneously results in cell death. Although targeting SL interactions holds immense therapeutic potential, only PARP inhibitors have translated to the clinic. PARP inhibitors are unique in that they cause a gain-of-function (GoF) change in the PARP protein resulting in selective cytotoxicity in BRCA1/2-mutated tumours. The concept of GoF opens new target opportunities for therapeutic design. The cohesin complex (SMC1, SMC3, RAD21, and STAG2) is a compelling target for GoF therapeutic design. Cohesin plays roles in sister chromatid cohesion, DNA damage repair, and chromatin organization and is frequently mutated in a wide range of tumour types. The Hieter Lab demonstrated that cohesin is a conserved SL network hub that interacts with many cancer-associated mutations, including cancer-associated cohesin mutations. One way to cause SL in cohesin-mutated tumours is to further disrupt the cohesin complex.

Approach: *S. cerevisiae* will be used to employ a novel screening approach focused on dominant GoF synthetic lethal genetics. Screening for dominant mutations allows for the study of essential gene targets such as the cohesin complex. Missense mutational mapping will identify states of the target protein, Smc1, that yield more significant effects than loss or partial loss of function to provide insight into druggable pockets for therapeutic design.

Results: Smc1 mutations were screened in a cohesin-compromised strain to identify GoF mutations. This screening revealed 10

key residues all mapping to the ATPase domain, with specific clustering in the signature motif. These mutations are dominant SL with other cohesin subunits and SL in backgrounds with disrupted cohesin levels and replication defects. When mapped to the 3D structure, many of these mutations cluster in ATP interacting regions, revealing a potentially druggable site. The identified mutations will be further characterized to understand the mechanism of dominance, including evaluating their effects on chromosome cohesion, DNA replication and repair.

Significance: Understanding these mutations lays the groundwork for guiding the development of small molecule inhibitors that phenocopy the dominant protein state. My work aims to better translate genetic interactions into anti-cancer SL therapeutics.

1496T **Quantifying tolerance and resistance to fluconazole in *Cryptococcus neoformans*** Jessica Keeran, Lukasz Kozubowski Genetics and Biochemistry, Clemson University

Rates of antifungal drug tolerance and resistance are a growing concern across the globe. Azole antifungal drugs remain an attractive choice in antifungal therapy due to their low toxicity and affordability, an important factor especially in regions where systemic fungal infections are particularly common. Unfortunately, tolerance and resistance to azoles is common due to their mostly inhibitory effect on fungal cells and relatively lower cidal effect. Studies investigating the response of fungal pathogens to azoles are mostly executed in vitro under conditions that are significantly different than the host environment. Therefore, systematic studies of how environment impacts tolerance and resistance to antifungals are essential to improve therapies. The effects of various conditions on tolerance and resistance to the azole drug, fluconazole, have been modeled quantitatively using *Candida albicans*, a common fungal pathogen. However, minimal research has been done to quantify and model azole antifungal drug tolerance and resistance in *Cryptococcus neoformans*. *C. neoformans* is a basidiomycetous pathogenic yeast spread ubiquitously across the globe and is the major causative agent of fungal meningoencephalitis. This pathogen is responsible for approximately 15% of all AIDS-related deaths. One of the most applied antifungal medications for maintenance therapy in cryptococcosis is fluconazole. This study utilizes quantitative techniques that have been previously utilized in *C. albicans* to characterize how various environmental factors impact fluconazole resistance and tolerance in a variety of wild type *C. neoformans* strains. Disk diffusion assays and the image analysis software, diskImageR, were utilized to assess the influence of temperature, media type, and the pretreatment of the cells with various environmental stressors on the development and dynamics of tolerance and resistance to fluconazole. Both temperature and media type significantly impacted *C. neoformans* evolution of resistance and tolerance to fluconazole. Interestingly, some of these effects were also strain specific. Overall, this research displays the complex nature of antifungal drug responses in *C. neoformans*, points the way towards future studies, and could provide insights to help optimize anticryptococcal therapy.

1497T **Overexpression screen of chromosome 21 orthologs in larval zebrafish** Anna J Moyer[1], Claire Conklin[2], Mary Shay Capps[1], Eshika Kudaravalli[2], Summer B Thyme[1] [1]UMass Chan Medical School, [2]University of Alabama at Birmingham

Although Down syndrome is a leading cause of intellectual disability, understanding which chromosome 21 genes contribute to its neurodevelopmental phenotypes remains a critical barrier to developing effective therapies. Larval zebrafish models provide access to high-throughput in vivo brain imaging, behavioral assays, and drug screens that are not possible in Down syndrome mouse models. We leveraged the unique advantages of zebrafish to generate 76 transgenic lines representing 26 human chromosome 21 genes. We are evaluating the neurodevelopmental effects of overexpressing these transgenes using the GAL4/UAS system. A leading candidate gene is *HMGN1*, which competes for binding with histone H1 and promotes chromatin decompaction by binding to the nucleosome core particle. Overexpression of *HMGN1* inhibits Sonic hedgehog signaling, which is disrupted in Down syndrome. To understand how *HMGN1* overexpression affects neurodevelopment in vivo, we cloned cDNAs of three zebrafish HMGN1 homologs (*hmgn6*, *si:ch73-1a9.3*, and *si:ch73-281n10.2*) as well as cDNAs encoding *HMGN1* and *hmgn6* with mutations in the 'RRSARLSA' nucleosome-binding domain. Initial characterization of these lines found that overexpression of hmgn6 using a pan-neuronal driver results in pronounced changes in brain structure and activity, including reduced volume of the midbrain, increased activity of the optic tectum, and reduced activity of the hindbrain. *Hmgn6* overexpression also affected larval behavior, with transgenic fish showing significant disruptions in daytime activity, center preference, and response to acoustic stimuli. Using bulk RNA sequencing, we found that *hmgn6* overexpression affects the expression of transcripts encoding both epigenetic and synaptic proteins. We are currently using single-nucleus RNA sequencing to explore whether overexpression of *HMGN1* homologs disrupts cellular composition or state. Our ultimate aims are to understand how overexpression of trisomic genes affects brain development and behavior in people with trisomy 21 and to identify potential drug targets for treating Down syndrome-associated intellectual disability.

1498T **Progressive motor and non-motor symptoms in park7 knockout zebrafish** Lakshmi Narasimha Murthy Chavali[1], Ingeborg Iddal[2], Ersilia Bifulco[2], Simen Mannsåker[1,1], Dagne Røise[1], Jack O Law[2], Ann-Kristin Frøyset[1], Sushma N Grellscheid[2], Kari E Fladmark[2] [1]Molecular Biology, University of Bergen, [2]University of Bergen

In our exploration of the connection between DJ-1 mutations and early-onset Parkinson's Disease (PD), a disorder marked by a range of motor and non-motor symptoms, we've honed in on DJ-1's pivotal role in shielding against oxidative stress. Building on insights gained from our DJ-1 null fish model displaying diminished tyrosine hydroxylase levels, respiratory mitochondrial failure, and reduced body mass during aging, we delved into the age-related escalation of PD symptoms. Our investigation, encompassing behavioral analyses and scrutiny of mitochondria and associated proteins, uncovered intriguing nuances. While current research underscores a decline in NAD+ as a potential PD contributor, with NAD+ precursor supplementation suggested for slowing disease progression, our study revealed a distinct narrative. In the aging zebrafish, the NAD+/NADH ratio in the brain dipped, but intriguingly, it did not align with behavioral changes induced by DJ-1 loss. Notably, reductions in NAD+ and NADPH manifested later in adulthood. Our findings advocate strongly for the utility of our DJ-1 null fish model, not only in unraveling PD progression intricacies but also as a robust platform for evaluating proposed therapeutic interventions.

1499F **A *C. elegans* Model for Hyperhomocysteinemia: Implications for Disease and Aging** Karli P Sunnergren, Jessica Tanis Biological Sciences, University of Delaware

The amino acid homocysteine is broken down into cystathionine by cystathionine beta-synthase (CBS) or converted to methionine by methionine synthase, which requires vitamin B_{12} as an essential cofactor. Low vitamin B_{12} and CBS deficiency can cause hyperhomocysteinemia, which is characterized by an abnormally high level of total homocysteine in the blood. Hyperhomocysteinemia is a risk factor for cardiovascular disease, vascular dementia, and Alzheimer's disease (AD), although the mechanism underlying the connection between increased homocysteine and these pathologies is not well understood. Loss of cystathionine beta-synthase in mice, flies, and zebrafish causes lethality, preventing the use of these models to understand how elevated homocysteine affects aging and organismal homeostasis. We have knocked out *cbs-1* in C. elegans, which is 54% identical to human *CBS*, creating the first viable model of hyperhomocysteinemia. Loss of *cbs-1* results in increased homocysteine, which is reduced with B_{12} supplementation due to increased conversion of homocysteine to methionine. *cbs-1* mutants exhibit delayed development, reduced brood size, decreased body length, and extended lifespan, all of which return to wild-type levels when the animals are supplemented with B_{12}. Surprisingly, loss of *cbs-1* paralog *cbs-2* does not result in any changes to the aforementioned phenotypes, which may be due to differences in spatiotemporal expression. We have also discovered that *cbs-1* mutants are resistant to paralysis when exposed to the acetylcholinesterase inhibitor aldicarb, suggesting decreased acetylcholine (ACh) in the synaptic cleft. Additionally, *cbs-1* mutants are hypersensitive to the acetylcholine receptor agonist levamisole, indicating compensatory mechanisms on the post-synaptic side of the neuromuscular junction. Together, these results suggest that high levels of homocysteine, resulting from loss of cystathionine beta-synthase, may decrease ACh release from cholinergic neurons, providing new insight into a potential mechanism by which hyperhomocysteinemia impacts risk for AD.

1500F **Nanodrop method for quantification of Orsay virus particle concentration** Jay Ni, Jessica N Sowa West Chester University of Pennsylvania

The natural infection of *C. elegans* by Orsay Virus supports the study of host-pathogen interactions in *Caenorhabditis* species. Knowledge of viral concentration in experiments involving viral infection is necessary for standardization of further downstream processes. Typical assays for virus particle quantification utilize quantitative polymerase chain reaction (qPCR) to amplify viral DNA/RNA for quantification by fluorescence or ELISA for protein detection of the virus. We pursued a different approach to purify and quantify viral particles using the positive-sense RNA virus, Orsay Virus. Our approach features the Thermo Scientific NanoDrop One^{C} Microvolume Spectrophotometer as an alternative to virus quantification by qRT-PCR and other assays.

We have developed a virus prep and purification protocol using an ammonium sulfate precipitation method and Capto Core 700 chromatography beads. The NanoDrop spectrophotometer is utilized to record measurements of protein quantitation with Modified Lowry Assays. Our data is used to determine the viral particle constant and extinction coefficient of Orsay Virus as those values are directly related to protein concentration. A qRT-PCR standard curve of Orsay RNA1 is used for virus quantification. The data from the NanoDrop spectrophotometer will be compared to qRT-PCR assay of viral particle samples. We predict that our UV absorbance method of virus quantification will be an attractive alternative to qRT-PCR and will present the results of the comparison of our spectrometry method versus qRT-PCR.

1501F **The Role of *C. elegans* Metaxins in Mitochondrial Homeostasis** Jonathan Dietz, Eunchan Park, Nathaly Salazar-Vasquez, Nanci Kane, Carol Nowlen, Christopher Rongo Rutgers University

Mitochondria are critical for neuronal function and health, as they are the primary supplier of energy and calcium storage for neurons. Mitochondrial dynamics – fusion, fission, and motility – facilitate energy production and calcium buffering by mitochondria at specific subcellular sites within neurons. Disturbances in mitochondrial function or dynamics contribute to

various neurodegenerative disorders. Using a forward genetic screen in *C. elegans* searching for novel mutants defective in neuronal mitochondrial dynamics, we found that mutations in metaxin 1 (MTX-1), metaxin 2 (MTX-2), and VDAC-1 resulted in fewer mitochondria in *C. elegans* interneuron dendrites. Mammalian metaxin homologs interact with SAM50 to form the sorting and assembly machinery (SAM) complex, which mediates β-barrel protein assembly in the mitochondrial outer membrane (MOM). VDAC-1 is a highly conserved SAM complex substrate that acts as a channel for metabolites across the MOM. We hypothesize that the metaxins promote mitochondrial motility along *C. elegans* interneuron dendrites by mediating assembly of VDAC-1 in the MOM. Mutants for *mtx-1*, *mtx-2*, and *vdac-1* are viable but have reduced lifespans. We found that the mitochondrial unfolded protein response (UPRmt) was activated in *mtx-2* and *vdac-1* mutants, resulting in heat stress resistance and mitohormesis. We are currently investigating the role of *C. elegans* MTX-1 and MTX-2 in MOM β-barrel protein (VDAC-1) assembly and how that impacts neuron integrity.

1502F **The myosin chaperone UNC-45 has an important role in maintaining the structure and function of muscle sarcomeres during adult aging** Courtney J. Matheny[1], Hiroshi Qadota[1], Aaron O. Bailey[2], Andres F. Oberhauser[2], Guy M. Benian[1] [1]Emory University, [2]University of Texas Medical Branch (UTMB)

Sarcopenia, the decline in muscle mass and function without underlying disease, is a major contributor to physical disability and death in the elderly. The molecular mechanisms responsible remain uncertain. *C. elegans* is an excellent model to study muscle sarcomere assembly, maintenance and regulation, and the genetic basis of aging. *C. elegans* undergo an age-dependent decline in animal locomotion and deterioration of muscle sarcomeres, and thus *C. elegans* is a good model for sarcopenia (Herndon et al. 2002). The myosin head domain requires the conserved chaperone UNC-45 for folding after translation and is likely used to re-fold to functionality after thermal or chemical stress induced unfolding. UNC-45 consists of an N-terminal TPR region that binds to Hsp90, and a central region and UCS domain that bind to myosin heads. We observe early onset sarcopenia when UNC-45 is perturbed at the beginning of adulthood, in a ts *unc-45* mutant, indicating that UNC-45 is important during adulthood. During adult aging, there is sequential decline of HSP-90 (day 3), UNC-45 (day 4), and MHC B myosin (day 8). The mRNAs for these proteins decline earlier, on days 1 or 2. Loss of function of one component of the insulin-like signaling pathway, AGE-1 (PI3 kinase), that results in increased longevity has delayed onset of sarcopenia, including maintenance of A-band numbers even at day 16 of adulthood, and delayed loss of HSP-90, UNC-45 and myosin. There is a similar age-related decline of Hsp90 and UNC-45B in mouse skeletal muscle. During the age-dependent loss of UNC-45, there is phosphorylation of UNC-45, beginning at day 3. In day 4, but not day 0, mass spectrometry reveals phosphorylation of 6 serines and 2 threonines, 7 of which occur in the UCS domain, and 2 of which are in residues conserved between nematode and human UNC-45. Of these 7 sites, 3 are on the surface and 4 are buried inside the UCS domain. Molecular dynamics simulations on the known UCS structure indicate that the UCS domain undergoes large scale movements. We predict that the surface residues are likely phosphorylated first, and that buried sites are exposed by structural changes induced by the phosphorylation of the surface residues. Heat shock promoter driven expression of UNC-45 results in sustained levels of UNC-45 and increased MHC B myosin in older animals. Our results suggest that increased expression or activity of UNC-45 might be a strategy for prevention or treatment of sarcopenia.

1503F **Serotonin deficiency from constitutive SKN-1 activation drives a pathogen apathy state** Tripti P. Nair, Brandy P. Weathers, Sean P. Curran University of Southern California

When an organism encounters a pathogen, the host innate immune system is activated to defend against pathogen colonization and the toxic xenobiotics produced. *C. elegans* employ multiple defense systems to ensure survival when exposed to *Pseudomonas aeruginosa* (PA14) including activation of the cytoprotective transcription factor SKN-1/NRF2. Although wildtype *C. elegans* quickly learn to avoid pathogens, here we describe a peculiar apathy to PA14 in animals with constitutive activation of SKN-1 whereby animals choose not to leave while continuing to feed on the pathogen even when a non-pathogenic food option is available. Although lacking the urgency to escape the infectious environment, animals with constitutive SKN-1 activity are not oblivious to the presence of the pathogen and display a typical intestinal distension from PA14 colonization and eventual demise, but surprisingly, fail to learn to avoid pathogen with training. SKN-1 activation, specifically in neurons and intestinal tissues, orchestrates a unique transcriptional program which leads to defects in serotonin signaling from both neurons and non-neuronal tissues that drives the pathogen apathy behavior and pleiotropic responses to selective serotonin reuptake inhibitors (SSRIs). Taken together our work reveals new insights into how animals perceive environmental pathogens and subsequently alter behavior and cellular programs to promote survival.

1504F **Mitochondrial stress in GABAergic neurons non-cell-autonomously regulates organismal health and lifespan in *Caenorhabdities elegans*** Laxmi Rathor, Shayla Curry, Taylor McElroy, Sung Min Han Physiology and Aging, University of Florida

Mitochondrial dysfunction plays a pivotal role in diseases and aging. Recent studies demonstrate that mitochondrial stress in

the nervous system triggers non-cell-autonomous responses in peripheral tissues. However, the specific neurons responding to mitochondrial damage and their impact on health and aging remain unclear. Using *C. elegans*, we investigated the non-cell autonomous effects of mitochondrial stress in gamma-aminobutyric acid (GABA) neurons. Our findings reveal that mitochondrial stress in GABAergic neurons significantly alters organismal lifespan, healthspan, and stress tolerance. These effects coincide with changes in mitochondrial mass, energy production, and reactive oxygen species levels in peripheral tissues. Enhanced DAF-16/FoxO activity is observed in response to mitochondrial stress in GABAergic neurons. This heightened activity is crucial for the observed non-cell autonomous effects on lifespan and stress resistance. Genetic epistasis analysis suggests that GABA neurotransmitter signaling and mitochondrial stress function through the DAF-16/FoxO pathway in a convergent manner, proposing a common mechanism for lifespan extension and healthspan enhancement. Collectively, our data suggested that local mitochondrial dysfunction in GABAergic neurons could influence mitochondria homeostasis, health, and aging of the whole organism through the DAF-16/FoxO pathway.

1505F **Loss of nonsense-mediated mRNA decay and its impact on the *Caenorhabditis elegans* neuromuscular system** Taylor McElroy, Han Gil Kim, Ezgi S. Karabulut, Sung Min Han Physiology and Aging, University of Florida

Aging alters the activity of nonsense-mediated mRNA decay (NMD), a conserved RNA quality control mechanism. However, whether NMD, which degrades both aberrant and some endogenous mRNA transcripts, has a role in age-related motility decline remains undetermined. In *C. elegans*, aging decreases NMD activity in various tissues, including muscle. Several long-lived strains, including *daf-2* mutants, which exhibit enhanced motility later in life, require intact NMD activity for longevity. Thus, we sought to characterize the role of NMD in normal aging and its effects on motility. We show that C. elegans strains with null mutations in components of NMD, including *smg-2*, *smg-5*, and *smg-6*, show decreased movement early in adulthood by reduced speed and body bending in liquid. Markedly, *smg-2* exhibited resistance to aldicarb and levamisole paralysis indicating altered neurotransmission at the neuromuscular junction. *Smg-2* mutants also showed increased neuronal branching in GABA motor neurons at Day 1 of adulthood, suggesting accelerated neuronal aging. Notably, NMD activity declined in GABA neurons of aging wild-type worms. We propose loss of NMD affects age-related motility decline by undermining neuromuscular system integrity. Therapeutics targeting this pathway could improve motility in age-related conditions.

1506F **Adenylosuccinate Lyase Plays a Role in Neuromuscular Coordination** Mia M Peifer, Latisha P Franklin, Wendy Hanna-Rose Biochemistry and Molecular Biology, Pennsylvania State University

Inborn Errors of Purine Metabolism are rare disorders characterized by changes in the activity of enzymes involved in purine synthesis and salvage. The mechanisms underlying the development of their devastating symptoms, including severe neurological and muscular defects, are poorly understood. Understanding these mechanisms is fundamental to developing proper treatment plans and more effective therapeutics.

Adenylosuccinate Lyase (ADSL) Deficiency is one such disorder caused by mutations in the ADSL gene. We model ADSL Deficiency using *C. elegans* with a deletion in *adsl-1* or fed with *adsl-1* RNAi. Disruption of *adsl-1* function results in irregular muscle structure, uncoordinated and slowed swimming movement, slowed crawling, slowed embryonic and post-embryonic development, embryonic lethality, and reproductive defects. We are interested in using the locomotive phenotypes to understand the neurobehavioral functions of *adsl-1*.

C. elegans locomotion is accomplished by the interplay of two key factors: generation of the force required for muscle contraction and coordinated contraction and relaxation of the body wall muscles. Control animals swim with the majority of body bends falling between 61° and 90°. However, an *adsl-1* deficiency results in the randomization of body bend angles with no preference for a specific angle.

Because *adsl-1* have abnormal muscle structure we investigated whether muscular defects are linked to dysregulation of bending angle during locomotion. Using the sarcomere mutant (*unc-95*), which is incapable of generating the force required for normal muscle contraction, we confirmed that loss of muscle integrity causes decreased swimming speeds and thrashing rates, but found that coordination remains unaffected. As an alternative hypothesis, we reasoned that *adsl-1* deficient animals lack the energy required to produce coordinated locomotion given the crucial role *adsl-1* plays in the purine nucleotide cycle, a vital energy maintenance process. Using the mitochondrial complex I mutant (*nuo-6*), we observed decreased swimming speeds and thrashing rates as expected, but no changes in coordination. We argue that the coordination phenotype seen in *adsl-1* deficient animals reflects the role of *adsl-1* in neural function as opposed to muscle function or energy production.

1507F **Transcriptomic Analysis Reveal Modulators of Longevity in an Insulin Growth Factor-1 (IGF-1) "*daf-2*" and Nuclear Hormone Receptor "*daf-12*" Double Mutant in *Caenorhabditis elegans*** Jerald Tan[1], Jan Gruber[1,2] [1]Department of Biochemistry, Yong Loo Lin School of Medicine, National University of Singapore, [2]Science Divisions, Yale-NUS College

Genetic synergies that extend lifespan involve genes that when mutated, on their own, produce lifespan effects but when impacted together result in amplified effects. One such gene combination is the *daf-2; daf-12* longevity synergy; where *daf-2* mutation extends lifespan *via daf-16* FOXO transcription activation by 1.5 to 2-fold while *daf-12* mutants do not extend lifespan. When mutated together, the resulting lifespan extension versus wild-type is close to 3-fold. In the attempt to understand what drives this longevity, we performed a transcriptomic analysis on a canonical allele *daf-2 (e1370)* and heterochronic allele *daf-12 (m25)* as a *daf-2 (e1370); daf-12 (m25)* double mutant. We found that out of 23,435 Differentially Expressed Genes (DEGs), only a small subset of genes were specific to this double mutant. We validated these results *via* RNAi knockdown experiments for lifespan survival. Our results revealed that the genes identified by transcriptomics promote lifespan extension beyond these double mutants without affecting reproductive capacity of the lifespan-extended animals. These results suggest that altering these genes may have an impact in driving longevity in this long-lived *daf-2; daf-12* mutant model.

1508F **Reproductive system aging in the canonically "non-aging" *C. elegans* dauer** Fred Koitz, Kacy Lynn Gordon Biology, University of North Carolina at Chapel Hill

Stressful conditions early in development are often correlated with shortened lifespans; however, the *C. elegans* dauer larval stage is induced by early life stress and is a diapause state in which development–and apparently aging–ceases. Entering dauer diapause can extend an organism's total lifespan many times over, with time spent in dauer not affecting the animal's post-recovery lifespan. Dauer is induced by starvation (among other triggers) and pauses development until conditions are more favorable for reproduction. While much research on dauer has focused on its effects on lifespan, it is the preservation of reproductive ability that makes dauer adaptative.

An overlooked finding is that animals that spend longer periods in dauer have a higher incidence of later reproductive defects and reduced fertility. This conflicts with the notion of dauer as "non-aging," as aging involves a time-correlated deterioration of internal physiology. As the reason for this reproductive system decline in extended dauers is unknown, we set out to identify reproductive system changes during dauer that could explain this post-dauer reproductive defect using genetic analysis and live-imaging of dauers to examine changes to the reproductive system over the span of six weeks (a duration equal to 2-3 standard *C. elegans* lifetimes).

We discovered that there is a dramatic reduction in germline cell number as dauer duration increases, correlated to a reduction of overall gonad size. Remarkably, we observed that the number of germ cell nuclei per gonad arm never declined to fewer than two germ cells. The dauer constitutive mutant for an insulin receptor gene, *daf-2(e1370),* did not recapitulate the germ cell reduction seen in starvation-induced dauers. Thus, germ cell reduction requires insulin signaling, and it is not simply a consequence of accumulated damage from prolonged starvation during the non-eating dauer stage.

We hypothesize that germ cell reduction is a regulated response to starvation that protects the surviving germ cells, and we are working to identify its genetic regulators. The decline of reproductive system components over time in dauer argues against the "non-aging" dauer paradigm, and could illuminate how organisms modify their reproductive capacity in the face of stresses such as starvation.

1509F **The Role of MicroRNA-71 in a Model of PolyQ Toxicity** Olivia C Dempson[1], Alexandre de Lencastre[2] [1]Quinnipiac University, [2]Biology, Quinnipiac University

Huntington's Disease is a neurodegenerative disorder associated with polyglutamine (PolyQ) repeats in the Huntingtin gene (HTT). Expression of these repeats leads to misfolding of the protein and aggregation in neurons. MicroRNAs (miRNAs) are non-coding RNAs that span 22 nucleotides and have been associated with the regulation of gene expression. Previous research has shown that miR-71 is a pro-longevity gene in *C. elegans* and delays phenotypes associated with the expression of proteins containing long polyglutamine (polyQ) repeats. In *C. elegans* strains expressing proteins in the muscle containing polyQ repeats fused to a fluorescent protein (Q35 and Q40), miR-71 overexpression rescues the motility defects associated with PolyQ expression. This study analyzes the influence of miR-71 in *C. elegans* expressing longer repeats in neurons, such as nQ67. To observe the influence of miR-71 on polyglutamine expression in neurons, we measured the motility of double mutant strains that express a pan-neuronal fluorescent protein that contains 67 repeats of Q (nQ67) and overexpress miR-71. This study also aimed to determine if the DNA replication inhibitor FUdR may be used during these motility assays. The results suggest that FUdR may be used in these strains and that overexpression of miR-71 can rescue *C. elegans* strains expressing polyQ67 in neurons.

1510F **Community connections power health disparities research** Ebony Dyson[1], Drea Darby[1,2], Dara Ruiz-Whalen[1], Alana M O'Reilly[3] [1]eCLOSE Institute, [2]Department of Entomology, Cornell University, [3]Fox Chase Cancer Center

Cancer, diabetes, mental health, infectious disease and other preventable health conditions are more common and more lethal in communities lacking representation in biomedical research. Despite demonstration of the existence of these health disparities over decades, little progress has been made. We created the eCLOSE Undergraduate Bridge to Research Program to begin to address health disparities prevalent in communities represented by program participants. Senior high school students, undergraduates, and recent college grads with limited research experience first learn laboratory techniques in the context of research projects leveraging Drosophila models of diseases of personal importance. After completion of "Bootcamp", students create independent projects that address the community health need of highest interest, using molecular genetics, developmental biology, educational interventions, and biochemistry. A project highlight focuses on HPV-dependent cancers in underserved communities, with more than a dozen student participants contributing insights to a testable, molecular model for prevention of HPV disease. Generous grants from FlyBoard have supported 14 UG Bridge participants since 2019.

1511F **Investigating Presenilin as a Potential Molecular Target of Opportunity for Exploring Alzheimer's Disease** Christopher Ramirez, Maria Lourdes Mendoza Aragon, Laura Galvan, Judy Especial Abuel, Blake Riggs Biology, San Francisco State University

Alzheimer's disease (AD) is a prevalent neurodegenerative disease affecting 6.7 million Americans aged 65+ in 2023, with projections to triple by 2060. Current treatments primarily slow disease progression, emphasizing the need for novel therapeutic strategies. We investigate Presenilin (PSN) as a promising therapeutic target in AD. While PSN's signaling function is recognized, its role in neurodevelopment, particularly its regulation of Tau expression via Notch/Amyloid Precursor Protein (APP) signaling, remains elusive. We hypothesize that PSN defects can induce AD-like symptoms. We use *Drosophila melanogaster*, with its versatility for genetic studies, to investigate PSN's neurodevelopmental role and its influence on neural behavior. We will examine PSN mutant lines in Drosophila larval brains for any defects that resemble a Tau-like phenotype. Our approach involves immunohistochemistry to identify AD-like markers with PSN lines in 3rd Instar larvae brains. Using a STELLARIS Confocal Microscope and Imaris software, we will differentiate and count neuronal, glial, and mushroom body cells. Expected results may reveal behavioral variances between controls, including differences in negative geotaxis, larval movement, and feeding behaviors. Our findings seek to highlight PSN's vital neurodevelopmental role and its potential as an AD therapeutic target, offering insights into improved treatments for neurodegenerative disorders worldwide.

1512F **Optimizing NADPH assay conditions for analysis of a CRISPR screen for *Zwischenferment* (*Zw*)/Glucose-6-Phosphate Dehydrogenase (G6PD) mutations in *Drosophila melanogaster*** Jason Hare, Alexis Nagengast Biochemistry, Widener University

Glucose-6-phosphate dehydrogenase (G6PD) is the most common enzyme deficiency in humans, affecting 400 million people worldwide. The *Drosophila Zw* (*Zwischenferment*) gene codes for the conserved G6PD enzyme that is the rate limiting step in the pentose phosphate pathway (PPP). The PPP provides NADPH required for lipid biosynthesis under high nutrient conditions and NADPH levels can be measured to assay G6PD enzyme activity. In both humans and *Drosophila,* G6PD is alternatively spliced in the 5' UTR (untranslated region) to produce two different protein products that vary in length and initial N terminal sequence. Isoform A results in the longer protein product and Isoform B/C produces the shorter product yet the functional significance of this is not fully understood. A CRISPR/Cas9 screen targeted the Isoform A coding sequence to allow for the characterization of Isoform B independently and this resulted in several different frameshift mutations. Additionally, sequencing of the parental fly lines *yw* and *FM7* revealed a frameshift deletion mutation in *FM7* predicted to also result in a premature truncation of Isoform A. The G6PD enzyme activity levels in these different fly lines will be assayed to better understand the functional significance of the products of Isoform A and B.

1513F **Kefir Treatment in a Parkinson's Disease Model of Drosophila Melanogaster** Rachael B.D. Triglia, Regina Lamendella, Kathryn A. Jewett Biology, Juniata College

Parkinson's disease (PD) is a neurodegenerative condition characterized by the deterioration of motor skills, sleep, memory changes, and the accumulation of irregular protein clusters. Increasingly, the gut microbiome and dietary choices have been found to influence physical and cognitive health. New research indicates that probiotics may present a pathway for promoting a healthier lifestyle and potentially managing PD symptoms. Several studies have explored the impact of manipulating the gut microbiome in humans with PD with results showing enhanced mobility and improved sleep patterns.

The gut-brain axis, or gut-brain connection represents a bidirectional connection between the enteric nervous system and the central nervous system. The introduction of probiotics into one's diet directly influences this network. To explore how dietary factors might affect PD-like symptoms in a *Drosophila melanogaster* model, adult fruit flies will be provided food treated with kefir, a probiotic made of 12 active cultures and over 20 billion colony forming units. We hypothesize that manipulation of the gut microbiome will reduce the PD-like symptoms of the flies.

Previous research has shown positive outcomes when manipulating the diet of *Drosophila* in an Alzheimer's disease model

(Batista et al., 2021, Sci Rep 11:11262). This study compares healthy flies (RV) and sick flies (GBA del) expressing PD-like symptoms (due to the deletion of PD genetic risk factor gene GBA encoding the enzyme glucocerebrosidase). Adult flies will be placed on untreated food as a control group and their performance compared with flies placed on kefir-treated food. Flies will be assayed to determine whether kefir-infused food enhances their climbing abilities, extends their life span, normalizes sleep, and decreases the accumulated protein aggregation. Additionally, the gut bacteria of each group will be analyzed through gut dissections subjected to 16S rRNA gene sequencing. The kefir will also be sequenced through 16S rRNA gene sequencing. We hypothesize that flies on the kefir-treated food will exhibit improved climbing abilities, extended lifespans, normalized sleep, and protein aggregation (measured by western blot) will be decreased in the kefir-treated groups. If correct, researching kefir as a potential treatment to mitigate the symptoms of Parkinson's Disease in human patients could be the next step for experts studying neurodegenerative diseases.

1514F **Understanding changes to sleep behavior and gene expression caused by glucocerebrosidase deficiency in a *Drosophila melanogaster* model of Parkinson's disease** Jason Brandon[1], Sam Anderson[2], Regina Lamendella[1,2], Kathryn A. Jewett[1] [1]Biology, Juniata College, [2]Contamination Source Identification (CSI)

Sleep/wake cycles within many animals, including *Drosophila melanogaster*, is a complex, and not yet fully understood phenomena. Sleep disorders from associated neurodegenerative diseases, such as Parkinson's disease (PD), stem from alterations in cellular processes, sometimes altered because of a genetic mutation. Through this project, we seek to develop an understanding into how genes with a role in sleep regulation that are also associated with extracellular vesicles (EVs) may play a part in PD.

EVs are small, membrane-bound particles released by cells into the extracellular environment. PD can be characterized by the development of protein aggregation within the brain, which can disrupt endosomal functions such as the release of EVs. A genetic form of PD is associated with mutations in the *GBA* gene which encodes a lysosomal lipid-modifying enzyme, glucocerebrosidase. *GBA* deletion in *Drosophila* leads to lipid alterations, increased protein aggregation, changes in EVs, and sleep alterations. When *GBA* expression is rescued in specific cell types, abnormal protein aggregation decreases.

Using western blot techniques, we will assess protein aggregation in healthy and mutant (homozygous *GBA* deletion) flies as well as the effects of glial cell-specific expression of *GBA* in both groups. Preliminary data suggests that glial cell *GBA* expression is sufficient to rescue protein aggregation. Using the Drosophila Activity Monitoring System (DAMS), sleep differences were observed between healthy and mutant flies, specifically in their response to temperature-induced sleep deprivation. The sleep of healthy and mutant flies with and without glial cell *GBA* expression will be analyzed as well.

Using The Database for Annotation, Visualization, and Integrated Discovery (DAVID), enriched genes between two pathways of interest, sleep homeostasis and extracellular vesicle biogenesis have been identified. We are using these results to target specific genes, with RT-qPCR to quantify expression differences among healthy and mutant flies with and without glial cell *GBA* expression. We predict changes in gene expression to reflect the observed changes in sleep and EVs seen in healthy and mutant flies.

1515F **Identifying and characterizing CRISPR/Cas9 medicated mutations in *Zwischenferment* (*Zw*), the *Drosophila* ortholog of Glucose-6-Phosphate Dehydrogenase (G6PD)** Katharyn Mackiewicz[1], Kathleen Miller[2], Morgan Grace[1], Michael Toneff[1,2], Alexis Nagengast[1] [1]Biochemistry, Widener University, [2]Biology, Widener University

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzyme deficiency in humans. It is a non-lethal mutation that causes acute hemolytic anemia which is where the red blood cells are broken down more rapidly than they are produced. The *Zwizchenferment* (*Zw*) ortholog, which is used to study the role of G6PD in *Drosophila melanogaster*, has an alternative splicing pattern that is conserved between *Drosophila melanogaster* and humans. This splicing pattern results in three isoforms of the gene and leads to two different protein products that vary in length and have an alternative N-terminal protein sequence. The significance of these protein products is not fully understood. CRISPR/Cas9 screens were conducted to knockout isoform A and study the functional significance of isoform B/C. PCR and sequencing of the established stocks identified two stocks with a two-base deletion, one stock with a one-base deletion, and one stock with a one-base insertion. These deletions and insertions caused frameshift mutations that result in an early stop codon and possible prematurely truncated protein products. This project aims to investigate the function of each isoform in minimizing reactive oxygen species (ROS) damage. Future work will test the significance of the alternative protein products on minimizing ROS damage through the use of paraquat challenges. These challenges will look at the difference in survival between fly lines with and without a CRISPR-mediated mutation in hopes to better understand treatment for this deficiency in humans.

1516F **Extracellular Vesicle Protein Aggregation Analysis within a *Drosophila melanogaster* Neural Cell Culture Model of Parkinson›s Disease** Allison M. Johnston, Kathryn A. Jewett Department of Biology, Juniata College

The *GBA* gene encodes for the enzyme, glucocerebrosidase which is associated with lipid modifications and resides within the lysosome. Mutations of *GBA* are commonly associated with Parkinson's disease (PD) conveying an increased disease risk. Since PD is known to be a neurogenerative disease with protein aggregation causing deficits within the brain, and both humans and *Drosophila melanogaster* naturally have the *GBA* gene, studying the effects of *GBA deletion* within *Drosophila* models can give us a unique insight on the neural effects of protein aggregation. When *GBA* is ubiquitously deleted in *Drosophila* the flies have a shortened lifespan and protein aggregation can be found in the brain, muscle tissue and extracellular vesicles. Extracellular vesicles produced and sent by various cell types *in vivo* may explain how protein aggregation spreads throughout the body and brain during neurodegenerative disease states. In this study, we aim to establish primary *Drosophila* neural cell cultures as a viable option for studying GBA-associated PD and to assay the presence and effect of protein aggregation within extracellular vesicles isolated from culture media.

1517F **Immune-stimulation of Drosophila larval hemocytes drives the rapid generation of lipid droplets via an NFkB and DGAT1 dependent pathway** Roger White[1], Asmita Dutta[1], Jinghong Tang[1], Neal Silverman[2], Michael Welte[1] [1]University of Rochester, [2]University of Massachusetts Medical School

Lipid droplets (LDs) play critical roles in energy homeostasis, lipid metabolism, and protein sequestration in numerous cell types. It is increasingly recognized that they also have important functions in the immune system, but in most cases the underlying mechanisms remain to be characterized. We discovered that exposing Drosophila larvae to *E. coli* by gentle pricking leads to LD accumulation in hemocytes, fly macrophages. Within just three hours, LD numbers double. This rapid, massive accumulation suggests that these LDs might play a role in the immune response. We observe similar LD accumulation when using heat-killed bacteria or the bacterial cell-wall component peptidoglycan (PGN), implicating the IMD pathway in this response. Indeed, in mutants for the NFkB family member Relish LD accumulation is abolished. Further, we find that LD accumulation is cell autonomous in hemocytes. First, hemocyte-specific knockdown of the PGN receptor PGRP-LC severely blunts the response, and hemocytes exposed to PGN *in vitro* accumulate more LDs. The increase in LD number is likely due to new LD biogenesis as PGN stimulation leads to the appearance of tiny LDs and these LDs are highly enriched for the marker LiveDrop, a protein that relocalizes from the ER to newly emerging LDs. From these data, we conclude that PGN drives the formation of new LDs. In many cells, triglyceride synthesis is the rate limiting step for LD biogenesis. Indeed, in mutants for the triglyceride synthase DGAT1/Midway, LD production upon PGN challenge is indistinguishable from controls exposed to buffer. We conclude that the immune-induced LDs contain mostly triglyceride and are due to new LD biosynthesis. We are now testing candidate lipid metabolism genes induced upon bacterial infection to determine if their upregulation mediates LD accumulation after PGN treatment. The long-term goal is to specifically prevent immune-induced LDs in hemocytes to be able to address which immune functions might depend on these LDs.

1518F **Deciphering the Molecular and Cellular Mechanisms Governing Tissue-Selectivity of *Ras* Oncogenic Mutations** Takuya Akiyama[1], Matthew C Gibson[2] [1]Biology, Indiana State University, [2]Stowers Institute for Medical Research

Mutations in *Ras* are detected in various cancers. Ras family proteins play pivotal roles as small GTPases, orchestrating cellular growth and cytoskeleton remodeling. Comprehensive cancer genome sequencing unveils that certain *Ras* mutations appear more frequently in specific tissues. Deciphering the molecular and cellular basis underlying the emergence of this tissue selectivity can have significant implications for cancer initiation and progression. To investigate the impact of *Ras* mutations on cancer development, we established inducible alleles by leveraging CRISPR/Cas9 genome editing. In the wing primordial tissue, introducing a mild *Ras* oncogenic mutation did not affect the tissue architecture, whereas a strong mutation disrupted it by forming cysts. In the adult intestine, cells carrying the mild oncogenic mutation had a growth advantage compared to *wild-type* cells, ultimately taking over the intestine and causing intestinal barrier dysfunction. As expected, when we induced the strong *Ras* mutation, the mutant cells hyper-proliferated and rapidly occupied almost the entire intestinal tissue. However, soon after the clonal expansion of mutant cells, they were eliminated from the gut epithelia, restoring *wild-type* cells in the intestine. Our results indicate that the strong *Ras* oncogenic mutation is counterintuitively less harmful than the mild mutation in the intestine due to the allele-dependent clonal regression. These distinct mutant cell behaviors likely contribute to the tissue-selectivity of *Ras* oncogenic mutations. Our findings also suggest that a partial reduction of *Ras* oncogenic activity by any means, such as drug treatment, has a detrimental effect by prolonging the persistence of mutant cells in some contexts.

1519F **Neuronal expression of the P3 peptide (Aβ17-42) in Drosophila has deleterious effects on lifespan, behavior, degeneration, and gene expression and exacerbates the effects of full-length Aβ1-42** Jacquelene Hundelt, Ginger Holmer, Megan Saefong, Rebekah Larreynaga, Hannah Moalla, Emily Broutian, Jeremy Lee University of California: Santa Cruz

Alzheimer's disease (AD) is a neurological disorder that leads to a loss of cognitive function and memory. Approximately 1 in 9 people in the United States 65 years old and older have AD. An important protein in AD is the amyloid precursor protein (APP), which is expressed in neurons. APP is cleaved in two major ways. It can be cleaved by β-secretase and then ɣ-secretase to

produce the 42-amino acid peptide, amyloid beta (Aβ). An alternative pathway involves cleaving APP by α-secretase and then ɣ-secretase to produce a 26-amino acid peptide, called P3 (aka Aβ 17-42). P3 is a truncated form of Aβ and is 16 amino acids shorter than Aβ (Aβ 1-42). Research has shown that Aβ aggregates into oligomers, fibrils, and plaques that disrupt neuron function. Recent research indicates that P3 is similarly amyloidogenic and is cytotoxic in vitro.

Our experiments focus on P3 to determine whether it has similar effects on neurons as Aβ in vivo. In our experiments, we compare the effects of P3 to those of Aβ in Drosophila expressing the human peptides pan-neuronally, using the APPL-Gal4 driver. A longevity assay was conducted to assess the effects of Aβ and P3 on lifespan. Results indicated that P3, when expressed alone, decreases lifespan, and, when expressed with Aβ, exacerbates Aβ's negative effects. A Rapid Iterative Negative Geotaxis (RING) assay was also conducted to analyze the effects of the expression of both peptides. We found that P3 and Aβ affect the flies' locomotive ability. Furthermore, scanning electron microscope imaging was carried out on the eyes of flies expressing these peptides under the GMR-Gal4 driver. Our results showed that both P3- and Aβ-expressing flies had eye bristle and ommatidial defects, with the most substantial impacts in flies co-expressing the peptides. All these results indicate that P3 has similar but less severe effects as Aβ on neurons and exacerbates Aβ's effects when co-expressed with P3. RNA sequencing was performed on flies pan-neuronally expressing these peptides. This revealed that expression of Aβ and P3 had similar down-regulatory effects on gene expression, especially of proteolytic genes. We are now conducting olfactory assays to assess the effects of the expression of both peptides on learning and memory. Our next step will be to conduct coimmunoprecipitation experiments to determine whether P3 interacts with Aβ directly, so it might contribute to Aβ aggregation and its pathological effects.

1520F **Role of neuronal tRNA processing enzyme in the formation of mushroom bodies in *Drosophila*** Saathvika Rajamani, Lucia Vilchez, Edward Dubrovsky Biological Sciences, Fordham University

RNase Z is a highly conserved gene that codes for an endonuclease playing an important role in the maturation of tRNA molecules. Mutations in the human homolog of this gene have been associated with variable neurological presentations ranging from seizures and neurodevelopmental delay to microcephaly and ataxia. As a first step in understanding the mechanism underlying the associated neuropathology, we generated fly models with neuron-specific RNase Z knockout using CRISPR/Cas9 technology. This disruption led to severely reduced longevity and loss of motor activity, accompanied by smaller sized brains in both larval and adult stages. One of the most evident observations was the loss of morphologically distinct structures in the adult brain, specifically the absence of neurite tracts surrounding the mushroom bodies (MBs). MBs are a pair of neuropils in the central brain that mediate olfactory learning and memory in insects. Further investigation with an antibody specific to the MB revealed several aberrant phenotypes in the adult knockout brains; these defects included truncated, thin or missing α lobes, and fused or missing β lobes. The damage was less extensive in the brains expressing a disease variant, Thr494Ile, with the defective morphologies limited to thinner α lobes and fused β lobes. We hypothesize that the loss of lobes could be due to improper neurogenesis. To explore this, we studied the MB phenotypes at pre-adult stages. Surprisingly, we saw no difference in the lobe morphology in the knockout or mutant larval brains when compared to the controls; this finding indicates that the abnormal morphologies in the adults stemmed from the need for neuronal RNase Z function, specifically during the metamorphic transition. Given that abnormal MB morphology has been linked to impaired cognitive ability, we also hypothesize that flies harboring mutant forms of neuronal RNase Z will show defective learning and memory retention. Altogether, our research suggests a critical role for RNase Z in proper mushroom body formation with a potential link to intellectual disability.

1521F **Characterizing the effects of obesogenic diets on Drosophila *melanogaster* immune responses across control lines** David J Duncan Biological Sciences, University of South Carolina

Diet impacts organismal health by providing macromolecules to support cellular survival and function. Obesogenic, or high-fat and high-sugar, diets can lead to long-term detrimental health effects including multiple cancer types, type 2 diabetes, insulin resistance and excess body fat. Over 60% of adults in the United States are overweight or obese and 42% of obese individuals also present with chronic inflammation. Despite this association, the cellular and molecular mechanisms that link obesity and associated diseases remain unclear. We use *Drosophila melanogaster* as an *in vivo* model to better understand the effects of obesogenic diets on the immune response and begin examining the potential therapeutic effects of dietary plant compounds on obesity-associated chronic inflammation. Given the broad range of "standard" diets and "control" fly lines used in the field, we are first characterizing lifespan and reproduction of several control lines across commercially and non-commercially available foods to identify an optimal-base diet. Thus far, we find there is a difference in lifespan and reproduction patterns across the different control lines fed different standard diets. Oregon-R and yw control lines have a longer lifespan on a diet in which the sugar source is molasses, while w^{1118} control line has the shortest lifespan. A high fecundity rate was observed in yw control line fed a corn syrup-based diet and molasses diet. While molasses diet supports higher egg production for all control lines. We will also identify an obesogenic dietary condition that induces immune responses in adult flies by measuring immune

response pathway activity and antimicrobial peptide production in flies fed high-sugar or high-fat diets. In future studies, we will use this approach to screen botanical supplements for their ability to suppress the diet-activated immune response. We hope that this work will inform the development of treatments for diet-induced obesity-associated diseases in humans.

1522F **Blue light shortens development and longevity across generations in *Drosophila melanogaster*** Monica Andrea Lopez Bautista, Viviana Matilde Mesa Cornejo, Jorge Enrique Mejía Sánchez Centro Universitario de los Lagos, Universidad de Guadalajara

Ambient light affects multiple biological and behavioral functions in living beings that have set the guideline for their evolution and development; however, the growing use of artificial light, coming from light-emitting diodes (LED), has marked a new paradigm, in which all organisms have been involved. Although LED technology represents a great advance worldwide due to its energy efficiency, useful life and cost, it should be reported that chronic exposure over a long period of time, especially in the blue range of the visible light spectrum, causes desynchronization of the circadian cycle, which can impact sleep imbalance, hormonal disorders, mood, among others. Therefore, in this work it was evaluated the effect of blue light (**λ**: 457.33 ± 45 nm) at an illuminance of 100 Lux across five generations in two strains of the model organism, *Drosophila melanogaster* (*Canton-S* and w^{118}) in four different photoperiods: 12:12 LD (Light: darkness), 16:8 LD, LL (constant lighting) and DD (constant darkness), to observe their behavior at the level of development of each larval and pupal stage, reproduction, courtship and longevity. The results confirm that exposure to blue light exerts a toxic effect on the development of the fly regardless of the type of photopigments that they lack both at the level of reproduction and longevity and is maximized throughout each generation. On the other hand, the w^{118} strain showed a higher population rate compared to the wild-type strain, except for that obtained in the LL treatment. In fact, it has been determined that throughout the various stages of development in the fly, these can be accelerated or slowed down by being chronically exposed to blue light depending on the strain. These results conclude that although the flies are exposed to a low intensity of illuminance, its cumulative effect across five generations exerted a significant change depending on the time of exposure to blue light.

1523F **Hippo-activated cells induce non-cell autonomous carcinogenesis in *Drosophila*** Daichi Honda[1], Misako Okumura[1], Chisako Sakuma[2], Masayuki Miura[3], Takahiro Chihara[1] [1]Program of Biomedical Science, Graduate School of Integrated Sciences for Life, Hiroshima University, [2]RIKEN Center for Biosystems Dynamics Research, [3]Graduate School of Pharmaceutical Sciences, The University of Tokyo

The Hippo pathway is known as the tumor suppressor pathway and overwhelming studies indicate that inhibition of the Hippo pathway leads to excessive cell proliferation and carcinogenesis. However, the genetic analysis of cancer has revealed that the Hippo pathway is activated in some cancers, suggesting that activation of the Hippo pathway may be involved in carcinogenesis and that the Hippo pathway has a paradoxical role in carcinogenesis. Therefore, we decided to investigate the possibility that activation of the Hippo pathway contributes to carcinogenesis.

First, we genetically induced Hippo-activated cells in the *Drosophila* wing disc (epithelial tissue) by knocking down or overexpressing the Hippo-pathway components (*strip*, *warts*, and *yorkie*), and examined the effects on two cancer markers, the activity of the mTOR pathway and MMP1 expression. Hippo-activated cells upregulated these cancer markers in their surrounding cells, thereby transforming the surrounding cells into “tumor-like cells”, suggesting that Hippo-activated cells become a “tumor-inducing center”. Second, we analyzed how Hippo-activated cells cause non-cell-autonomous activation of the mTOR pathway by inhibiting downstream signaling of the Hippo pathway (apoptosis signaling). We found that the upstream regulator (Dronc: initiator Caspase) but not the downstream regulator (Dcp-1, etc.: executor Caspase) of apoptosis signaling is required for non-cell-autonomous activation of the mTOR pathway. We hypothesize that the initiator Caspase would regulate the expression or secretion of secretory molecules that activate the mTOR pathway in their surrounding cells. In addition, we conducted genomic deficiency screening to identify the regulator of the induction of tumor-like /mTOR-activated cells and discovered the uncharacterized amino acid transporters, which we named *sat1/2*. In the *sat1/2* mutant background, Hippo-activated cells could not effectively induce the mTOR-activated cells. We hypothesize that Hippo-activated cells can use amino acids to cause carcinogenesis in their surrounding cells. We will discuss the possible mechanism underlying carcinogenesis caused by activating the Hippo pathway.

1524F **Investigating the role of Pvr signaling in myotonic dystrophy type 1** Delaney Baratka, Madeline Brunt, Ginny R Morriss Biological Sciences, University of Mary Washington

Myotonic Dystrophy Type One, DM1, is a progressive, multisystemic, and autosomal dominant disorder caused by expansion of CTG-repeats in the 3’-UTR of the DMPK gene. While we understand the causal mutation that leads to DM1, the underlying mechanisms of disease progression remain unclear. Prior research in a mouse model of DM1 identified deregulated PDGFR- β signaling. PDGFR-β plays a role in cell survival and differentiation. Another study implicated the ligand for Pvr, the Drosophila ortholog of PDGFR-β, as a modifier of DM1 phenotypes. This study will evaluate the role of the Pvr signaling pathway in the

Drosophila DM1 model. The Drosophila DM1 model uses the Gal4/UAS system to express the expanded CUG repeats. We plan to modulate the expression of pvr by RNAi knock down (pvr-RNAi) and overexpression (Pvr-OE) in flies with and without the CUG-repeat expression (CUGexp). A mating scheme has been set up to obtain flies driving expression of CUGexp RNA, pvr-RNAi, Pvr-OE, CUGexp RNA + pvr-RNAi, and CUGexp + Pvr-OE using the Mef2-Gal4 driver. The use of the fruit fly model allows us to study the signaling pathway in a more simplified view to understand its role in both normal muscle function and in DM1. Our main goal is to determine the role of Pvr signaling for proper skeletal muscle function and in DM1 pathology. A secondary goal is to determine whether overexpression of Pvr in flies affected by DM1 can rescue the DM1 muscle phenotype.

1525F **Assessing progression of muscle phenotypes in an adult-onset model of myotonic dystrophy in Drosophila melanogaster** Kayla Rodriguez, Ashlyn Rauch, Ginny R Morriss Biological Sciences, University of Mary Washington

Myotonic Dystrophy Type One (DM1) is a multisystemic disorder caused by expansion of CTG repeats in the dystrophia myotonica protein kinase (DMPK) gene. Individuals diagnosed with DM1 may display a wide spectrum of CTG expansions, ranging from 50 to 4000 repeats. Unaffected individuals typically have between 5 to 37 CTG repeats. In individuals with shorter repeat expansions, development of symptoms typically occurs in the later adult years, where individuals with very long expansions can have a juvenile or congenital onset. Individuals diagnosed with the congenital form of myotonic dystrophy commonly exhibit developmental defects, in addition to some of the classical DM1 symptoms. Since DM1 results in progressive worsening of symptoms over generations, it is important to understand the progression of the disease. The Drosophila DM1 model uses the GAL4/UAS system to drive expression of expanded CUG repeat-containing RNA (CUGexp). Typically, GAL4 drivers that have been used have shown severe muscle atrophy, reminiscent of human DM1, but these drivers are expressed embryonically, making it difficult to tease apart defects that are due to repeat expression and defects that are due to impaired development. This study uses the 1151-Gal4 driver to study the progression of skeletal muscle weakening and wasting. The onset of expression of the 1151-Gal4 driver is during the pupal stage, we are able to understand the progression of DM1 physiological phenotypes, without the confounding effects of developmental defects. We crossed the 1151-Gal4 lines with transgenic lines containing 60 (UAS-CTG60) and 250 (UAS-CTG250) to represent the unaffected and DM1 mutant phenotypes. 1151-Gal4>UAS-CUGexp flies do not show skeletal muscle defects after one or two weeks of expression, as was observed in the Drosophila DM1 model using embryonic drivers. We are in the process of testing 1151-Gal4>UAS-CUGexp flies for physiological defects at 3, 4, and 5 weeks of CUGexp expression. We use tests that measure climbing velocity and flight ability in the flies to assess defects in physiological function in the flies. A subset of flies of each genotype will also be prepared for histological analysis to measure whether repeat-expressing flies exhibit muscle atrophy, as do the embryonic onset model. This study determine the time of onset of the DM1 muscle phenotypes for Drosophila DM1 model. If physiological defects are observed, this model will allow for a simplified model to perform mechanistic studies into DM1 that are unclouded by developmental defects caused by expressing repeats embryonically.

1526F **Determining the Impact Sweet Taste Receptors and Gut Microbiome have on Feeding Behavior and Glucose Metabolism in *Drosophila melanogaster*** Mikesha D Carter, Blake Riggs Biology, San Francisco State University

Diabetes mellitus is the most common metabolic disease and the 7th leading cause of death globally. One of the major factors that lead to diabetes is obesity. Obesity can be the result of addictive behaviors towards food or sugar or an altered gut microbiome. It has been proven that individuals with diabetes mellitus have dulled sweet taste reception and addictive response to sugar based on this lack of sensation. Understanding the impact that sweet taste receptors and gut microbiome have on feeding behaviors is poorly understood. We are investigating the connection between defects in sweet taste receptors and the effects on the gut microbiome. As a model organism, Drosophila are easy to manipulate genetically and can be produced with known gut bacterial species and without any gut microbiome. Drosophila have two major species of gut bacteria, Lactobacillus and Acetobacter and two primary sweet gustatory receptor neurons (GRNs) Gr64a-f and Gr5a. Here we used a Two-Choice test (feeding assay) and spectrophotometry to measure feeding preference of these flies. Also, using qPCR to measure DILP (Drosophila insulin-like peptide), a protein that is homologous to insulin and insulin-like growth factor (IGF), to measure the impact on glucose homeostasis. These results will show the effect sweet taste reception and the gut microbiome have on feeding behavior and diabetic phenotypes.

1527F **The Role of Two isoforms of Fis1 Protein in Pink1/Parkin pathway** CHUNHONG CHEN[1], Rei-Wen Liu[2] [1]National Institute of Infectious diseases and Vaccinology, [2]Institute of Bioinformatics and Systems Biology, National Chiao Tung University

Mitochondrial quality plays an important role in aging-related diseases. Mitochondria fission/fusion, and mitophagy cooperate to maintain physiological health by eliminating damaged mitochondria. Mitophagy is a process that dysfunctional mitochondria are eliminated by autophagy. Mitophagy is mainly regulated by the Pink1 (PTEN-induced kinase 1)/Parkin (E3 ubiquitin ligase) signaling pathway. Previous study showed Fission1 (Fis1) controls mitochondrial fission in yeast and Fis1

contributes to mitophagy. In this study, we are interested in whether Fis1 is involved in the Pink1/Parkin-mediated mitophagy. Accumulation of phagophore, reactive oxygen species (ROS) and ubiquitinated proteins in mitochondria were detected in the fis1 mutant. There are two major isoforms of Fis1 in fly, Fis1-LL/LS. In fis1 mutant, mitophagy marker accumulation and ROS stress were compromised by genetically expressing an isoform of Fis1-LS (Fis1-long- form short), but not by Fis1-LL (Fis1-long-form long). These results indicated that Drosophila Fis1-LS isoform functions similar to mammalian Fis1 and Fis1-LL locate on the mitochondrial contact site imply it may involve in other mitochondrial dynamics. And Fis1-LS may involve in peripheral fission. In this study, We found Fis1 protein expression is regulated by Pink1. Fis1-LS can partially rescue Pink1 mutant defect including mitochondria integrity and locomotion defect. This study may provide a new role of Fis1 in fission and mitophagy.

1528F ***Drosophila* models for investigation of mitochondrial dysfunction in gliomagenesis** Tzu-Yang Lin Institute of Cellular and Organismic Biology, Academia Sinica

Glioblastoma (GBM) is the most aggressive and deadly form of brain tumor with no cure. Prior investigations into GBM patients have demonstrated obvious distinctions in the size and shape of glioma mitochondria. These morphological irregularities may impede their function and have been associated with increased tumor malignancy (Arismendi-Morillo and Castellano-Ramirez, 2008). Additionally, functional transcriptomic analyses had unveiled significant alterations in mitochondrial function in GBM specimens (Garofano et al., 2021). However, little is known about how mitochondrial morphological alterations lead to functional deficits or vice versa. We utilized *Drosophila* models for tracking gliomagenesis from health to disease. Expansion microscopy (ExM) allows us to visualize subtle structural alterations of glial mitochondria during gliomagenesis. Our preliminary data showed that the fly glioma brain harbors many fragmented mitochondria and exhibits defective mitophagy. We also discovered the upregulation of mitochondrial fission proteins and downregulation of fusion proteins occurs in glioma brains. Further assessments of mitochondrial metabolic phenotypes and the molecular mechanisms in gliomagenesis will be presented.

Arismendi-Morillo and Castellano-Ramirez. (2008). J Electron Microsc 57, 33-39.

Garofano., et al. (2021). Nat Cancer 2, 141-156.

1529F **Transcriptional Regulation of Intestinal Stem Cell Ageing** fanila shahzad, David Doupe biosciences, Durham University

Ageing is associated with a reduction in physiological functions and increased incidence of several chronic diseases. Many tissues are constantly turned over throughout adult life and the balance of cell loss and replacement is often perturbed in ageing. The *Drosophila* intestine has emerged as an excellent model for epithelial ageing. In normal homeostasis the tissue is constantly turned over as differentiated enterocytes are lost and replaced by the proliferation of stem cells. In ageing, the stem cells become misregulated, initially overproliferating and eventually failing to maintain the tissue. This occurs in parallel to decline in epithelial barrier function and dysbiosis of the intestinal microbiota. Epigenetic changes have been described as a hallmark of ageing and we are exploring how transcriptional regulation and chromatin states change with age in the intestinal stem cells. Based on published transcriptomic data we have identified a number of transcription factors whose expression changes in ageing intestine. We have used enhancer traps to characterise the expression patterns of these transcription factors in normal homeostasis and in the ageing intestine, validating age-related changes in expression. We are currently using stem/progenitor specific knockdown and overexpression to explore their functions in normal homeostasis. Future work will use targeted DamID to identify the downstream transcriptional targets of these factors in intestinal stem cells.

1530F **The effects of Tip60 Histone Acetyltransferase on cellular degeneration and motor dysfunction in Drosophila model of Machado-Joseph Disease** Sarah E Clark[1], Hung Pham[2], John M Warrick[3] [1]Biology, University of Richmond, [2]University of Richmond, [3]Biology, Univ Richmond

Machado-Joseph Disease (MJD) is a polyglutamine (PolyQ) disease that causes lethal motor neuron degeneration resulting from a CAG repeat in the Ataxin3 (ATX3) gene. These excess CAG repeats cause the ATX3 protein to misfold, altering its function and forming aggregates (clumps of protein) in cells. The biggest aggregates form in the nucleus but can also be found elsewhere in the cell. It is believed these aggregates then trap other proteins like Histone Acetyltransferases (HATs). This may prevent acetylation of histones, reducing gene transcription, and/or the production of other proteins doing essential functions in the cell. This dysfunction is hypothesized to lead to cellular dysfunction and degeneration. Additionally, without properly functioning HAT's, it is hypothesized that motor skills in larval *Drosophila* may be negatively impacted as a result of the subsequent cellular dysfunction. HAT Tip60 is a type of histone acetyltransferase responsible for neuronal gene control and cell apoptosis. Increased levels of HAT Tip60 have been shown to reduce protein aggregation and blockages in motor axonal pathways and preventing degeneration in Alzheimer *Drosophila* models. Previous work on our model showed that the upregulation of Tip60 reduced neurodegeneration. Through immunohistochemistry and confocal microscopic analysis, we have observed reduced levels of blockages in photoreceptor axons in *Drosophila* with upregulated Tip60 protein and increased

blockages in flies with downregulated Tip60. We are currently examining larval locomotor behavior. As expected, larvae with MJD have reduced locomotor abilities. We intend to determine if co-expression of Tip60 will rescue this behavior. These results support the hypothesis that Tip 60 has a rescuing effect on cellular and motor degeneration in *Drosophila* MJD.

1531F **Modeling Dentatorubral-pallidoluysian atrophy in *Drosophila*** Matthew V Prifti, Nikhil C Patel, Kozeta Libohova, Kristin A Richardson, Sokol V Todi Pharmacology, Wayne State University

Dentatorubral-pallidoluysian atrophy (DRPLA) is an autosomal dominant, progressively degenerative disorder that is predominantly distinguished by ataxia, myoclonus, epilepsy, choreoathetosis, dementia, and psychiatric disturbances. DRPLA is a member of the polyglutamine (polyQ) family of diseases, which comprises nine members and is caused by abnormal expansion of a polyQ tract repeat in specific proteins. The gene at the core of DRPLA is ATROPHIN-1 (ATN1). ATN1 is a transcriptional co-repressor that is expressed in the central nervous system and other organs. When the polyQ repeat of ATN1 is expanded beyond normal ranges, it causes neuronal toxicity and ultimately cell death. The precise molecular mechanisms underlying DRPLA are unclear. The pathogenic CAG repeat length of ATN1 ranges from 48 to 93. To assist with the understanding of the biological processes at the core of DRPLA, and with the hope of supporting the identification and development of therapeutics for this incurable disease, we recently generated isogenic *Drosophila melanogaster* transgenic lines that express full-length, human ATN1 with a normal (Q7) or pathogenic (Q88) repeat. We are in the process of characterizing these new models via longevity and motility assays and will present a full phenotypic and biochemical characterization of these new lines.

1532F **Modeling and exploring Spinal and Bulbar Muscular Atrophy in *Drosophila*.** Kristin Richardson[1], Medha Sengupta[2], Alyson Sujkowski[1], Kozeta Libohova[1], Autumn C. Harris[1], Robert J Wessells[3], Diane E Merry[2], Sokol V Todi[1] [1]Pharmacology, Wayne State University School of Medicine, [2]Thomas Jefferson University, [3]Physiology, Wayne State University School of Medicine

Spinal and bulbar muscular atrophy (SBMA) is a rare X-linked, neurodegenerative disorder resulting from pathogenic PolyGlutamine (polyQ) tract elongation within the androgen receptor (AR) protein. To add to the existing toolbox of SBMA models for studying disease pathology and therapeutics, we have generated a new model of SBMA in *Drosophila.* The newly generated lines express full-length, human AR, with either wild-type (Q20) or polyQ-expanded (Q112) AR inserted into the same “safe-harbor” site on the third chromosome. PolyQ-AR expression in adult muscle or nervous tissue leads to consistent, progressive reductions in lifespan and mobility, accompanied by aggregation of polyQ-AR protein and deterioration of the neuromuscular junction. These phenotypes are generally worsened by the addition of the AR ligand, Dihydrotestosterone. Experiments are in progress using these new lines to examine the impact of strategic mutations that will further illuminate the biology of AR protein in SBMA.

1533F **Protein L-Isoaspartyl Methyltransferase (PCMT) expression levels affect *Drosophila melanogaster* tolerance to certain bacterial infections** Maryam I Azeem[1], Maricarmen S. Carreto[2], Anđela Savić[2], Jessica Ahon Sanchez[2], Jessica Ashley Allen[1,3] [1]Columbia College of SC, [2]Roosevelt University, [3]Biological, Physical, and Health Sciences, Roosevelt University

Protein L-isoaspartyl methyltransferase (PCMT) is an evolutionarily conserved protein which initiates repair to proteins damaged by oxidative stress. PCMT is known to be important for cell survival across various cell types in different environments. Reports have shown that *Drosophila melanogaster* overexpressing *Pcmt* have an extended lifespan when raised at elevated temperatures and that male flies lacking *Pcmt* die faster during systemic *Listeria monocytogenes* infections despite a functional immune response limiting bacterial growth. Here we share data further elucidating the role of PCMT during bacterial infection.

We report that overexpression/knockdown of *Pcmt* extends/reduces the lifespan of both male and female flies infected with *Staphylococcus aureus* via septic prick. The same is true for flies infected with *Serratia marcescens* via oral infection, but not during *S. marcescens* infection via septic prick. *Pcmt* expression levels do not affect resistance to either bacterium via either infection method, as overexpressing and knockdown flies control bacterial load equally well throughout infection. Consistent with a potential role in tolerance during infection, wild type Oregon-R and Canton-S male flies induce expression of *Pcmt* upon infection with *S. marcescens.* We are currently working to determine how *Pcmt* expression levels impact non-survival measures of physiological health throughout infection and in which cell types *Pcmt* expression is important for increased tolerance to infection.

1534F **The circular RNA *circ_ATP8B* regulates ROS production and antiviral immunity** Weihong Liang[1], Wei Liu[1], Xiao-Peng Xiong[2], Jennifer W. Li[3], Jian-Liang Li[4], Ranjan J. Perera[1], Rui Zhou[5] [1]Johns Hopkins University, [2]Sanford Burnham Prebys Medical Discovery Institute, [3]Brown University, [4]National Institute of Environmental Health Sciences, [5]Johns Hopkins University School of Medicine

Circular RNAs (**circRNAs**), which are products of "head-to-tail" back-splicing events, have been discovered in diverse eukaryotes, and constitute a new addition to the non-coding and regulatory RNA collection. CircRNAs have been implicated in a wide variety of biological processes, including antibacterial innate immunity, neurodevelopment, and gene control.

To investigate the role of circRNAs in antiviral defense in *Drosophila*, we performed RNA sequencing and identified and validated of a collection of circRNAs that display significant changes in expression levels upon viral infection. We found that depletion of the pro-viral circular RNA *circ_ATP8B*, but not its linear sibling, led to a reduction in levels of viral RNA, protein and titer in cultured *Drosophila* SL2 cells upon infection by a panel of RNA viruses, including Flock House virus (**FHV**), *Drosophila* C virus (**DCV**) and Cricket paralysis virus (**CrPV**). Similarly, ubiquitous depletion of *circ_ATP8B in vivo* reduced viral load and enhanced host survival upon viral infection. Importantly, restoring *circ_ATP8B* expression in *circ_ATP8B*-depleted cells or flies suppressed the viral replication and/or host survival phenotypes. In addition, our analyses revealed that *circ_ATP8B* is a gut-enriched circRNA that is induced specifically by oral ingestion of viruses but not bacteria, and that gut-specific depletion of *circ_ATP8B* compromises viral replication in an oral infection model. Furthermore, we found that defects in viral RNA replication in *circ_ATP8B*-depleted flies correlated with elevated levels of ROS and enhanced expression of *Dual oxidase* (***Duox***), which encodes a ROS-producing enzyme. Notably, *circ_ATP8B* and Duox associate with each other, and expression of various versions of *circ_ATP8B* that are competent in binding Duox, but not a mutant *circ_ATP8B* that is incapable of binding Duox, restored physiological levels of ROS in *circ_ATP8B*-depleted cells. Lastly, we show that feeding flies with N-acetyl-L-cysteine (**NAC**), a ROS inhibitor, depletion of *Duox* or *Gaq,* a G protein required for optimal Duox activity, or overexpression of *immune-regulated catalase* (***IRC***), an enzyme that removes ROS, led to a reduction in ROS levels and suppressed the viral replication defects elicited by *circ_ATP8B* depletion. Thus, our study demonstrates that ROS acts as an antiviral agent against infection via the oral route and that *circ_ATP8B* regulates antiviral immunity, at least in part, by modulating Duox-dependent ROS production.

1535F **Targeted genetic screen for enhancers and suppressors of lifespan in a model of Huntington's Disease in *Drosophila*** Sevinch Kamaridinova, Tadros A Hana, Sabita Basnet, Kiel Ormerod Biology, Middle Tennessee State University

Huntington's Disease (HD) is an inherited neurodegenerative disorder highlighted by a progressive breakdown in neurons leading to progressive loss of motor control. Unlike other neurodegenerative disorders, HD research has focused mostly on one gene, the: Huntingtin gene (HTT). The disease is attributable to an abnormal expansion in CAG codon repeats in the gene, causing the protein product, huntingtin protein (htt), to have an expanded region of glutamine repeats (PolyQ region) which is linked to misfolding and aggregation of the protein within nerve cells. The severity of the disease and the age of onset have been shown to correlate with the degree of expansion within the PolyQ region of htt where an increase in glutamine repeats increases the pathogenicity and reduces age of onset. A *Drosophila* model of HD was previously created in the Littleton lab, where the first Exon of human htt was altered to include either 15 or 138 glutamine repeats in the PolyQ region (htt-Q15, and htt-Q138). These transgenic lines also included an RFP-tag for fluorescent imaging. Using the UAS/Gal4 system to express these transgenes in motor neurons ($Elav^{C155}$,) we demonstrated that htt-positive aggregates accumulate in the axons and at the neuromuscular junction (NMJ) in third-instar larvae which significantly reduces the intracellular trafficking of organelles like synaptic vesicles, mitochondria, and dense core vesicles. We also repeated the observation that expression of htt-Q138 in motor neurons ($Elav^{C155}$) significantly reduces adult viability. Here we target 50 different genes associated with HD pathology or huntingtin protein function using RNA interference (RNAi) and screened for changes in adult viability. Positive hits were then examined for molecular changes, like axonal and NMJ aggregation, to elucidate putative pathways altered in HD pathology or htt biological function. The results from our genetic screen may help to identify novel therapeutic targets for treatments of HD.

1536F **Investigating the role of rare genetic variants in BMP signaling genes in neurological diseases using *Drosophila*** Haley A Dostalik[1,2], Jung-Wan Mok[1,2], Oguz Kanca[2,3], Yufeng Shen[4], Carrie Welch[4], Center for Precision Medicine Models (CPMM)[5], Michael F Wangler[1,2], Hugo J Bellen[1,2], Wendy K Chung[4,6,7], Shinya Yamamoto[1,2] [1]Molecular and Human Genetics, Baylor College of Medicine, [2]Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, [3]Molecular and Human Geneetics, Baylor College of Medicine, [4]Columbia University, [5]Baylor College of Medicine, [6]Boston Children's Hospital, [7]Harvard Medical School

BMP signaling is critical for development and maintaining adult tissue homeostasis. Pathogenic variants within this pathway often cause genetic diseases or cancer. Previously, rare variants in a couple genes from the canonical BMP signaling pathway have been associated with neurodevelopmental disorders (NDD) through meta-analysis and case reports. However, there have

been no functional analyses or *in-vivo* studies of these variants to verify their pathogenicity.

Recently, we identified a rare, heterozygous, recurring *de novo* missense variant in *BMPR2* in 4 patients with overlapping NDD phenotypes, including autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD). Loss-of-function (LOF) *BMPR2* variants have previously only been implicated in pulmonary arterial hypertension (PAH), which is not seen in any of these patients. Through functional studies in *Drosophila*, we have shown this variant is a gain-of-function (GOF) allele, leading to overactivation of BMP signaling. We have also identified 13 likely LOF variants in *SMAD6* associated with various NDD phenotypes, such as ASD, seizures, global developmental delay, and abnormal brain development. Previously, *SMAD6* variants have only been implicated in causing an aortic valve disease, which is not seen in the 13 affected patients. Since SMAD6 is known to function as a negative regulator of this pathway, these variants may also lead to overactivation of BMP signaling, causing clinical phenotypes that overlap with patients who carry the GOF *BMPR2* variant. In *Drosophila*, while functional studies of BMP signaling mediated by dpp and gbb have been studied in the context of neuromuscular junction development and physiology, the role of this pathway kin the central nervous system is ill defined. The goal of this ongoing study is to test the hypothesis that *BMPR2* GOF and *SMAD6* LOF variants cause overactivation of BMP signaling, leading to neurological phenotypes in humans using a *Drosophila* model. By generation of transgenic lines that allow expression of human *BMPR2* and *SMAD6*, and manipulating their fly orthologs *wit* and *Dad*, we are investigating the biological function of this conserved pathway in the larval and adult nervous system in *Drosophila*.

1537F **Functional analysis and classification of rare genetic variants in SATB2 using *Drosophila*** Hirokazu Hashimoto[1,2], Samantha L Deal[3], Oguz Kanca[1,2], Kenji Yokoi[4], Shinya Yamamoto[1,2] [1]Molecular & Human Genetics, Baylor College of Medicine, [2]Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, [3]Howard Hughes Medical Institute and Chronobiology and Sleep Institute, University of Pennsylvania, [4]Nanomedicine, Houston Methodist Research Institute

SATB2-associated syndrome (SAS, a.k.a. Glass syndrome: OMIM #612313) is a rare genetic disorder with over 750 known cases worldwide. This syndrome is characterized by developmental delay, intellectual disability, and craniofacial dysmorphisms with variable expressivity and penetrance. This gene encodes for an evolutionarily conserved DNA binding protein that regulates chromatin remodeling. Because genotype-phenotype relationships in SAS have not been clearly established, we assessed the functional consequences of disease-associated variants in *SATB2* using fruit flies. After generating transgenic flies that express human *SATB2* under the control of the GAL4/UAS system, we compared the phenotypes induced by tissue-type or cell-type specific ectopic overexpression of reference or variant SATB2 *in vivo*. We studied two nonsense variants and 12 missense variants (5 variants at CUT1, 5 variants at CUT2, and 2 variants at HOX domain) previously reported in SAS patients. We found that overexpression of reference and variant human SATB2 in the wing, dorsal thorax, eye, neuron, or glia of *Drosophila melanogaster* permits the classification of disease-associated genetic variants. First, two nonsense variants behaved as strong loss-of-function (LOF) alleles *in vivo*, rather than as dominant negative alleles. Second, the early CUT1 variants behaved as a milder LOF allele compared to the nonsense variants. Last, the late CUT1 and CUT2 variants behaved primarily as gain-of-function (GOF) alleles *in vivo*.

In conclusion, some *SATB2* variants found in SAS patients behaved as LOF alleles, whereas others behaved as GOF variants. Understanding the functional consequence of each patient's variant has clinical implications because therapeutic design should be different for patients with LOF variants (e.g., gene therapy) and GOF variants (e.g., antisense oligonucleotide).

1538F **The Effects of Mutated Amyloid Peptide Expression in a Drosophila Model of Alzheimer's Disease** Kaliah Wood[1], Brett Chan[1], Aahwan Koirala[2], Olivia Nardell[2], Caroline Yu[2], Anisha Kavarthapu[2], Jorge Moran[2], Jevgenij Raskatov[3], Jeremy Lee[1] [1]Department of Molecular, Cell and Developmental Biology, University of California Santa Cruz, [2]University of California Santa Cruz, [3]Department of Chemistry and Biochemistry, University of California Santa Cruz

Alzheimer's disease (AD) is a neurodegenerative disorder that currently affects over 55 million people worldwide and is expected to affect closer to 140 million people by 2050. AD is characterized by plaques composed of amyloid beta (Aβ) peptide, which aggregates and is believed to be a major cause of neurodegeneration in AD. Recent research has demonstrated that amyloid alpha (Aα, also known as P3), a truncated form of Aβ without the first 16 amino acids, also aggregates and induces neurodegeneration. The Raskatov Lab at UCSC has identified 2 key missense mutations in Aβ, Q15E and N27D, which reduce its aggregation and cytotoxicity in vitro. We are testing the effects of expressing these 2 mutant forms of Aβ in vivo in a Drosophila model. Prior research has shown that flies expressing wild type (WT) Aβ and Aα have shorter life spans, behavioral deficits, and decreased locomotor capabilities. For this study, we transgenically express each Aβ mutation individually as well as in a double mutant. We are also working to generate flies that express WT and mutant forms of Aα.

A series of assays will be used to compare the phenotypes of WT (non-expressing) flies, flies expressing WT Aβ, and flies expressing the mutated forms of Aβ. In the longevity test, we hypothesize that WT flies will survive longest and flies pan-

neuronally expressing WT Aβ will have decreased survival. If the mutant forms of Aβ have decreased toxicity and aggregation in vivo, consistent with the in vitro results, the flies expressing mutated Aβ pan-neuronally will survive longer than WT Aβ flies. We will also perform olfactory learning assays to measure the flies' short and long-term memory. We expect that WT flies will have the best memory, and flies expressing WT Aβ will have the worst, with flies expressing mutated Aβ performing better than flies expressing WT Aβ. We will also compare the phenotypes of flies expressing the various forms of Aβ in the eyes by expressing WT and mutated forms of Aβ exclusively in the developing neurons of the eyes using a GMR-Gal4 driver. We have shown that flies expressing WT Aβ in eye neurons show defects in eye morphology, and hypothesize that expression of the mutant forms of Aβ will lead to a less severe phenotype. This research will provide essential information about structural elements of Aβ that contribute to its neurotoxicity and may guide the development of more effective therapeutics.

1539F **Tubulin and actin cytoskeletons of *Drosophila* nephrocytes and their roles in maintaining the filtration structure** Megan Delaney[1], Yunpo Zhao[2], Joseph Lee[2], Zhe Han[2] [1]Epidemiology and Human Genetics, University of Maryland-Baltimore, [2]Precision Medicine and Disease Modeling, University of Maryland-Baltimore

Drosophila nephrocyte shares striking similarities with human podocytes in the highly specificized filtration structure called Slit Diaphragm (SD). It has been established that changes in the podocyte actin cytoskeleton affect the integrity of the SD and the overall function of the glomerular filtration barrier. Nephrotic Syndrome (NS), a disease that affects 16 in 100,000 people worldwide, can be caused by variants in genes encoding cytoskeleton components. However, the main components of the nephrocyte cytoskeleton remain unclear. It is also not known whether tubulin cytoskeleton plays important roles in nephrocyte or podocyte structure and function. Using single-cell RNA-seq, my lab elucidated the genes encoding actin and tubulin cytoskeleton components for nephrocytes. We then silenced each of them using a nephrocyte Gal4 driver and the UAS-RNAi transgenic lines for these genes and identified main cytoskeleton components for nephrocytes. We found that Act5C and βTub56D are the key components for nephrocyte cytoskeleton, since silencing these genes individually will totally abolish the formation of nephrocytes. Although the knockdown of αTub84B did not result in the complete loss of nephrocytes, it does show a drastic phenotype in the SD, actin, and tubulin structures. For other actin (Act57B, Act42A, and Act87E) or tubulin (αTub84D, αTub85E, βTub97EF, and βTub60D) genes expressed in nephrocytes, we observed a variety of phenotypes, including decreased SD density, internalized SD proteins, and clustering of the actin or tubulin cytoskeleton in certain areas of nephrocytes. We also found that tubulin and actin cytoskeleton are interdependent. When tubulin cytoskeleton is disrupted, actin cytoskeleton falls apart and SD proteins accumulated with aggregated F-actin. When actin cytoskeleton is disrupted, tubulin cytoskeleton is disrupted and aggregated but without SD proteins in the aggregation. We believe that the cell uses different variants of the actin and tubulin monomers during each phase of growth, allowing for formation, development, and maintenance of the nephrocyte. In conclusion, while previous research has focused on the importance of the actin cytoskeleton in podocytes and its roles in NS, we indicated that the tubulin cytoskeleton plays a previously unknown and key role in the structure and maintenance in Drosophila nephrocytes and SD structures.

1540F **Investigating the bidirectional relationship between traumatic brain injury and sleep homeostasis in *D. melanogaster*** Rebecca N Ray, Rebecca Delventhal Biology, Lake Forest College

Traumatic brain injury (TBI) occurs when a sudden, severe impact to the head causes brain damage. This can impact short- and long-term health and homeostatic behaviors, like sleep. Recent studies have established *D. melanogaster* as a model for TBI that displays many characteristics of TBI in humans. Since sleep is a conserved behavior in nearly all animals, we decided to investigate the relationship between TBI and sleep using *D. melanogaster.* To test how TBI affects sleep over time, we used the High-Impact Trauma (HIT) device to injure wild-type flies and measured their sleep in the days and weeks post-injury. We found that at 48 hrs and 1 wk post-TBI, injured flies had more fragmented sleep than uninjured controls but progressed to sleeping more at 2 and 4 weeks. We then asked if disrupting sleep via a genetically short-sleeping fly had a detrimental effect on TBI recovery. We found that injured short-sleeping flies had a significantly higher acute mortality than injured flies with normal sleep, suggesting sleep has a protective effect on TBI recovery. We next asked what the underlying mechanism of this bidirectional relationship between TBI and sleep might be. Prior research supports the theory that sleep helps clear reactive oxygen species (ROS), protecting against oxidative stress. To investigate whether ROS mediates the relationship between sleep and TBI, we manipulated the neuronal expression of the antioxidant *SOD2* in order to change neuronal ROS levels and measured both short- and long-term TBI recovery. *SOD2* knockdown in neurons had no effect on acute mortality or lifespan within injury conditions. Interestingly, injured flies with *SOD2* overexpression in neurons had significantly higher acute mortality than injured flies with normal *SOD2* expression. Injured and uninjured flies with *SOD2* neuronal overexpression also had a decreased lifespan compared to controls with normal *SOD2* levels. This poses new questions as to how neuronal antioxidant expression affects ROS levels and oxidative stress throughout the body and if successful TBI recovery requires clearance of ROS in other tissues besides neurons. Future research manipulating ROS levels ubiquitously and in other cell types could further our understanding of ROS's role in the relationship between TBI and sleep, which could have implications in new TBI prevention or recovery strategies.

1541F **Systemic cardiac dysfunction in tumor models of *D. melanogaster*.** Shubha Gururaja Rao[1], Harpeet Singh[2], Leah Pyter[2], Priyanka Karekar[2], Sarah Seeley[1] [1]Ohio Northern University, [2]The Ohio State University

Cancer and heart diseases are the two leading mortality and morbidities in the United States. Several cancer patients undergo heart related complications resulting in their death. Cardiotoxicity due to therapeutic agents used in cancer treatment is one of the main causes of cardiac dysfunction in cancer patients. However, it is not clear if cancers systemically affect heart function prior to treatment hence making them vulnerable to cardiac abnormalities in later stages. In order to test this, our study uses different genetic models to establish if cancers indeed cause cardiac defects on their own prior to therapeutic intervention. We analyze in depth, various oncogenic pathways in *Drosophila,* such as Yki, JAK-STAT, RAS etc. and study their system effects on cardiac function. Our results indicate that oncogenes not expressed in the heart can cause cardiac dysfunction. We rescue some of these cardiac phenotypes using antioxidant treatment, with which we conclude that, systemic effects of tumorigenesis caused increased ROS affecting cardiac function. Our results also show that different oncogenic pathways have variable degrees of effects on the heart and it is important to conduct further studies to understand the systemic effects of cancers on heart function.

1542F **JAK-STAT pathway activation compromises nephrocyte function in a *Drosophila* high-fat diet model of chronic kidney disease** Yunpo Zhao, Jianli Duan, Joyce van de Leemput, Zhe Han University of Maryland

Background Obesity is a major risk factor for diabetes and chronic kidney disease, and elevated body mass index (BMI), a marker for obesity, has been associated with diabetic nephropathy and end-stage renal disease. However, our understanding of the mechanisms that link obesity to kidney disease remains incomplete.

Methods This study used a *Drosophila* model of chronic kidney disease to investigate the effect of a high-fat diet (HFD) on nephrocyte function (FITC-albumin and 10 kD Dextran uptake assays) and morphology (anti-Pyd immunochemistry; transmission electron microscopy), and to identify the underlying molecular pathway (RNAi; mutant forms; overexpression; pharmacological treatment).

Results We show that HFD-reduced absorption function of nephrocytes, the functional equivalent to human podocytes, is due to it altering the morphology of the slit diaphragm filtration structure (Pyd localization; lacuna channel distance and electron dense vacuoles). We demonstrate that HFD activates the JAK-STAT pathway in nephrocytes and that this can be initiated by increased expression and release of the adipokine, Upd2, from the fat body. Upd2 is the functional equivalent of Leptin and a ligand for the JAK-STAT pathway. Finally, we show that inhibiting the JAK-STAT pathway, either genetically or by pharmacological intervention (methotrexate), can reverse the HFD-induced nephrocyte functional deficit.

Conclusions Our study reveals the importance of the JAK-STAT signaling pathway in the adipose tissue–nephrocyte axis and its contribution to HFD-associated nephropathy. These findings open new avenues for intervention in treating diabetic nephropathy and chronic kidney disease.

1543F **The therapeutic potential of sulforaphane on the cognitive and behavioral impacts of Alzheimer's disease in *Drosophila melanogaster*** Najeeb Marun[1,2,3], Nguyen Le[4], Carmen P. Wong[2,5], Chaz Kayser[1,2], Alysia D. Vrailas-Mortimer[1,2], Emily Ho[2,5], Nathan T. Mortimer[1,2] [1]Department of Biochemistry & Biophysics, Oregon State University, [2]Linus Pauling Institute, Oregon State University, [3]Honors College, Oregon State University, [4]School of Biological Sciences, Illinois State University, [5]School of Public Health and Nutrition, Oregon State University

Alzheimer's disease (AD) is a progressive neurodegenerative disease caused by accumulation of amyloid beta (Aβ) peptides, leading to the formation of amyloid plaques. These plaques are believed to contribute to AD pathogenesis via disruption of neural connections and neurodegeneration. *Drosophila melanogaster* are valuable model organisms for the study of neurodegenerative diseases including AD. Transgenic expression of human Aβ (hAβ) in flies induces amyloid plaque formation and Alzheimer›s-like phenotypes, making flies an excellent system for investigating AD pathogenesis. We, and others, have demonstrated that hAβ expression leads to defects in memory, sleep, and locomotor activity. More specifically, we find that hAβ expressing flies perform worse in climbing assays, in which they exhibit reduced climbing speed, suggesting potential neurodegeneration affecting their locomotor ability, and in memory assays, in which they fail to alter their behavior in a choice assay following exposure to parasitoid wasps. The objective of this project is to understand the behavioral and cognitive consequences of AD in flies and investigate the potential health benefits of sulforaphane (SFN), a compound found in broccoli, as a therapeutic intervention.

To explore the therapeutic potential of SFN, broccoli seed supplements containing high amounts of SFN precursors were mixed with standard fly food. Initial feeding experiments demonstrated that flies successfully consume SFN, and we have determined

the ability of flies to survive eating food with varying concentrations of SFN. We further find that SFN is metabolized within the flies' digestive system, leading to production of previously characterized metabolites, and indicating its bio-accessibility for further testing in our hAβ expressing flies.

1544F **Investigating the role of the *Drosophila* IMD NF-κB pathway in age-dependent immunity following infection with Flock House virus** Victoria Faber[1], Josiah Cooperwood[1], Lakbira Sheffield[2], Stanislava Chtarbanova[1] [1]Biological Sciences, The University of Alabama, [2]UAB

As organisms age they become increasingly susceptible to infection and disease, including infections with viral pathogens. Although considerable progress has been made in understanding the age-related functional decline of the immune system, a complete picture of the mechanisms contributing to survival outcomes of older hosts in response to infections is still lacking. Our lab has modeled aged host-virus interactions using *Drosophila melanogaster* and the positive stranded RNA virus Flock House Virus (FHV). We have previously shown that in comparison to younger hosts, FHV infection of aged *Drosophila* contributes to decreased survival associated with impaired disease tolerance and increased expression of several genes encoding for components of the *Drosophila* immune deficiency (IMD) NF-kB pathway. This led us to hypothesize that FHV infection results in immunopathology in older hosts because of elevated IMD activation. Using RNAi, we investigated how ubiquitous knockdown (KD) of the IMD components *Relish*, *Pirk*, and *dSTING* affects survival of FHV infection with aging. Our results show that in comparison to controls, Pirk KD caused significant decrease in survival of FHV for both young and aged cohorts in both sexes. Interestingly, *dSTING* KD led to a non-significant difference in survival of FHV in young flies, but a protective effect specifically in aged females. Both young and aged *Relish* KD flies of both sexes died faster of FHV infection, possibly because of secondary bacterial infection. These data point to a causative link of overactive NF-kB pathway and survival of virus infection at older age; however additional experiments are underway to prove that this is the case. Current work focuses on carrying additional survival analysis of null mutants for both *dSTING* and *Relish*, and determining virus loads in all experimental conditions tested. Because *Relish* mutants and KD are immunocompromised and prone to acquire secondary bacterial infections as they age, we are conducting similar analysis in germ-free flies. Overall, our studies suggest a possible involvement of the IMD pathway in immunopathology after virus infection with aging and that modulation of disease tolerance responses in the older hosts could represent a target for improving the outcomes of viral infection.

1545F **Exploring the Function of a Missense Variant in *WWC3* as a Potential Candidate for a Novel Mendelian Disease using Drosophila** Jasmine O Brown[1,2,3], Shelley B Gibson[1,3], Hector R Mendez[4], Chloe Reuter[5], Shruti Marwaha[4], Devon Bonner[5], Jennefer N Kohler[5], Elijah Kravets[4], Undiagnosed Disease Network[1,4], Oguz Kanca[1,3], Michael F Wangler[1,3], Hugo Bellen[1,3,6], Euan Ashley[4], Stephen B Montgomery[4], Jonathan A Bernstein[4], Matthew T Wheeler[4], Shinya Yamamoto[1,3,6] [1]Molecular and Human Genetics, Baylor College of Medicine, [2]Post-baccalaureate Research Education Program, Baylor College of Medicine, [3]Jan and Duncan Neurological Research Institute, Texas Children's Hospital, [4]Stanford University, [5]Stanford Health Care, [6]Department of Neuroscience, Baylor College of Medicine

Hippo signaling is an evolutionarily conserved signaling pathway that is important for proper development and physiology in diverse species. In humans, dysregulation of this pathway has been linked to diverse genetic disorders as well as cancer. *WWC3* encodes one of three paralogous scaffolding proteins that acts as a positive regulator of this pathway. While *WWC3* has been studied in the context of oncogenesis, this gene has not yet been associated with a Mendelian disease. Here we present a hemizygous missense variant (p.D928N) in *WWC3* that was identified by the Undiagnosed Disease Network as a prime candidate of a rare and undiagnosed disease in a 14-year-old male. This patient presents with developmental delay, cardiac defects, myopia, recurrent pneumothoraces, apical blebs, flat feet, digital contractures, gray sclerae, soft translucent skin, and dysmorphic features. Previous studies in fruit flies (*Drosophila melanogaster*) showed that loss of function alleles of the *WWC* family ortholog, *kibra*, is recessive lethal and causes an overgrowth phenotype in mosaic animals, consistent with its role in hippo signaling in this model organism. In addition, overexpression assays in flies induced multiple scorable phenotypes during development, suggesting that this is a dosage sensitive gene. In this project, we aim to 1) assess whether the function of WWC3 and Kibra are conserved, 2) determine the functional consequence of the p.D928N variant based on rescue and overexpression experiments, and 3) explore the precise expression pattern of fly *kibra* to gain additional biological insights. So far, we have successfully created constructs with human reference or patient variant WWC3 cDNA which were confirmed by whole-plasmid sequencing. Using these constructs, we will generate transgenic flies that allow the expression of either the reference or variant human WWC3 as well as wild-type or mutant (carrying a p.D993N mutation that is analogous to patient variant) fly Kibra. Next, we will assess the capability of the reference or the variant WWC3/Kibra's to rescue the phenotype found in *kibra* mutants. We will also overexpress these transgenes in different developmental contexts to assess whether the variant functions as a loss- or gain-of-function allele. Finally, I will determine when and where fly *kibra* is expressed by assessing the expression pattern of gene- or protein-trap alleles. These results will help to elucidate the role of WWC3 and the p.D928N variant in the potential novel Mendelian disorder and will also help provide new biological insights on *WWC3*'s function in human disease.

1546F **New insights into the role of MECP2 in Rett Syndrome and Autism Spectrum Disorder through functional analysis in yeast, flies and human cell lines** Christopher Loewen[1], Jessica Schmitt[2], Barry Young[2], Seevasant Indran[2], Jie Liu[2], Eric Chen[2], Graeme McIntosh[2], Sonia Medina Giro[2], Vedanta Khan[3], Sanja Rogic[2], Jesse Chao[3], Paul Pavlidis[2], Douglas Allan[2] [1]University of British Columbia, [2]University of British Columbia, [3]University of Toronto

Gene variant discovery is becoming routine, but it remains frustratingly difficult to interpret the functional consequence or disease relevance of most identified rare variants. Experimental assays are helping to fill this interpretation gap, but there remain many roadblocks in creating assays that can interpret variant function with clinical predictive value. These include issues with assay reproducibility, scalability to hundreds of variants, and relevance to the pertinent disease mechanism. We have developed an approach that utilizes complimentary functional assays engineered in yeast flies and human cell lines to address these problems. We report on our efforts towards characterizing variants found in Rett syndrome and ASD in the MECP2 gene. In yeast, we exploited the slow growth phenotype resulting from MECP2 overexpression as a functional assay and tested 46 variants. Benign variants had little effect as expected, whereas pathogenic variants located in the MBD (the DNA binding domain) had large effects, indicating the disease-relevance of this assay. Genetic interaction screens for MECP2 showed enrichment for nuclear-related functions implicating these as the relevant disease pathways. MECP2 overexpression in the developing fly wing tissue caused generation of ectopic wing vein tissue in the wing. This was suppressed by heterozygosity for Asx, a fly co-repressor, indicating that MECP2 phenotypes arise through excess transcriptional repression. Benign and pathogenic behaved as normal and loss of function variants as expected. We then found that 4/7 ASD MECP2 variants are likely loss of function variants, and 3 are likely benign. Using HEK293 cells we assessed protein stability and cellular localization of all variants. Together our results reclassify ASD variants of uncertain significance as either likely benign or pathogenic.

1547F **Role of SETDB1 in hematopoiesis: A hold on expression of *HOX* genes** Indira Paddibhatla[1,2], Dushyant Kumar Gautam[3], Sreevani Palat[4] [1]Cardiology, Johns Hopkins University, School of Medicine, [2]Biochemistry, University of Hyderabad, [3]Biochemistry, School of Medicine, University of Hyderabad, [4]Indian Institute of Science Education and Research (IISER) Tirupati.

Proper regulation of genome by the epigenetic mechanisms is crucial for an error-free and steady growth of cells. Epigenetic mechanisms are heritable alterations affecting physical or chemical organization of the chromatin. *SETDB1* is a gene that encodes a histone methylase and mediates epigenetic modification; methylation of histone-3 occurs at lysine-9 silencing its target genes. In various cancers (like melanoma, breast cancer, hepatocellular cancer, lung cancer) *SETDB1*expression is elevated. We have discovered that in *Drosophila* SETDB1 is required for hematopoiesis. Mutants with loss of SETDB1 function (*dSETDB1*$^{-/-}$) exhibit hematopoietic overgrowth of the lymph gland (hematopoietic organ) decreased crystal cells along with an increase in the lamellocyte population that form blood-tumors. While dSETDB1 is essential for normal hematopoiesis, the molecular mechanism by which SETDB1 functions is poorly understood. We have recently identified that *HOX* genes as likely targets of SETDB1. We used microarray studies to determine differentially expressed genes in third instar mutant (*dSETDB1*$^{-/-}$) larvae relative to their heterozygote siblings. Microarray results revealed 653 genes to be down-regulated and 598 genes to be up-regulated. Of these, some de-regulated genes were associated with development. After validation by qRT-PCR, we chose to focus on the four *HOX* genes (*Abd-a*, *Abd-b*, *Dfd* and *Ubx*) because their ectopic expression using the immune cells' (blood cells and/or the fat body) specific GAL4s (*Collagen-Gal4*and *Hemese-Gal4*) in *Drosophila* resulted in tumor formation along with infiltration of the fat body tissue. Furthermore, *Collagen>Abd-A* larvae with overexpression of *SETDB1* expression (*UAS-SETDB1*) did not show any melanotic tumors in the circulating hemolymph. Lastly, we have discovered that the penetrance of blood tumors formed in *Collagen>Abd-A*larvae was decreased upon azacytidine (anti-leukemia drug) treatment along with increased expression of *SETDB1* and restoration of cell cycle regulators' expression (*Cyclin A*, *Cyclin D* and *P21*). Based on these observations, we speculate that SETDB1 is involved in the regulation of *HOX* genes in *Drosophila* blood cells.

1548F ***Drosophila* Modelling Reclassifies VoUS in *EED* and *SUZ12*: Relevance for Clinical Interpretation and Rare Variant Burden Testing in Population Cohorts** Douglas W Allan[1], Sonia Medina Giro[2], Sharri Cyrus[2], Jie Liu[2], William Gibson[2] [1]Cellular and Physiological Sciences, University of British Columbia, [2]University of British Columbia

Polycomb Repressive Complex 2 is an epigenetic reader and writer that methylates lysine 27 of histone H3 (H3K27), thereby assisting in chromatin condensation and transcriptional silencing. Rare germline partial loss of function (LoF) variants in core member EED cause Cohen-Gibson Syndrome, whereas pLoF variants in EZH2 cause Weaver syndrome and pLoF variants SUZ12 cause Imagawa-Matsumoto syndrome. Constitutional variants in the PRC2 "core" proteins are thus implicated in overgrowth and intellectual disability syndromes, whereas somatic variants are implicated in a variety of cancers.

GnomAD v4.0 reports that rare coding VoUS in PRC2 core proteins are, collectively, relatively common among the "general population." Summation of the gnomAD-derived minor allele frequencies for all VoUS, LP and P variants (excluding Benign and

Likely Benign variants) catalogued rare PRC2 variants in 1.3% of chromosomes, or 2.6% of the gnomAD population. The signal is largely driven by rare SUZ12 variants. Variants in these genes may represent an underappreciated risk factor for common, complex diseases.

In order to classify VoUS in patients with neurodevelopmental disorders, and to power future Rare Variant Burden tests in population cohorts, we developed a *Drosophila* mimetic approach: an *in vivo* assay that builds human-derived variants in *EED* or SUZ12 into its fly orthologue *esc, or Su(z)12*. We used CRIMIC technologies in both cases to replace each gene with a cDNA for the mimetic variant gene. To create assays of variant function with clinical predictive value, we calibrated assays with known benign and pathogenic variants, and examined phenotypes of pathogenic variants, benign variants and VoUS relevant to the known function of the PRC2 complex in Drosophila.

We report that our fly mimetic approach accurately assesses the loss of function of pathogenic variants and the 'normal' function of benign variants. This successful calibration of functional assays allows us to assess and re-classify VoUS as likely benign or likely pathogenic. We are proceeding to study and reclassify multiple EED and SUZ12 VoUS from gnomAD and other cohorts, and are building similar fly assays for EZH2.

1549F **Dissecting the cell-cell communication between senescent cells and the surrounding normal cells *in vivo*** Takao Ito[1], Tatsushi Igaki[2], Lucy Erin O'Brien[3] [1]Stanford University, [2]Graduate School of Biostudies, Kyoto University, [3]Department of Molecular & Cellular Physiology, Stanford University

Cellular senescence, a state of irreversible cell-cycle arrest, has been attracting much attention as the leading cause of organismal aging. Senescent cells accumulating in tissues during aging are considered to cause or contribute to aging phenotypes and aging-associated diseases. However, the underlying mechanisms still remain unclear: little is known about how senescent cells affect their surrounding cells and tissues, and in the first place, how senescent cells accumulate *in vivo* is unknown. Here, using *Drosophila melanogaster* as a model, we show that senescent cells promote cell mitosis in their surrounding normal cells in the intestinal epithelium of the young adult fly. Using the MARCM technique, we induced mosaic clones expressing the ETS transcriptional activator Pointed, which was identified as a master regulator of cellular senescence in the fly larval epithelial tissue (Ito and Igaki, 2021, *Sci Signal*), in the young adult intestinal epithelium. We found that Pointed clones induced in the tissue are positive for various cellular senescence markers. Thus, this approach allows us to explore the cell-cell communication between senescent epithelial cells and the surrounding normal epithelial cells *in vivo*. Using this method, we discovered that Pointed clones strongly increase the mitotic cell number in their surrounding normal cells in the young intestine. In addition, we found that these surrounding cells are positive for Delta (a marker for intestinal stem cell) and Erk phosphorylation. Erk signaling is known to play a key role in activating stem cell division (Liang *et al*, 2017, *Nature*). These observations suggest that senescent cells could open up the proliferative potential of their surrounding stem cells via elevation of Erk signaling. On the other hand, interestingly, we found that Pointed clones induced in the young intestine are eliminated from the epithelium over time. We will further discuss about the underlying mechanisms regulating these cell-cell communications *in vivo*.

1550F **Genetic diversity of Collaborative Cross mice reveals highly variable antibody response to seasonal influenza vaccine** Lucie Dupuis[1], Cécile Apert[2], Juliette Meyer[3], Pascal Campagne[3], Pascal Blanc[4], Geneviève Renauld-Mongénie[5], Daniel Larocque[6], Sylvie van der Werf[7], Gérard Eberl[8], Xavier Montagutelli[9] [1]Mouse Genetics Laboratory, Institut Pasteur, Paris, [2]Micrenvironment and Immunity, Institut Pasteur, [3]Bioinformatics and Biostatistics Hub, Institut Pasteur, [4]Global Immunology Group, Sanofi, [5]Global Antigen Design Group, Sanofi, [6]Innovation and Emerging Science Group, Sanofi, [7]Molecular Genetics of RNA viruses Unit, Institut Pasteur, [8]Microenvironment and Immunity, Institut Pasteur, [9]Mouse Genetics Laboratory, Institut Pasteur

Vaccination is one of the most effective interventions to protect against infectious diseases. Vaccines have been developed for a variety of microorganisms. Depending on the desired immune response targeted, vaccines may present antigens in different forms (e.g. attenuated or inactivated organism, purified antigen, nucleic acid encoding antigen) in the presence or absence of adjuvants aimed at enhancing immune responses. One of the most used vaccines is the seasonal influenza vaccine (IV) which composition is adapted every year to sample the most circulating influenza strains. However, induction of protective, neutralizing antibodies to this inactivated, unadjuvanted vaccine, is variable between individuals and decreases with age. Multiple host-related factors contribute to this incomplete efficacy, and studies in humans are complicated by the heterogenous history of previous exposure to influenza virus. To identify genetic factors influencing antibody response and which may contribute to the vaccine efficacy, we immunized mice from 39 CC strains with a human tetravalent IV and analyzed their antibody response against influenza H1N1 virus at several time points. CC mice showed large heritable variations in the magnitude and kinetics of antibody response, as well as in the distribution of IgG subclasses. Cytokine levels before immunization and one day after boost were also variable between strains, and random forest analysis identified patterns

associated with high or low antibody responses. These results show that CC mice, which exhibit the same variability of humoral response to IV as humans, could be a useful platform for evaluating vaccine efficacy and allow the identification of genetic variants and biomarkers associated with diverse antibody responses.

1551F **RESF1 is a tandem G4-associated tumor suppressor in triple negative breast cancer** Megan Majocha[1,2], Devin Jackson[1], Ngoc-Han Ha[1], Kent Hunter[1] [1]National Cancer Institute, [2]Georgetown University

In the US, women diagnosed with localized breast cancer have a 5-year survival rate of approximately 99% but drops to 30% when women develop metastases. Therefore, a better understanding of metastatic biology is necessary to prevent or treat metastases. To accomplish this, we have used the highly metastatic genetically engineered mouse model (GEMM) MMTV-PyMT to identify inherited factors that influence metastasis. Genetic mapping analysis was performed in a backcross between the MMTV-PyMT model and the MOLF/EiJ mouse strain to identify genes associated with tumor burden, latency, and metastasis. A significant peak on the distal chromosome 6 was observed and several putative metastasis susceptibility genes, including *Resf1*, were identified that predict distant metastasis free survival in ER-negative breast cancer. RESF1 is a large, unstructured protein whose intron-exon structure is conserved across species, but the amino acid sequence is not. Using a CRISPR-mediated knockout mouse model, as well as a genetrap model, of RESF1 depletion, crossed to the PyMT GEMM, our lab demonstrated that *Resf1* loss is associated with increased lung metastasis, consistent with patient data. In addition, 50% reduction in RESF1 resulted in a significant increase in tumor growth and a shortened overall survival time. Furthermore, analysis of matched tail and primary tissue from the *Resf1* heterozygous and PyMT cross revealed loss of the wildtype copy, consistent with *Resf1* being a tumor suppressor at the primary site. RNA-seq data, however, showed that *Resf1* is more highly expressed in metastases compared to primary tumors, suggesting that Resf1 has opposing roles in the primary and secondary site. To study the underlying mechanism of RESF1 in metastasis, bioinformatic analyses of metastatic cell lines and mouse tumors were performed. Genomic analysis suggests that RESF1 binds to tandem G4-quadruplex DNA structures, which are alternative knot-like structures that can form in DNA with high GC content resulting in altered transcription or DNA replication. Currently, our experiments are focused on investigating this novel mechanism of RESF1 in ER-negative breast cancer metastasis.

1552F **Identification of Homeostatic Predictors of Severe Infection with Machine Learning Methods** Kalika Kamat[1,2], Brea Hampton Brown[1], Jessica Graham[3], Elizabeth Anderson[1,4], Sharon Taft-Benz[1], Tim Bell[1], Pablo Hock[1], Sarah R Leist[5], Colton L Linnertz[1], Emily Madden[6], Kenneth Plante[1], Sanjay Sarkar[1], Alexandra Schaefer[5], Ginger D Shaw[1], Victoria K Baxter[4,7], Jennifer Lund[3], Fernando Pardo Manuel de Villena[1,8], Ralph S Baric[6], Mark T Heise[1,6,8], Martin T Ferris[1] [1]Department of Genetics, University of North Carolina - Chapel Hill, [2]Bioinformatics and Computational Biology Curriculum, University of North Carolina - Chapel Hill, [3]Fred Hutchinson Cancer Research Center, [4]Department of Comparative Medicine, University of North Carolina - Chapel Hill, [5]Department of Epidemiology, University of North Carolina - Chapel Hill, [6]Department of Microbiology and Immunology, University of North Carolina - Chapel Hill, [7]Department of Pathology and Laboratory Medicine, University of North Carolina - Chapel Hill, [8]Lineberger Cancer Center, University of North Carolina - Chapel Hill

Infectious diseases manifest with differing severity in individuals due to a number of underlying factors including genetics, age, gender, environmental exposures and overall health of the immune system. Therefore, predicting disease outcomes prior to infection is challenging due to limitations in our ability to study any of these factors in isolation in the human population. One potential approach to better understanding how genetic variation affects the ability to predict different disease outcomes is to utilize mouse models that incorporate genetic diversity. Here, we utilize the Collaborative Cross (CC) genetic reference panel to assess whether aspects of steady state (homeostatic) transcription and immune cell composition can be used to predict disease outcomes to viral (SARS-CoV-2, chikungunya) infections. Harnessing the power of machine learning, we phrased this task as a classification problem for separating susceptible mice from resistant ones based solely on measurements taken prior to infection. We trained algorithms including random forest, support vector machines, logistic regression and neural networks to identify resistant mouse strains from a mixed group in our training set. We then assessed accuracy in a separate test dataset, and found that depending on the methodology, we could achieve accuracy between 50 and 78%. Our preliminary results with chikungunya infection data show highest accuracy and replicability with neural networks (NN). We further were able to compute SHAP values from these NN classifiers, and can point to important predictors of disease outcome across genetic backgrounds.

1553F **Unraveling the role of mitochondrial and NAD^+ metabolism in acute and chronic kidney disease through a cross of resistant and sensitive mouse strains** Jean-David Morel SV, EPFL

Acute kidney injury (AKI) and chronic kidney disease (CKD) are global health issues steadily rising in incidence and prevalence. Animal models on a single genetic background have so far failed to recapitulate the clinical presentation of human nephropathies. We implemented two models of kidney injury in 7 highly diverse mouse strains: (1) the AKI-to-CKD transition over 6 weeks after folic acid (FA) exposure, and (2) kidney alterations upon a prolonged feeding with western diet and housing at thermoneutrality (WD/TN). We measured plasma and urine parameters, as well as renal histopathology and mRNA expression. We observed an extensive strain-specific response, ranging from complete resistance of the CAST/EiJ mouse strain to high sensitivity to FA-induced kidney damage in the PWK/PhJ strain. In susceptible strains, AKI is accompanied by the induction of the mitochondrial stress response (MSR) and the attenuation of NAD^+ synthesis pathways. This is associated with delayed healing and a prolonged inflammatory and adaptive immune response 6 weeks after insult, heralding a transition to CKD. In the WD/TN model, the CAST/EiJ strain was again remarkably resistant to kidney damage, while kidney histology indicated tubular damage and immune infiltration in other strains. Through a thorough comparison between the transcriptomic response in mouse and human disease, we showed that critical metabolic gene alterations are shared across species and highlighted the PWK/PhJ strain as an emergent model of kidney disease and the CAST/EiJ strain as exceptionally resistant to both injury and metabolic challenge of the kidney. In order to map specific genes responsible for resistance or susceptibility to kidney disease, we performed a second generation (F2), 4-way cross between the C57BL/6J, CAST/EiJ, 129/SvlmJ and PWK/PhJ strains, and submitted the F2 mice to WD/TN treatment over 20 weeks. Across 500 F2 mice, we observe a continuum of responses of body weight gain and obesity, markers of liver disease, or of kidney disease, enabling precise gene mapping, which will be presented.

1554F **The Efficiency of Arsenic Metabolism Depends on Genetic Background in Mice Carrying the Same Humanized *AS3MT* Gene** Timothy A Bell[1], Joseph Farrington[1], Pablo Hock[1], Ginger D Shaw[2], Paul Cotney[2], James G Xenakis[2], Christelle Douillet[2], Peter H Cable[2], Matt W Blanchard[2], John S Sigmon[2], Chidima Ahulamibe[2], Joyce Woo[2], Tianyi Liu[2], Qing Shi[2], Fei Zou[2], Rebecca C Fry[2], Miroslav Stýblo[2], Fernando Pardo-Manuel de Villena[2] [1]Genetics, UNC-CH, [2]UNC-CH

In mice and humans, the arsenite methyl-transferase gene (*AS3MT*) encodes for the key enzyme responsible for metabolizing/detoxifying arsenic. Humans and mice have a single copy of this gene, but the murine version is significantly more effective in converting inorganic arsenic (iAs) into the less toxic dimethyl-arsenic (DMA). Thus, although laboratory mice have been used for decades to model the effects of arsenic exposure, the ability to translate any finding to humans remains unclear. In 2020, we and our UNC collaborators, generated a humanized mouse by replacing the entire mouse *As3mt* gene and its regulatory sequences with the homologous human sequence and demonstrated that these mice metabolize iAs in human-like fashion. As a resource to test whether genetic background has any effect on arsenic metabolism or in arsenic mediated disease phenotypes, we used these humanized animals and Collaborative Cross (CC) mice to generate multiple congenic lines carrying identical human *AS3MT* genes on diverse genetic backgrounds. To test the hypothesis that genetic background influences total arsenic (tAs), and the percent of iAs (% iAs), methyl-arsenic (% MAs), and dimethyl-arsenic (% DMAs) in excreted urine, we exposed 4 humanized congenic strains to three doses of arsenic: 0.1, 1, and 5 ppm, in drinking water in addition to controls drinking deionized water. We measured iA, MA, and DMA and calculated tAs. Urine was collected at three timepoints during the experiment, pre-exposure, midpoint, and the end of the multi-week of exposure. We performed these experiments on 12 replicates of both male and female mice from each congenic line. As expected, the levels of tAs in urine increases as the dosage increases across strains and sexes. However, the tAs excreted in the urine varies significantly between for a given dose (this is true for 1ppm and 5ppm exposures). Specifically, humanized B6 excrete significantly more (3x) than humanized mice in the CC003 background. Strain differences are also observed for arsenic composition. Finally, there is evidence for sex and diet effects. We conclude that despite the important role that *AS3MT* plays, there are additional genetic factors that influence arsenic metabolism in laboratory mice. The humanized congenic strains can be used to develop better models of exposure and identify these additional genetic factors.

1555F **Deficiencies in the mitochondrial associated membrane (MAM) component FAM105A (now OTULINL) disrupt innate immune signaling and cause fibrostenotic inflammatory bowel disease (IBD) in mice and very early onset IBD (VEO-IBD) in humans** Brooke A. Green[1,2], Anjali Thomas[1,2], Rieko Niibori[1], Amber-Anne Mullin[1,2], Neil Warner[3], Aleixo Muise[3,4,5,6], Mahmoud El-Maklizi[3,7], Miki Gams[3,7], Cynthia Guidos[3,7], Sabine P. Cordes[1,2] [1]Lunenfeld-Tanenbaum Research Institute, [2]Department of Molecular Genetics, University of Toronto, [3]The Hospital for Sick Children, [4]Department of Biochemistry, University of Toronto, [5]Department of Pediatrics, University of Toronto, [6]Insitute of Medical Sciences, University of Toronto, [7]Department of Immunology, University of Toronto

Inflammatory bowel disease (IBD) is a debilitating inflammatory intestinal condition that can involve fibrosis and strictures, which are especially frequent in Crohn's Disease (CD) and in very early onset IBD (VEO-IBD). The paucity of mouse models that recapitulate fibrostenotic IBD has limited research into identifying cell populations, such as different immune cell types, that drive intestinal fibrosis and could be targets for anti-fibrotic therapies.

A key hub for integrating innate immune signals are the contacts between mitochondria and the endoplasmic reticulum (ER) called mitochondria-associated membranes (MAMs). Disrupting immune signaling at MAMs can cause IBD and increase risk for intestinal fibrosis; for example, variants in the cytosolic bacterial immune sensor Nucleotide-Binding Oligomerization Domain Containing 2 (NOD2), which activates signaling at MAMs, confer the highest risks for ileal CD with strictures.

The Ovarian Tumor (OTU) domain protein OTULINL, unlike other OTU domain proteins, does not bind or cleave ubiquitin chains and contains a transmembrane domain that tethers it to MAMs. We have generated an *Otulinl* knockout mouseline that, excitingly, shows inflammation and fibrosis in the small intestine, recapitulating the pathology of CD. Highlighting its importance in human IBD, we identified multiple *OTULINL* variants unique to VEO-IBD patients at the Hospital for Sick Children in Toronto.

Previous analyses of NOD2-deficient CD patient tissues have led to the untested hypothesis that disrupting innate immune signaling solely in immune cells can drive fibrostenotic IBD. Here, using adoptive transfer experiments we show that immune cells drive the intestinal inflammation and fibrosis seen upon *Otulunl* loss. Moreover, in luciferase assays, OTULINL suppresses *IFNB1* transcription driven by the Mitochondrial Antiviral Signaling Protein (MAVS), which oligomerizes at MAMs and is promoted by NOD2 signalling. Strikingly, some of the VEO-IBD variants heighten this suppression and one variant enhances NOD2-driven NF-κB activity and alters subcellular NOD2 localization. Taken together, our findings suggest that immune cells drive NOD2-deficient fibrostenotic IBD and that OTULINL regulates MAM-dependent inflammatory responses.

The *Otulinl* knockout mouse presents a novel model of fibrostenotic IBD that could be harnessed for determining the cellular and molecular drivers of intestinal fibrosis which could open avenues towards its arrest or reversal.

1556F **Understanding the Mechanisms Mediating Gene-Environment Interactions in Congenital Heart Defects** Irene Zohn, Irene Zohn Center for Genetic Medicine, Children›s National Hospital

The developing embryo has the remarkable ability to buffer genetic and environmental insults to ensure normal development, but congenital anomalies result when these insults exceed a disease threshold. We aim to elucidate how these buffering systems mediate the interplay between genes and the environment and if their disruption contributes to structural birth defects in genetic syndromes. Developmental robustness, or the ability to resist perturbations, can potentially be achieved through miRNA-mediated negative feedback loops to buffer insults. However, it remains known whether miRNA-mediated buffering mechanisms have any role in birth defects. Maternal diet is an important environmental factor that can influence the development of congenital anomalies. For instance, intake of either too much or too little vitamin A can result in congenital heart defects. Moreover, pregnant women may ingest varying amounts of vitamin A, depending on diet and supplement usage, and the embryo must buffer these variations to ensure normal cardiac development. A precise gradient of retinoic acid, established by feedback loops involving retinoic acid synthesis and degradation enzymes, is necessary for the proper specification and development of cardiac progenitors. Our studies demonstrate that genetic mutations can interact with the maternal diet to alter the establishment of this retinoic acid gradient and the development of cardiac progenitors. For instance, 22q11.2 deletion syndrome (22q11DS) is associated with variable aortic arch and outflow tract defects in humans. It is well accepted that the variability in 22q11DS is due to the influence of genetic and environmental factors, but the identity of these factors and how they interact remains unknown. Utilizing a mouse model of 22q11DS, we demonstrate that variability may be due to impaired buffering of retinoid signaling. We find that a significant proportion of 22q11DS embryos from dams fed normal levels of vitamin A exhibit aortic arch but not outflow tract defects. But, when dams are fed slightly more vitamin A, 22q11DS embryos, but not their wild-type siblings, exhibit both aortic arch and outflow tract defects. Changes in buffering of retinoid signaling, miRNAs, and cardiac progenitor specification and development precede these malformations. These findings reveal a new mechanism through which genetic mutations and maternal diet changes can influence phenotypic variability in genetic syndromes.

1557F **A Machine Learning Approach to Predicting Tumor Status through Telomere Length Variation (TLV) Analysis** Priyanshi Shah, Arun Sethuraman Biology, San Diego State University

Telomeres, the protective caps at the ends of chromosomes, consist of a repetitive nucleotide sequence (TTAGGG) in humans and play a crucial role in chromosomal replication. With each cell division, telomeres shorten due to the end-replication problem. Telomere shortening is therefore associated with age-related diseases, early mortality, and has implications for cancer biology, particularly in the context of cellular senescence and tumor progression. Our preliminary analyses of Telomere Length Variation (TLV) in the 1000 Genomes Project data indicate significant variation in TLV among human populations, between sexes, and age classes. A recent study (Burren et al., 2023) also performed a large scale estimation of telomere length variation across the UK BioBank data and identified several associated rare variants that correlate with myeloid cancer precursors. Here we use data from The Cancer Genome Atlas (TCGA) in congruence with variants identified by Burren et al.,

2023 to achieve three primary objectives: 1. Quantify telomere length variation (TLV) across different cancer types and tissues. 2. Identify genetic variants associated with telomere length variation, spanning both cancer and non-cancer genomes. 3. Utilize estimated telomere lengths from the whole-genome sequencing (WGS) data, rare variant data, and phenotypic data available on TCGA to train a supervised machine learning model that predicts tumor status (cancer versus non-cancer).

1558F **Functional characterization of a pancreatic cancer GWAS signal at the chr13q12.2/*PLUT*/*PDX1* locus** Trevor A Christensen[1], Erin Char[2], Daina Eiser[2], Michael Mobaraki[2], Irene Collins[2], Jun Zhong[2], Aidan O'Brien[2], Gauri Prasad[2,3], Katelyn Connelly[2], Jason Hoskins[2], Laufey Amundadottir[2] [1]National Cancer Institute, National Institutes of Health, [2]Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, [3]2Laboratory of Receptor Biology and Gene Expression, Center for Cancer Research, National Cancer Institute, National Institutes of Health

Genome-wide association studies (GWAS) searching for common genetic variants associated with increased risk of pancreatic cancer have identified a prominent signal at chr13q12.2 overlapping the promoter region of *PDX1*, encoding a transcription factor involved in pancreas development, and the homeostasis lncRNA gene *PLUT*, which mediates *PDX1* expression. Fine mapping, epigenomic annotation, and experimental validation of allele-specific regulatory activity together implicated rs9581943 (P=1.21x10^{-12}, OR=1.16) as the most likely functional variant driving this association signal. Analysis of expression quantitative trait locus (eQTL) from the Genotype-Tissue Expression (GTEx) project identified a significant association between rs9581943 genotype and *PDX1* expression in the pancreas (P=2.5x10^{-6}), suggesting *PDX1* as a likely mediator of the association. To assess the phenotypic effects of altered *PDX1* expression, doxycycline-inducible *PDX1* overexpression models were generated in pancreatic cancer cell lines. Increasing *PDX1* expression resulted in reduced cell proliferation and an increased proportion of cells entering apoptosis. Differential expression analysis of time-course RNA-seq data found that several pathways linked to immune system activity, inflammation, diabetes, and other cancer-related pathways were affected. While allele-specific protein binding at rs9581943 has been observed by electromobility shift assays (EMSA), efforts to identify the responsible transcription factor(s) continue. To directly assess its allele-specific effects on gene expression, all three diploid rs9581943 genotypes (GG, GA, AA) were engineered from heterozygous pancreatic cancer cell lines using CRISPR/Cas9 nuclease single-base editing. After editing and clonal selection, *PDX1* expression was measured across all three genotypes and found to negatively correlate with copies of the risk allele, consistent with the eQTL results. Taken altogether, these data implicate rs9581943 as a likely mediator of functional pancreatic cancer susceptibility by modulating *PDX1* expression.

1559F **Phylogenetic Analysis of HIV Antiretroviral Drug Resistance Evolution in Sub-Saharan Africa** Pleuni S. Pennings, Takudzwa Chirenje Biology, San Francisco State University

Out of the estimated 39 million people worldwide living with HIV, 29 million are receiving antiretroviral drugs (ARVs). However, HIV drug resistance poses a formidable challenge to the effectiveness of antiretroviral drugs (ARVs) in HIV treatment. Transmitted drug resistance (when resistance evolves in one host and the resistant strain is transmitted to one or more other hosts) is seen at high levels in Sub-Saharan Africa. Understanding the evolution and transmission dynamics of HIV drug resistance mutations is imperative in addressing this growing concern. This study is directed towards investigating the evolution of resistance in Sub-Saharan Africa, given the region's limited treatment options and high HIV infection rates, which contribute to the complexity of HIV drug resistance. Using phylogenetic tools, an analysis of well-known drug resistance mutations in publicly available HIV sequences will be conducted. The primary goal is to determine the roles of transmitted drug resistance by constructing a comprehensive phylogenetic tree and then quantifying cluster sizes of drug resistance in the tree and analyzing the transmission patterns across distinct classes of HIV drugs. Anticipated outcomes include the identification of genetically related clusters of drug-resistant strains and inferring the distribution of cluster sizes, hypothesized to vary due to differences in the fitness costs of drug resistance mutations which influence their transmissibility. This research is expected to significantly contribute to the understanding of the transmission and evolution of drug resistance in HIV. The findings hold the potential to inform the development of strategies aimed at mitigating the transmission of drug resistance, consequently reducing the prevalence of drug resistance in HIV patients and preventing unnecessary fatalities. The specific aims of this study involve acquiring 40,000 HIV sequences from Sub-Saharan Africa with associated metadata to construct dated phylogenetic trees (Aim 1) and quantifying and comparing cluster size distributions for 10 important resistance mutations that confer resistance to specific classes of HIV drugs (Aim 2). This will result in an increased understanding of the roles of de novo evolution and transmission for important HIV drug resistance mutations. By addressing critical gaps in knowledge concerning HIV drug resistance evolution and transmission, this research attempts to provide valuable insights and strategies to combat the transmission of drug resistance, thereby improving the overall outcomes for individuals living with HIV.

1560F **circRNA Transcriptomic Associations with Parkinson's Disease Severity and Genetic Mutations** Sayan Biswas, Arti Jajoo, Sebastian Kadener Biology, Brandeis University

Parkinson's Disease (PD) is the second most common neurodegenerative disorder worldwide. There is an unmet need in PD diagnosis to characterize novel biomarkers that arise from molecular dysregulation in the brain due to the disease. circRNAs, a non-canonically spliced form of pre-mRNAs, accumulate with age in the brain and are enriched in neurons. circRNAs as promising biomarkers due to their unusual stability, diversity, and abundance in the brain, and detectability in minimally-invasive fluids like blood. Our study investigates the circRNA transcriptome in a cohort of over 4000 human blood samples to understand its relationship with Parkinson's Disease (PD). This is, to the best of our knowledge the largest population circRNA study until now. We identified more than 10,000,000 circRNA types in this population. Importantly, we found that most of them are expressed in only few individuals, demonstrating that most circRNAs are likely splicing noise. However, we found thousands of cicNRAS that are robustly expressed across the populations. Our analysis identified a subset of circRNAs with consistent expression patterns, potentially linked to biological relevance in PD. We performed differential expression analysis and found that circRNAs are globally downregulated in PD patients compared to controls. In longitudinal comparisons, we identified several circRNAs with consistent downregulation across PD progression visits, suggesting their potential as indicators of disease trajectory. Furthermore, we observed pronounced circRNA dysregulation in genetically determined PD cases (GBA+, LRRK2+, SNCA+ mutations) compared to idiopathic PD, reflecting the distinct influence of genetic factors on the circRNA transcriptome. By correlating circRNA expression with Unified Parkinson's Disease Rating Scale (UPDRS) scores, we uncovered strong positive correlations with scores I & IV in idiopathic PD, which were absent in genetic PD cases. Our findings highlight the value of circRNA profiling in understanding PD's molecular underpinnings and suggest circRNAs as potential biomarkers for PD severity and progression, with implications for both idiopathic and genetic forms of the disease. Moreover, we are performing additional population analysis in order to determine whether circRNAs correlate with biomark other physiological parameters.

1561F **Concurrent Evolution of Antiaging Gene Duplications and Cellular Phenotypes in Long-Lived Turtles** Stephanie E Bulls[1], Scott Glaberman[2], Juan M Vazquez[3], Ylenia Chiari[1], Vincent Lynch[4] [1]Biology, George Mason University, [2]Environmental Science and Policy, George Mason University, [3]Biology, University of California-Berkeley, [4]Biological Sciences, University at Buffalo

There are many costs associated with increased body size and longevity in animals, including the accumulation of genotoxic and cytotoxic damage that comes with having more cells and living longer. Yet, some species have overcome these barriers and have evolved remarkably large body sizes and long lifespans, sometimes within a narrow window of evolutionary time. Here, we demonstrate through phylogenetic comparative analysis that multiple turtle lineages, including Galapagos giant tortoises, concurrently evolved large bodies, long lifespans, and reduced cancer risk. We also show through comparative genomic analysis that Galapagos giant tortoises have gene duplications related to longevity and tumor suppression. To examine the molecular basis underlying increased body size and lifespan in turtles, we treated cell lines from multiple species, including Galapagos giant tortoises, with drugs that induce different types of cytotoxic stress. Our results indicate that turtle cells, in general, are resistant to oxidative stress related to aging, whereas Galapagos giant tortoise cells, specifically, are sensitive to endoplasmic reticulum stress, which may give this species an ability to mitigate the effects of cellular stress associated with increased body size and longevity.

1562F **Genetic background modifies metabolic related outcomes after inorganic arsenic exposure in humanized *As3mt* mice.** Ginger D Shaw[1], Timothy A Bell[1], Joe Farrington[1], Pablo Hock[1], Chidima Ahulamibe[1], Matt Blanchard[1], Paul Cotney[1], David Truong Ngyen[1], John Sebastian Sigmon[2], Joyce Woo[1], Christelle Douillet[3], James G Xenakis[1,4], Rebecca C Fry[4,5], Mirek Styblo[3], Fernando Pardo Manuel de Villena[1,6] [1]Genetics, University of North Carolina-Chapel Hill, [2]Computer Scieince, University of North Carolina-Chapel Hill, [3]Department of Nutrition, University of North Carolina-Chapel Hill, [4]Curriculum in Toxicology and Environmental Medicine, University of North Carolina-Chapel Hill, [5]Department of Environmental Sciences and Engineering, University of North Carolina-Chapel Hill, [6]Lineberger Comprehensive Cancer Center, University of North Carolina-Chapel Hill

In mammals, the arsenic 3 methyl transferase gene (*AS3MT*) encodes the key enzyme responsible for metabolizing arsenic. Humans and mice have a single copy of this gene, but the murine version is significantly more effective in converting inorganic arsenic (iAs) into the less toxic dimethyl- arsenic (DMA). Thus, although laboratory mice have been used for decades as models of arsenic exposure, the ability to translate any finding to humans remains unclear. In 2020, we and our UNC collaborators generated a humanized mouse by replacing the entire mouse *As3mt* gene and its regulatory sequences with the homologous human sequence and demonstrated that these mice metabolize iAs in human-like fashion. To evaluate whether genetic background has any effect on iAs mediated disease phenotypes including metabolic phenotypes, we generated multiple distinct congenic mouse strains carrying the identical humanized locus but otherwise variable background genome wide. We exposed both male and female mice from four congenic strains, B6Crl.129S6-*hAs3mt (*B6), CC003.129S6-h*As3MT* (CC003), CC040.129S6-h*As3mt* and CC057.129S6-h*As3mt* to three doses of (iAs) in deionized drinking water (0.1, 1 or 5ppm) in addition to controls (0 ppm). For each mouse we measured body weight every 2 weeks, body composition (fat and lean mass), fasted

blood glucose (FBG), and blood glucose at 15 minutes (BG15) after glucose challenge, prior to exposure, at the end of the experiment and at midpoint. Mice were fed a semi-purified chow with either low or high fat content. Two examples of strain effects on these phenotypes are: 1) Exposure of female mice to 1 ppm iAs leads to a significant increase in body weight and lower FBG in CC003 but not in B6; and 2) Exposure of male mice to 5 ppm iAs leads to a significantly higher BG15 in CC003 but not in B6. In addition to obvious sex effects, 1 ppm and 5 ppm doses lead to opposite outcomes for weight, FBG, and body composition independently of the strain. This preliminary data using just two congenic strains and two doses show a significant effect of genetic background in metabolic phenotypes after iAs exposure in humanized *As3mt* mice.

1563F **Defining the molecular mechanism of *NARS1*-mediated dominant neurological disease** Sheila Marte[1], Anthony Antonellis[1,2] [1]Human Genetics, University of Michigan, [2]Neurology, University of Michigan

Aminoacyl-tRNA synthetases (ARSs) are essential enzymes that ligate amino acids to cognate tRNAs in the cytoplasm and mitochondria. Although ARSs are essential and ubiquitously expressed, loss-of-function (LOF) missense mutations in six dimeric ARS enzymes have been associated with dominant inherited neuropathy. In addition, heterozygosity for missense and protein-truncating variants in asparaginyl-tRNA synthetase (*NARS1*; the gene encoding the enzyme that ligates asparagine to tRNA molecules in the cytoplasm) have been identified in patients with early-onset neurodevelopmental delay. Thus, ARS genes cause a spectrum of dominant neurological diseases. Interestingly, all ARS enzymes implicated in dominant neurological disease (including NARS1) function as dimers and we previously showed that neuropathy-associated alanyl-tRNA synthetase (*AARS1*) alleles act via a dominant-negative mechanism.

Here, we test pathogenic *NARS1* variants for a dominant-negative effect to determine if this mechanism is common to ARS-associated dominant neurological disease. We performed yeast complementation assays to test R322L and R534* *NARS1* in isolation, which revealed that both alleles exhibit a loss-of-function effect. To test for dominant-negative properties of ARS-mediated neurological alleles, we developed a humanized yeast assay to co-express human mutant *NARS1* with wildtype human *NARS1*. These studies revealed that both mutant alleles repress the ability of the wild-type allele to rescue yeast cell growth, consistent with a dominant-negative effect. To test the neurotoxic effects of these alleles, we developed a *C. elegans* model heterozygous for R534* *NARS1*; we will next characterize this strain and test if overexpression of wild-type *NARS1* rescues any neurological phenotypes. Here, I will present my unpublished data on disease-associated *NARS1* variants, which will provide insight into pathogenic mechanisms.

1564F **Excess accumulation of polyphosphate causes a short replicative lifespan in budding yeast** Chiharu Umeda, Yukio Mukai Graduate School of Bioscience, Nagahama Institute of Bio-Science and Technology

The budding yeast *Saccharomyces cerevisiae* provides numerous insights into cellular aging and lifespan research. The replicative lifespan of the yeast is defined as the number of cells produced by a cell before dying and is unique for the accurate determination of an individual cell's lifespan. Most genetic and environmental factors related to replicative lifespan have been identified, such as calorie restriction, NAD-dependent deacetylase sirtuin and target of rapamycin pathways.

We previously demonstrated that deletion of *PHO80* (cyclin) and *PHO85* (cyclin-dependent protein kinase) genes, which negatively regulate phosphate starvation-responsive genes, drastically shortened the replicative lifespan. The shortened lifespan of the *pho80*Δ mutant was rescued by additional deletion of *PHO4* (transcriptional activator), suggesting that overexpression of the Pho4p target genes causes the shortened lifespan. To identify lifespan-related genes, a transcriptome analysis screened upregulated genes in the *pho80*Δ mutant, and we focused on the *VTC* genes, which encode the vacuolar polyphosphate (polyP) polymerase complex. PolyP, a linear polymer consisting of hundreds of orthophosphate residues for phosphorus and energy storage, mainly accumulates in the vacuole in yeast. The *pho80*Δ mutant was confirmed to highly accumulate intracellular polyP. Deletion of *VTC1*/*VTC2*/*VTC4* restored the lifespan and polyP levels in *pho80*Δ. In the wild type, overexpression of *VTC5* or a combination of the other *VTC*s caused high polyP accumulation and a shortened lifespan. Similar phenotypes were caused by the deletion of polyP phosphatase genes—vacuolar *PPN1* and cytosolic *PPX1*. The polyP-accumulating *pho80*Δ strain exhibited oxidative and heavy-metal stress sensitivities. Thus, we demonstrated that polyP metabolic enzymes participate in yeast replicative lifespan, and high accumulation of polyP leads to a shortened lifespan. Furthermore, the expression of the *Escherichia coli* polyP kinase gene *Ecppk1* shortened yeast lifespan, which was improved by *PPX1* overexpression. Taken together with sequestration of polyP in the vacuole, these data suggest that an increase in cytosolic polyP accelerated the cellular aging process.

1565F **New instrumentation and software for high-resolution, high-throughput yeast fitness profiling to measure genetic interaction globally, discover phenomic modules, and model genetic buffering of disease** Sean Santos, John Rodgers, Jingyu Guo, Ryan Mancinone, John Hartman IV Genetics, Univ Alabama, Birmingham

Phenotypic dependencies involving combinations of functionally variant loci and/or external perturbation are called genetic

interaction and influence disease phenotypes in largely unknown ways. Evolutionarily, genetic interaction contributes population phenotypic variance that is subject to natural selection and underlies differential phenotypic robustness and variable buffering of disease between individuals. Genomic mutant collections are a powerful resource to quantify gene interaction globally for better predicting complex phenotypes across different species and cell types. Cell proliferation is the fundamental fitness phenotype of single-cell eukaryotes like *S. cerevisiae*, and it is resolved with highest precision by growth curves. To promote growth curve analysis for the genomic library of ~ 6000 mutant *S. cerevisiae* strains, we developed a time-lapse imaging instrument to monitor cell proliferation for ~60,000 cultures per experiment. Data, fit ($R^2 > 0.995$) to a logistic growth curve model, yield growth curve parameters to quantify genetic interactions rigorously and precisely. Custom software automates analysis of growth curves from cell array images, measurement of gene interaction, and clustering of gene interaction profiles to compare perturbations phenomically. The approach, quantitative high throughput cell array phenotyping (Q-HTCP), involves serial imaging of dilute cultures spotted onto agar, via a custom robotic line scanner integrated with a commercial robotic incubator and custom program logic control (PLC) for experiment management and data organization. Cell array imaging facilitates visualization of raw data to assess quality and directly examine selected spot cultures in a traditional way. The system capacity is 180 384-culture arrays. Fine resolution of genetic interaction aids identification of protein complexes and molecular pathways, and detection of relatively small or subtle phenotypic effects that may be otherwise elusive in a disease-modeling context. Disease-relevant perturbations explored with Q-HTCP include response to chemotherapeutic agents, quiescence maintenance in stationary phase (chronological survival), and modeling of cystic fibrosis (CFTR) disease mutations in the yeast homolog, Yor1. The presentation shares recent efforts making Q-HTCP more user friendly for bench scientists, including a standardized experimental structure to streamline analysis, assure quality control, and integrate results from independent studies. Examples illustrate use of Q-HTCP and yeast phenomics for modeling genetic complexity of human disease and for collaboration across model systems.

1566F **Evolutionary Rescue of Human Disease Mutations** Brooke Dubyna[1], Ryan Vignogna[1], Ethan Perlstein[2], Gregory Lang[1] [1]Lehigh University, [2]Perlara PBC

Individuals affected with rare diseases often face significant challenges in accessing appropriate medical care due to a lack of research focusing on these conditions. Yeast provides a model system for advancing a basic understanding of human disease associated alleles. Using experimental evolution, we previously identified mutations that arose to compensate for disease phenotypes of human pmm2, an ortholog of yeast sec53. We will extend this approach to other human disease genes, focusing on those involved in congenital disorders of glycosylation, mitochondrial dysfunction, and transcriptional regulation. Our results will map local genetic interaction networks centered around disease-associated alleles. A greater understanding of evolutionary processes and the interactions between these genes and pathways will help in developing targeted therapies for disease management in patients with rare disorders.

1567F **Inhibition of NADPH Oxidase 2 Improves Survival in Zebrafish Infected with Influenza A Virus** Brandy-Lee Soos[1], Alec Ballinger[1], Mykayla Weinstein[2], Julianna Grampone[1], Benjamin King[1] [1]Molecular and Biomedical Sciences, University of Maine, [2]School of Biology and Ecology, University of Maine

Influenza A virus (IAV) is a major health concern since it can cause severe lung infections, especially in older adults and individuals with chronic health conditions. The innate immune system is the host's first defense against pathogens, including IAV. The long-term goal of our research is to understand the molecular mechanisms of the innate immune response to IAV infection and use that information to find new antiviral therapeutic targets. Neutrophils have essential roles in innate immunity to bacterial and fungal infections, but their roles in antiviral responses are understudied. Neutrophils generate an inflammatory response following infection, but that response must be carefully regulated. A sufficient level of inflammation is needed to clear infection, but too much inflammation results in a damaging hyperinflammatory response. The zebrafish (*Danio rerio*) is a powerful vertebrate model system that is used to study IAV infection. Zebrafish larvae are used to study innate immune responses as the adaptive immune system is not active until approximately one month of age. Using zebrafish larvae, we study the roles neutrophils have in controlling IAV infection and how over-activation of neutrophils during IAV infection trigger a damaging hyperinflammatory response. During the inflammatory response, reactive oxygen species (ROS) are produced and released by NADPH oxidase 2 (NOX2) in neutrophils through the respiratory burst response. We hypothesize that reducing the respiratory burst response will limit tissue damage and improve survival. Using RNA sequencing, we found that the oxidative stress response pathway was upregulated in IAV-infected larvae compared to uninfected controls at six hours post infection. To test our hypothesis, we compared survival and respiratory burst response in IAV-infected larvae treated with and without a NOX2 inhibitor, GSK205739, to controls. The NOX2 inhibitor improved survival with IAV infection. Respiratory burst assays that measure the capacity of larvae to generate ROS showed an improved response in IAV-infected larvae with NOX2 inhibitor treatment compared to controls. These and other studies will help us identify how inflammation is regulated during IAV infection so that therapeutic measures that preserve the antiviral response, yet contain the associated inflammation, can be developed.

1568F **Zebrafish as a Translational Model of Chronic Early Life Stress: Insights Along the Oral-Gut-Brain Axis** Christina Graves[1], Erik Norloff[1], Darius Thompson[1], Cassandra Sang[1], Oksana Kosyk[2,3], Anthony Zannas[4] [1]Biomedical Sciences, UNC-Chapel Hill, [2]Genetics, UNC- Chapel Hill, [3]Psychiatry, UNC- Chapel Hill, [4]Psychiatry and Genetics, UNC- Chapel Hill

Chronic early life stress (ELS) is known to alter the development and functioning of the nervous and immune systems and has been associated with a myriad of negative health outcomes along the Oral-Gut-Brain axis. In addition to it's relatively well-described effects on the developing brain, ELS is known to be an important environmental modifier of gut inflammation in humans and has also been associated with the earlier emergence of pre-permanent teeth suggesting that the teeth can serve as a biometric indicator of stress-induced premature aging. Though physiological stress responses are appreciated to have major tissue targets throughout the body, the mechanisms linking ELS to tissue dysfunction later in life is incompletely understood. Here, we employed a novel, prolonged chronic stress paradigm recently developed by our lab (Graves et al. 2023) in which random, unpredictable environmental stressors are initiated at the onset of exogenous feeding and continued throughout larval development mimicking early childhood stress. Behavioral analysis was performed by videographic recording and analysis of free-swimming behavior in a novel tank test and showed that ELS-exposed zebrafish demonstrated a significant increase in anxiety-like behaviors as well as a significant – yet transient – reduction in body size. We found that ELS reduces enteric neuronal density, delays intestinal transit, and results in the differential expression of neuroimmune genes in a tissue- and time-dependent manner suggesting that ELS impacts the enteric nervous system in similar-yet-distinct ways to that of the developing brain. We have also recently established an experimental pipeline to develop zebrafish as a model organism to advance our understanding of the fundamental mechanisms underlying the impacts of prolonged ELS on the developing dentition. By leveraging high-resolution X-ray microtomography (micro-CT) and whole mount tissue clearing immunofluorescent confocal imaging of cleared whole-mount zebrafish (3-DISCO), our preliminary data suggest that ELS disrupts both the timing and morphology of newly emerged pharyngeal teeth. Altogether, our findings provide insights linking ELS with gut dysfunction and disrupted dental development, highlighting the zebrafish model system as a valuable tool in uncovering how "the body keeps the score" along the Oral-Gut-Brain axis.

1569F **Leveraging gametogenesis-specific rejuvenation pathways to counteract cellular aging** Tina L Sing[1], Katie Conlon[1], Stephanie H Lu[1], Nicole Madrazo[1], Tianhao Yin[1], Kaitlin Morse[1], Juliet Barker[1], Ina Hollerer[1], Gloria Brar[1], Peter H Sudmant[2], Elçin Ünal[1] [1]Molecular and Cell Biology, University of California, Berkeley, [2]Integrative Biology, University of California, Berkeley

Aging manifests as an accumulation of cellular defects that eventually cause functional decline, disease, and organismal death. Significant research into the causes of cellular aging has revealed a growing list of age-associated factors that are conserved from yeast to humans. Interestingly, gametogenesis contains inherent rejuvenation pathways that prevent age-associated damage from being passed onto progeny, which leads to lifespan resetting. Thus, there is strong incentive to understand how gametogenesis-specific rejuvenation genes can eliminate aging biomarkers and determine which of these pathways can be leveraged to counteract cellular aging in somatic cells. Gametogenesis is a highly regulated developmental program whereby diploid progenitor cells undergo cell division (meiosis) and differentiation to produce haploid gametes; however, the complete complement of gametogenesis genes involved in cellular rejuvenation remains largely unknown. Our lab and others are working to identify and understand how gametogenesis-specific mechanisms remove aging biomarkers to reset lifespan in *Saccharomyces cerevisiae*. Excitingly, overexpression of the meiotic transcription factor, Ndt80, is sufficient to extend lifespan suggesting that at least a subset of gametogenesis-specific rejuvenation pathways can be repurposed for use outside of their natural context (reviewed in Sing et al., 2022a).

We have constructed 5 inducible cDNA libraries (Sing et al., 2022b) and developed a screening pipeline to measure the effect of gametogenesis genes on competitive fitness in both young and old yeast cells. This led to the identification of 80 rejuvenation gene candidates, including genes with roles in different organelles (e.g. mitochondria, endoplasmic reticulum, Golgi apparatus, and vacuole) and genes with diverse biological functions (e.g. genome maintenance, RNA processing, cell cycle regulation, metabolism, and stress response). We believe that the diversity in this list is exciting because it may represent multiple pathways that converge to rejuvenate aging cells. We also found several rejuvenation candidates that are potential targets of Ndt80, which may facilitate nucleolar rejuvenation and lifespan extension that has been previously reported. Currently, we are using a microfluidic pedigree system to perform single-cell lifespan measurements in strains overexpressing each of the rejuvenation candidates identified in our screen. Future research will be focused on: (i) understanding how these genes promote cellular rejuvenation; (ii) determining if there is crosstalk between these rejuvenation genes; and (iii) optimizing gene dosing and synergy to promote longevity.

1570S **Lifespan and mitochondrial effects of 6PPD in *Caenorhabditis elegans*** Steven Beck[1], Laxmi Rathor[2], Taylor McElroy[1], Stephanie Wohlgemuth[1], Myon Hee Lee[3], Moon Jung Hyun[4], Sung Min Han[1] [1]Physiology and Aging, University of Florida, [2]Physiological and Aging, University of Florida, [3]Eastern Carolina University, [4]Korea Institute of Toxicology

The synthetic antioxidant N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) is commonly utilized in rubber-based products like tires, and its release into the environment during tire wear poses a threat to wild salmon populations. However, the toxicity of 6PPD in other species and the underlying mechanisms still need to be better understood. In this study, we investigated the potential toxicity and targets of 6PPD using the in vivo model system C. elegans. Exposure to 0.5 mM 6PPD in C. elegans resulted in adverse effects, including delayed development, decreased body growth, and reduced reproduction. Additionally, 6PPD exposure negatively impacted healthspan parameters, such as body motility and stress tolerance, leading to a shortened lifespan. 6PPD-exposed C. elegans also exhibited disrupted mitochondrial function, characterized by reduced mitochondrial membrane potential, lower oxygen consumption, diminished ATP levels, and decreased reactive oxygen species (ROS). Notably, 6PPD exposure influenced the activity of SKN-1/Nrf2, a key transcription factor involved in stress response and longevity. Suppression of SKN-1 attenuated reductions in lifespan and tolerance against paraquat, suggesting the involvement of SKN-1/Nrf2 in mediating the toxic effects of 6PPD. Together, these findings provide insights into the potentially toxic effects of 6PPD on development, health, and aging processes, identifying mitochondria as a potential target organelle affected by 6PPD exposure. Understanding the mechanisms behind the toxic effects of 6PPD is crucial for developing strategies to mitigate its environmental impact and protect vulnerable species.

1571S **Roles of purine biosynthesis represented in disease models of perturbed *de novo* and salvage synthesis** Maia Pappadakis, Mia Peifer, Adam Fenton, Wendy Hanna-Rose Pennsylvania State University

Purines, essential molecules to many biological processes, are produced by *de novo* synthesis and salvage synthesis pathways. Both of these pathways are highly conserved across organisms, evidence that each is important in maintaining purine homeostasis. Mutations in *de novo* and salvage synthesis enzymes are associated with Mendelian diseases in humans. Two examples of these diseases are adenylosuccinate lyase deficiency (ASLD), the result of a deficiency of the *de novo* enzyme adenylosuccinate lyase (ADSL), and Lesch-Nyhan disease, the result of a deficiency of the salvage enzyme hypoxanthine-guanine ribosyl transferase (HGPRT). We use the *Caenorhabditis elegans* model to study these diseases associated with purine synthesis, where all purine pathway enzymes have orthologs. In both human disorders and *C. elegans* models, phenotypes are quite distinct both between and within loss of function in *de novo* and salvage pathway enzymes.

In humans, ASLD causes phenotypes such as seizures and reduced psychomotor function where Lesch-Nyhan causes phenotypes such as self-injurious behaviors and gouty arthritis. In *C. elegans* models, *adsl-1* deficiency causes infertility and reduced motility where *hprt-1* deficiency causes no observable fertility or psychomotor phenotypes. These distinct phenotypes suggest specific biological roles are interrupted by the loss of function of these *de novo* or salvage pathway enzymes, and imply that intermediary purine metabolites may also play important roles. One curious observation in both human and *C. elegans* cases of ADSL/*adsl-1* loss of function is that while we observe significant phenotypes, there is no change in steady-state purine levels. Additionally, there is an increase in *hprt-1* expression in *adsl-1* loss of function, leading us to hypothesize that compensatory mechanisms between *de novo* and salvage pathways play a role in disease mechanisms. I aim to study the interactions between *de novo* and salvage synthesis that maintain purine levels by measuring the regulatory response of the salvage pathway in *de novo* loss of function and vice versa. Yet another interesting preliminary observation is a reduced fat content in the intestine of *hprt-1* loss of function *C. elegans*. I will report on experiments to examine the function of salvage in the etiology of *adsl-1* loss of function phenotypes and the phenotypic and metabolic analysis of *hprt-1* loss of function.

1572S **How do the Orsay virus and its variants affect the Intracellular Pathogen Response in *C. elegans?*** Abigail Rose Reese[1], Nicolas Martinez[2], Sehrish Khan[2], India Cannon[2], Jessica N Sowa[2] [1]Biology, West Chester University of Pennsylvania, [2]West Chester University of Pennsylvania

In 2011, the Orsay virus was discovered as the first virus known to naturally infect *C. elegans*. This is a ssRNA, non-enveloped, +sense virus that contains 4 proteins including capsid, alpha-delta, delta, and RDRP. Infection of *C. elegans* by this virus activates an innate immune response called the Intracellular Pathogen Response (IPR), which is a set of 80 genes that are transcriptionally upregulated. This response can also be triggered by heat, stress, other intracellular pathogens, or Bortezomib. Bortezomib is a chemotherapy drug that activates the *C. elegans* IPR when exposed, and preliminary data from our lab indicates that when worms are exposed to Bortezomib and the Orsay virus, the IPR levels decrease relative to Bortezomib exposure alone. This suggests that the IPR is lessened when the worms are infected with the Orsay virus.

Our current study seeks to understand how the Orsay virus affects the IPR in *C. elegans.* Evidence suggests that the Orsay virus dampens the IPR, so we are interested in determining which of the 4 Orsay proteins is responsible for this. Previous evidence has shown that the RDPR upregulates the IPR, not represses it, so we created transgenic strains that can be used to test the capsid, alpha-delta, and delta proteins individually. We are also investigating how variation in the virus affects the IPR by comparing infection rates in different Orsay variants. Our data indicates that divergent Orsay variants V2 and V13 show lower infectivity rates, and we are also assessing the effect of these variants on the IPR. Overall, our results add to our knowledge

of how this virus interacts with its' host, helping to guide and expand the use of *C. elegans* as a model organism for host-virus interactions.

1573S **Variation in Orsay virus affects progeny numbers of *C. elegans*** Solon Aguila, Sehrish Khan, Jessica Sowa West Chester University

C. elegans has been used as a model organism to study the innate immune system. To study their innate immune responses, they need to be infected and the only virus known to naturally infect *C. elegans* is the Orsay virus. Since the original discovery of the Orsay virus there have been several different variants of Orsay discovered in Europe. Two of those variants we discovered from samples collected in the Netherlands, and we named these variants V2 and V13. To compare V2 and V13 variants to the original Orsay isolate JU1580 we wanted to compare how they can affect host fitness. We have found that Orsay JU1580 decreases the number of progenies from infected worms. Previous experiments done by others looking at progeny effects did not find a difference in the overall number of progenies, but they found a delay in progeny production. The decrease in offspring we found in Orsay JU1580 infected *C. elegans* could be from the delay in progeny production. A previous experiment our lab has performed comparing V2 and Orsay JU1580 progeny numbers found that V2 did not affect the number of progenies produced. I am now comparing the different effects of Orsay JU1580 and its variant V13 have on the fertility of *C. elegans*. The organisms were time synchronized through bleaching and plated on three infection plates, one control, one Orsay JU1580, and one V13. Three adults were moved to normal NGM plates and left for two days to procreate in triplicate. The adult worms were removed and then the progenies were left to grow for two days. The progenies were then counted and compared using one-way ANOVA. Our results show that the average number of progenies produced by Orsay JU1580 infected *C. elegans*, 392 ±53 progeny, is significantly smaller than the average number of Orsay V13 infected, 188 ±106 progeny, and control *C. elegans*, 402 ±64 progeny. There was no statistically significant difference between the progeny count of V13 and the control group. The data was analyzed using a one-way ANOVA ($p=0.0013$, $n=3$). Based on these results, we concluded that V13 does not affect *C. elegans* fertility whereas Orsay JU1580 does.

1574S **Predictive modeling to define the locus heterogeneity of tRNA synthetase-related peripheral neuropathy** Allison Cale[1], Anthony Antonellis[2] [1]Human Genetics, University of Michigan, [2]University of Michigan

Aminoacyl-tRNA synthetases (ARSs) are ubiquitously expressed, essential enzymes that ligate amino acids to tRNAs. Variants in six genes encoding an ARS cause dominant axonal peripheral neuropathy, which presents the question: how do variants in ARSs, which are essential in all tissues, lead to phenotypes restricted to the peripheral nervous system? While defects in protein translation and activation of the integrated stress response have been implicated downstream of neuropathy-associated ARS variants, a unifying pathological mechanism that explains the locus heterogeneity has not been identified. All six neuropathy-associated ARSs function as dimers, which is consistent with a dominant-negative effect.

Seryl-tRNA synthetase (*SARS1*) is a dimeric ARS implicated in dominant peripheral neuropathy. We tested the pathogenic S396F *SARS1* allele for loss-of-function and dominant-toxicity in humanized yeast assays. We found that when the yeast ortholog *SES1* is repressed, S396F *SARS1* does not complement yeast growth, indicating it is a loss-of-function mutation. Furthermore, when co-expressed with wild-type *SARS1*, S396F *SARS1* reduces yeast growth, indicating that it exerts a dominant toxic effect on wild-type SARS1.

If a dominant-negative effect is the primary disease mechanism of ARS-mediated dominant peripheral neuropathy, then certain variants in any dimeric ARS could exert a dominant-negative effect and lead to dominant neuropathy. To test this, we engineered missense mutations (based on conservation and localization to functional domains) in threonyl-tRNA synthetase (*TARS1*), a dimeric ARS not yet implicated in neuropathy. We have tested seven variants to date: (**1**) five are loss-of-function alleles; and (**2**) two repress wild-type *TARS1*, consistent with a dominant-negative effect.

Based on these data, we generated two heterozygous *C. elegans* models to test if dominantly toxic *SARS1* and *TARS1* alleles cause dominant neurologic and motor behavior phenotypes in a multicellular organism. By using a two-pronged approach examining a *bona fide* pathogenic allele in *SARS1*, combined with a predictive modeling strategy of identifying dominantly toxic *TARS1* alleles, we aim to elucidate the mechanism by which numerous alleles across six ARS genes converge on a dominant peripheral neuropathy phenotype. Here, I will present all of my unpublished data on these studies.

1575S **TCER promotes embryonic health upon maternal infection** Laura Bahr[1], Danny Bui[2,2], Francis RG Amrit[3], Andre Viera[4], Carissa Olsen[4], Arjumand Ghazi[1] [1]Rangos Research Center, Departments of Pediatrics, Developmental Biology and Cell Biology & Physiology, University of Pittsburgh School of Medicine, [2]University of Pittsburgh, [3]Rangos Research Center, Departments of Pediatrics, Developmental Biology and Cell Biology & Physiology, University of Pittsburgh, [4]Departments of Chemistry and Biochemistry, Worcester Polytechnic Institute

Fertility and immunity are both energy intensive metabolic programs. Energy allocation by an organism to one process is a trade-off at the cost of the other. Lipids are an energy-rich resource whose mobilization is integral to both reproductive success and pathogen defense. We are investigating the role of lipid-metabolic pathways in the immunity-fertility dialogue through infection of the nematode *Caenorhabditis elegans*, a well-established molecular-genetic model organism, by the human opportunistic pathogen *Pseudomonas aeruginosa* (PA14).

Previously, we demonstrated that PA14 infection dramatically reduces fertility and that TCER-1, worm homolog of a human transcription elongation and splicing factor TCERG1, protects host reproductive fitness in the presence of pathogen.

Our recent data demonstrate that PA14 infection causes rapid depletion of stored lipids in somatic tissues, but that lipid stores in developing embryos are protected from depletion by TCER-1. Conversely, TCER-1 inhibits lipid deposition in the maternal hypodermis; which significantly does not mobilize lipids to the germline. Thus, TCER-1 diverts maternal energetic resources away from somatic storage toward reproduction. Furthermore, we show that TCER-1 promotes higher levels of polyunsaturated and monomethyl branched chain fatty acids in embryonic tissue upon PA14 infection. These fatty acids are required for formation of the innermost eggshell layer, the lipid permeability barrier. Accordingly, upon PA14 infection we observe a partially penetrant failure to form the lipid permeability barrier in *tcer-1* embryos, which is lethal. Together, this data demonstrates that TCER-1 promotes lipid allocation to embryos, and ensures their viability upon maternal infection with PA14.

1576S **Control of mitochondrial DNA purifying selection by regulators of aging and programmed cell death** Joel H Rothman, Sagen Flowers, Samantha Fiallo, Abhayjit S Saini, Rushali Kothari, Yamila Torres Cleuren, Melissa Alcorn, Chee Kiang Ewe, Geneva Alok, Pradeep M Joshi MCD Biology, University of California

Animal cells harbor many copies of the mitochondrial genome (mtDNA) and multiple mtDNA genome variants can be stably maintained in each cell. This heteroplasmy allows deleted mtDNA mutants to accumulate cryptically through replicative advantage. mtDNAs undergo high rates of mutation and defective mtDNAs, which accumulate during aging, are associated with a range of age-related diseases. Mechanisms to remove defective mtDNAs through mitochondrial “purifying selection” (MPS), notably mitophagy, function to ensure fidelity of mtDNA, particularly during development of the maternal germline, the source of the mtDNA that is inherited by the next generation. We found that pro-apoptotic regulators, including the CED-3 and CSP-1 caspases, the BH3-only protein CED-13, and engulfment factors, are required in *C. elegans* to attenuate germline abundance of an mtDNA deletion (*uaDf5*), which is otherwise stably maintained in heteroplasmy with wildtype mtDNA. In contrast, removal of pro-apoptotic CED-4/Apaf1 does not increase accumulation of the deleted mtDNA, suggesting a non-canonical role for CED-13 and the caspases. While we found that *uaDf5* increases the number of cell corpses observed in adult germlines, elimination of apoptotic cell death does not alter the burden of defective mtDNA, suggesting that a caspase-dependent, cell death-independent mechanism is required for MPS. We observed that the load of germline *uaDf5* increases with maternal age, and that this higher burden is passed onto the offspring, with only partial intergenerational removal of the defective mtDNA; thus, older mothers produce offspring with higher levels of mutant mtDNA. In mutants with the highest *uaDf5* burden, the intergenerational MPS is enhanced in older mothers, suggesting an age-induced mechanism of mtDNA quality control. Older mothers bearing the defective mtDNA also show more rapid decline in germline morphology, consistent with more rapid aging of this tissue compared to animals that carry only intact mtDNA. Further, we found that age-dependent accumulation of *uaDf5* is decreased in long-lived, and increased in short-lived, mutants. Thus, regulators of both PCD and the aging program are required for germline mtDNA quality control and its intergenerational transmission. Finally, we obtained evidence that different mtDNA mutants are eliminated by distinct mechanisms, suggesting that MPS requires multiple pathways to ensure that a variety of defects of the mitochondrial genome are removed.

1577S **Modulating material properties of cargo protein to probe exopher biology** Edward Chuang[1], Mayur Barai[2], Benjamin Schuster[2], Monica Driscoll[1] [1]Molecular Biology and Biochemistry, Rutgers University, [2]Chemical and Biochemical Engineering, Rutgers University

Propagation of pathological protein species is a hallmark of neurodegenerative disease progression. The mechanism of cell-to-cell transfer and the nature of the pathological protein species that spread in disease are not well understood. While protein aggregates are observed in postmortem tissue from neurodegenerative disease patients, many of the same proteins also form smaller oligomers or liquid and hydrogel condensates. In this work, we hypothesize that exophers act as a potential mechanism for proteins to spread from cell to cell. Exophers are large extracellular vesicles that were first observed in *C. elegans* and have since been observed in other mammalian systems. An exopher is generated when a cell extrudes up to half of its volume into a large membrane-bound vesicle that contains protein aggregates and damaged organelles. Notably, exophers preferentially recruit aggregates composed of mCherry and Htt-polyQ128, and preferentially exclude soluble GFP. Selection and recruitment of exopher cargo may be sequence-specific or a consequence of the aggregated state of the protein. Furthermore, it is unknown if exophers preferentially recruit liquid or hydrogel protein condensates that have intermediate material properties

between soluble and aggregated protein. To address this question, we express PGL-3, a native *C. elegans* germline protein, as a model substrate in our established touch neuron model of exophergenesis. We show that PGL-3 condensates are extruded in exophers but may also remain in the neuronal soma. We mutate the intrinsically disordered region of PGL-3 and characterize the altered phase behavior *in vitro* and *in vivo*, and we determine the effects of these mutations on exophergenesis and PGL-3 cargo recruitment to exophers. These findings further our understanding of exopher cargo criteria and condensate biology in the neurons of living animals.

1578S **RareResolve - Gene-humanized Animal Models for Discovery of Variant Pathology in Variants of Uncertain Significance (VUS).** Christopher Hopkins, Trisha Brock, Kathryn McCormick, Benjamin Jussila, Sarah Cheesman InVivo Biosystems

Whole genome sequencing is rapidly being adopted in the clinic and the rate of data acquisition into the ClinVar database continues to grow exponentially. Especially impacted are the Variants of Uncertain Significance (VUS) which are growing exponentially while the remaining categories of Pathogenic, Likely Pathogenic, Benign, Likely Benign show a small (linear) yearly increase. The result is unactionable VUS are forecast to take over the database by the end of the decade. The clinician may see a variant in their patient, but after cross reference to ClinVar, no clear guidance will be obtained. ACMG-AMP guidelines require functional studies to be performed as one of the major ways to enable reclassification of a VUS. We have developed a gene humanization methodology in C. elegans and Zebrafish as a way to quickly and affordably generate functional data that resolves VUS. In a C. elegans demonstration (Hopkins et al., 2023 Genetics in Medicine Open), over 80 variants were installed into a STXBP1-humanized locus and a diagnostic curve (AUC: 0.940) was generated, which enabled functional assessment of 5 of 23 VUS as pathogenic (21% yield). These results are in concordance with bioinformatics methods for predicting pathogenicity in VUS. Using AlphaMissense (AM) (Cheng et al., 2023, Science), we found our 5 pathogenic assessments of VUS were fully concordant. A second method using Gibbs Free Energy (GFE) calculations observed 4 of the 5 variants as pathogenic (80% concordance). However, the additional concordant calls for pathogenicity between AM and GFE suggests 3 variants were missed in the C. elegans model. Since our C. elegans method failed to achieve functional data to support for all 8 predicted variants, we have started studies to use transient expression studies in zebrafish (Crispant F0 knockouts with human mRNA rescue) as an alternative method to generate functional data. Better concordance is expected because functional testing in zebrafish can be performed closer to the physiologically-relevant temperature of humans (37 degree C). In conclusion, the combined use of these two animal models creates the RareResolve platform, which provides an on-demand diagnostic system to resolve pathogenicity in VUS seen in genomic sequencing of the patient.

1579S **Multifactorial *C. elegans* depression model** Dianelena Eugenio-Perez[1], Francisco D Dirzo-Diaz[2], José Pedraza-Chaverri[3] [1]Biology, Faculty of Chemistry UNAM, [2]Faculty of Chemistry, UNAM, [3]Biology, Faculty of Chemistry, UNAM

Current animal models of psychiatric diseases do not adequately model these pathologies mainly because they do not share the complex etiological origin of psychiatric illnesses. In this regard, a *C. elegans* model could be an alternative since combinations of genetic and environmental factors can be easily modelled. Furthermore, because of its short life cycle (3 days), factors affecting different developmental stages can be included in experimental models.

This presentation will describe a *C. elegans* depression model that includes both a genetic and an environmental factor, the latter being applied in the first larval stage (L1). The genetic factor is the usage of a knockout *npr-19* strain. Notably, the human homologue gene *CNR-1* has been reported to be altered in depressed patients. Concerning the environmental factor, we repeatedly induce the flight response in worms by periodically tapping their Petri dish with a microcontroller-driven solenoid. This repeated induction of stress response models chronic stress which is a relevant predictor of depression. Importantly, this factor is applied at early life because the link of early life stress and depression is well documented.

In this poster, we will present detailed results on the impact of the genetic, environmental and the combination of both factors in motivated behaviour of *C. elegans* adults, specifically in motivated food seeking, where worms are food-deprived and spontaneous movement for food seeking is assessed. Moreover, we describe the impact of each factor and their combination on redox status, which is known to be a relevant pathophysiological contributor of depression.

1580S **The broccoli derivative sulforaphane increases lifespan across diverse genetic backgrounds of *C. elegans* and resets the transcriptional aging clock toward a "youthful" state** Patrick C Phillips[1], Christine Sedore[2], Anna Coleman-Hulbert[2], Erik Johnson[2], Erik Segerdel[2], Brian Onken[3], David Hall[4], Theresa FitzGibbon[4], Yuhua Song[3], Hadley Osman[4], Madhuri Achanta[3], Elena Battistoni[4], Stephen Banse[2], Gordon Lithgow[4], Monica Driscoll[3] [1]Institute of Ecology and Evolution, University of Oregon, [2]University of Oregon, [3]Rutgers University, [4]Buck Institute for Research on Aging

Sulforaphane (SFN), an organosulfur isothiocyanate derived from cruciferous vegetables, has been shown to inhibit inflammation, oxidative stress, and cancer cell growth; it has also been shown to increase the lifespan of the *C.*

elegans nematode strain N2. Here, we tested the lifespan effects of SFN on an expanded set of three *Caenorhabditis* species, following the standard experimental procedures of the *Caenorhabditis* Intervention Testing Program (CITP). The CITP, a multi-institute research consortium, aims to identify chemical interventions that can robustly and reproducibly promote health and lifespan, testing compounds across a genetically diverse panel of *Caenorhabditis* strains and species. Our results indicate that SFN increases lifespan in a strain- and species-specific manner: *C. elegans* strains N2, JU775, and MY16 all exhibited a significant increase in median lifespan when treated with SFN (59%, 65%, and 47%, respectively), whereas SFN treatment either decreased or did not affect lifespan in six strains of the two *C. briggsae* and *C. tropicalis* species. To investigate the functional targets of SFN, we employed bulk RNA-Seq at a variety of ages to create a "transcriptional aging clock" using control individuals and then tested how global patterns of gene expression are altered under SFN treatment. Multi-dimensional scaling analysis of the transcriptome revealed transcriptional age under SFN treatment was similar to control individuals approximately four days younger, representing a nearly 20% shift relative to overall lifespan. These results support the idea that robust longevity-extending interventions can act via global effects across the organism, as revealed at a functional level via changes in gene expression.

1581S **Mitochondrial fusion promoter M1 molecule is sufficient to enhance mitochondrial function and organismal lifespan** Julia Bailey, Laxmi Rathor, Taylor McElroy, Sung Min Han University of Florida

Mitochondria play a crucial role in regulating organismal aging and health. Existing studies suggest a correlation between age-related decline in mitochondrial function and aging. Improving mitochondrial activity and homeostasis has been proposed as a potential strategy to mitigate the effects of aging. However, there is currently insufficient knowledge about the effectiveness of pharmacological manipulation of mitochondrial homeostasis in enhancing the lifespan and healthspan of a live animal.

Our study focuses on M1, a small molecule recognized for its ability to promote mitochondrial fusion and transport. To investigate the impact of M1 on mitochondrial homeostasis and organismal aging, we employed the nematode C. elegans as an in vivo model. Our findings indicate that M1 enhances mitochondrial membrane potential and reduces reactive oxygen species levels. Notably, M1 treatment results in a dose-dependent lifespan extension in worms, while the accumulation of lipofuscin, an aging pigment, remains unchanged.

These results provide promising insights into M1 as a potential modulator of animal lifespan. Our ongoing research aims to explore whether M1 requires mitochondria to influence lifespan and to assess its broader impact on various healthspan parameters, including mobility and stress tolerance.

1582S **ImR tumor induces kidney damage in adult *Drosophila* hosts Fei Cong, Hong-Cun Bao, Wu-Min Deng. Department of Biochemistry and Molecular Biology, Tulane University School of Medicine, New Orleans, LA** Fei Cong, Hongcun Bao Tulane University

Kidney damage is one of the paraneoplasia symptoms in cancer patients. Compared to those without CKD (chronic kidney damage), cancer patients with CKD may have an increased risk of death. However, the relationship between CDK and cancer is unclear. Here, using the transplanted ImR tumor model, we explored the mechanism underlying kidney damage in adult *Drosophila* hosts.

Previously, we demonstrated that overexpression of the Notch receptor's functional domain in the transition zone of larval salivary imaginal ring (ImR) can induce tumorigenesis through polyploid mitosis and depolyploidization. To sustain the growth of larval ImR tumors continuously, our lab has developed a new system for transplanting small tumor pieces into the abdomen of adult flies and passaging the tumor tissue across generations.

In tumor-host flies, we observed an increase in the size of pericardial nephrocytes and a decrease in their numbers. Pericardia nephrocytes, located in the posterior region of adult flies, is one of the two renal organisms in *Drosophila* which performs same function of podocyte in human nephron. Both podocytes and nephrocytes have structures known as slit diaphragms that filter hemolymph through endocytosis. Pyd, one of the component proteins of slit diaphragm forming a fingerprint pattern in *Drosophila*, is involved in endocytosis with other endosome proteins like Rab5. Data show that the Pyd expression pattern is disrupted, and Rab-family genes expression level are altered in nephrocytes of tumor-host flies. To determine the cause of nephrocyte destruction and loss, we used various methods to demonstrate that the function of host nephrocyte is more active than that of controls. Additionally, due to impaired degradation ability, toxin factors accumulate in nephrocytes, ultimately leading to inflammation and apoptosis.

To further emphasize the importance of nephrocyte function in tumor hosts, we use *klf15* mutant flies that lack nephrocytes in the adult stage as tumor hosts. Compared to control hosts, the lifespan of *klf15* mutant hosts was significantly reduced. Taken together, our results indicate that nephrocytes play a crucial role in prolonging host survival, and we provide new insights into

the mechanism of kidney damage in cancer.

1583S **A *Drosophila* Genetic Screening Platform to Identify Conserved Factors that Influence Biological Outcomes Following Traumatic Brain Injury Exposure** Jesse Rojas[1], Eddie Cho[1], Alec Candib[1], Robert Squire[1], Elizabeth Chai[1], Marta Lipinski[2], Kim Finley[1] [1]San Diego State University, [2]University of Maryland School of Medicine

Following traumatic brain injury (**TBI**) exposure a wide range of factors including genetic have the potential to influence the biological outcomes. Millions of people worldwide sustain a wide range of head trauma, resulting in diverse outcomes. The potential for genetic factors to influence TBI outcomes requires further studies. Here we use a high throughput *Drosophila* screening platform to elucidate key genes and pathways that may influence TBI outcomes. This included the use our BeadRuptor trauma technology and validated TBI phenotypes, along with the *Drosophila* Gal4-UAS system to modulate select genes in adult fly neural and glia tissues. RNAi knockdown (**KD**) technique was used to target autophagy (***ref(2)P***), lipidomic (***lipase3***), glycogenic (***shaggy***), and inflammatory (***crq***) pathway components. Adult cohorts were exposed to severe (**sTBI, 1x**) or mild repetitive trauma (**mTBI, 10x**) conditions to assess individual genetic changes to TBI outcomes. Biological assessments included modified longevity profiles, behavioral changes (negative geotaxis response, **NGR**), alterations to protein turnover (**autophagy**), and inflammatory profiles. Mortality indexes (**MI^{24hr}**) and aging studies show genotypic dependent changes, reflecting both sensitivity and resistance to following trauma exposure when compared to wildtype (**WT**) controls. Alterations to climbing behaviors (**NGR**) also showed similar genotype dependent responses following mTBI (**10x**). Neural Western analysis established basal and fasting induced alteration to autophagic responses. Further, each RNAi KD showed genotype dependent impact on NF-κB signaling targets (**AMP**). This included basal inflammatory profiles as well as following primary (4hr post mTBI) and secondary (24hr post mTBI) injury responses. In summary, there was a genotypic specific concordance between longevity and locomotor profiles following trauma, along with unique proteolytic, and neuroinflammatory responses highlighting potential key molecular mechanisms. This work demonstrates the versatility of *Drosophila* as a genetic screening platform to examine neural responses and outcomes following trauma. Genes examined here have human homologues and known genetic variants, highlighting potential targets for further investigation of trauma patients.

1584S **Dominant *OGDH* variants cause peripheral neuropathy with ataxia and optical atrophy** Wan Hee Yoon[1], Liedewei Van de Vondel[2,3], Juan Felipe Ramirez[1], Jonathan De Winter[2,3,4], Satoshi Matsuzaki[1], Abigail Sandoval[1], Sukyeong Lee[5], Rita Horvath[6], Kenneth M. Humphries[1], Jan de Bleecker[7], Stephan Züchner[8], Jonathan Baets[2,3,4] [1]Aging & Metabolism Research Program, Oklahoma Medical Research Foundation, [2]Translational Neurosciences, Faculty of Medicine and Health Sciences, University of Antwerp, [3]Laboratory of Neuromuscular Pathology, Institute Born-Bunge, University of Antwerp, [4]Neuromuscular Reference Centre, Department of Neurology, Antwerp University Hospital, [5]Department of Biochemistry & Molecular Biology, Baylor College of Medicine, [6]Department of Clinical Neurosciences, School of Clinical Medicine, University of Cambridge, [7]Department of Neurology, University Hospital Ghent, [8]Dr. John T. Macdonald Foundation Department of Human Genetics and John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine

2-oxyglutrate dehydrogenase (OGDH) is an E1 component of α-ketoglutarate dehydrogenase complex (α-KGDH) that plays a pivotal role in the Krebs cycle metabolism. Biallelic variants in *OGDH* have been reported to cause OGDH deficiency (OGDHD; OMIM: # 203740), an early-onset neurodevelopmental and mitochondrial disorder. However, whether monoallelic *OGDH* variants could lead to dominant effects in humans had not been known. In this study, we identified *de novo OGDH* c. 1909C>T (p.Arg637Trp) and heterozygousc.162T>G (p.Ser54Arg) variants by whole-exome sequencing (WES) in individuals exhibiting late-onset neurological phenotypes, including peripheral neuropathy, cerebellar ataxia and bilateral optic atrophy. Blood analysis for the individual with the p.Arg637Trp variant revealed ketogenosis. In patient lymphoblasts, OGDH protein levels did not appear altered, both in whole-cell lysate and in the mitochondrial fraction, compared to familial controls. In silico protein structure predictions using AlphaFold and homology modeling suggest that p.Arg637Trp mutation might influence protein structure and solubility. To determine whether the monoallelic *OGDH* variants act as dominant-negative mutations, we generated *Drosophila* models harboring *UAS-dOgdh (p.Arg639Trp)* and *UAS-dOgdh (p.Thr58Arg)* mutations, homologous to the human variants. We found that ubiquitous expression of *dOgdh (p.Arg639Trp)* or *dOgdh (p.Thr58Arg)* did not result in developmental lethality. While the mutant OGDH expression by *dOgdh-T2A-Gal4* driver did not lead to defects in development or locomotion in young adults (3-day-old), it did lead to locomotion defects in aged flies (14-day-old). These findings indicate that both variants are hypomorphic alleles and act as document-negative mutations, consistent with the observed clinical manifestations in individuals carrying these monoallelic *OGDH* variants. Our data suggest that monoallelic *OGDH* variants disrupt α-KGDH function, leading to a late-onset neurological disease in humans.

1585S **Utilizing Drosophila to Understand Second Heart Field Development** Brenna Blotz, Richard M Cripps Biology, San Diego State University

Many congenital heart defects result from the abnormal development of a progenitor cell type known as the second heart field (SHF). Heart defects arising from SHF malformation can be a symptom of 22q11.2 Deletion Syndrome (22q), which is a human disease resulting from a microdeletion on chromosome 22. The origins and importance of the second heart field continue to be firmly established, but a complete genetic analysis is yet to be completed. Recent findings reveal that a Drosophila cardiac muscle type known as ventral longitudinal muscles (VLMs) can be utilized as a genetic model for SHF development, since Drosophila orthologs of the mammalian factors Tbx1 and Islet1 are required for VLM formation. We used a UAS RNAi assay utilizing a VLM-specific Gal4 driver to knock down Drosophila orthologs of mammalian SHF determinants to confirm the use of Drosophila as an SHF model. A similar assay was performed to identify other genes involved in the contribution of heart defects in 22q besides TBX1. By discerning the phenotypes of the cardiac tubes and counting the longitudinal muscles present in the A3 and A4 regions of the heart field, it can be determined if any of the knocked-down genes create any cardiac abnormalities. Preliminary findings indicate that the genes sine oculis, moira, and CDC45L of the Digeorge (22q11.2) critical region, are all important in VLM development, and therefore warrant further study. Flies carrying knockdowns of these genes possess abnormal fiber counts that indicate they play a role in Drosophila cardiac formation and may be necessary for human cardiac formation. Findings generated from this research will be valuable in improving our understanding of, and potentially treating, 22q11.2 Deletion Syndrome and defects arising from SHF abnormalities.

1586S **Temporal effects of endosymbiont Wolbachia on the outcome of RNA viral infection in Drosophila melanogaster** Michael Rodwell[1], Casey Goltz[2], Brian Kmiecik[1], Madeeha Aziz[1], Lakbira Sheffield[3], Stanislava Chtarbanova[4] [1]University of Alabama, [2]Washington University School of Medicine, [3]BioGX, [4]Biology, University of Alabama

Wolbachia (*Wolb*) is an obligate, maternally-transmitted, intracellular bacterium known to infect ~50% of arthropods, including *Drosophila*. One aspect of *Wolbachia-Drosophila* interactions is a phenomenon called “pathogen blocking,” which corresponds to *Wolbachia*-mediated protection of *Drosophila* against pathogenic viral infections. The genetic and molecular mechanisms underlying this protection are not fully understood and are an ongoing area of investigation. Moreover, a gap in knowledge exists about the nature of the *Wolbachia-Drosophila* relationship as a function of host age. This is important to address as the aging process itself affects host physiology, including immunity to viral infections.

We have previously shown that aging impairs the ability of *Drosophila* to withstand the pathological consequences of infection (‘disease tolerance’ mechanism) with the RNA-containing Flock House Virus (FHV). Using 66 *Wolb*-free and 83 *Wolb*-positive lines from the *Drosophila* Genetic Reference Panel (DGRP), we demonstrate that the age-dependent survival of FHV infection is a continuous trait and is significantly modulated by the presence of *Wolb* independently of underlying lifespan. We established *Wolb*-free lines for several of the DGRP stocks in which older flies outlived younger flies after FHV infection and demonstrated that removing *Wolb* suppressed this phenotype. For one line, DGRP 320, using reverse transcription quantitative PCR (RT-qPCR), we show no significant changes in *Wolb 16S* gene expression, nor in FHV load between young and aged, *Wolb*-free and *Wolb*-positive hosts. Currently, we are confirming *Wolb* density in *Wolb*-positive samples for all experimental conditions and also conducting similar analysis in *Wolb*-positive DGRP lines in which older flies succumb faster of FHV infection. Our results indicate that *Wolb* possibly modulates disease tolerance to FHV with aging, independently of *Wolb* load.

1587S **Cellular and behavioral abnormalities in neurodegenerative models suppressed by altering heparan sulfate modifications in *Drosophila*** Nicholas Schultheis, Alyssa Connell, Scott Selleck BMMB, Pennsylvania State University

Mutations in *parkin* are the most common cause of early onset Parkinson’s disease (PD), and this gene plays a major role in mitophagy. Alterations in TDP-43 expression are highly associated with the progression of amyotrophic lateral sclerosis (ALS) and coincident mitochondrial dysfunction. This indicated the convergent biological importance of mitochondrial health in neurodegeneration. We identified heparan sulfate (HS) modified proteins as a class of cell surface and matrix molecules that regulate signaling and influence mitochondrial morphology and vesicular trafficking. By reducing expression of HS-constituent enzymes in *Drosophila* models, we achieved rescue of flight muscle degeneration and mitochondrial morphology in PD and pupal-stage lethality in ALS. Moreover, Alzheimer’s Disease (AD) is associated with mitochondrial and lipid catabolism dysfunction. Mutations in *presenilin/PSEN1* are the most common cause of familial, early onset AD. We examined the functional relationship between the cellular and behavioral pathology mediated by reduction in *presenilin* function and the activity of HS to modulate AD pathogenesis. In *Drosophila* and in human cultured cells, we explored the molecular characteristics of *presenilin* and HS downregulation through RNA sequencing analysis. Cell-type directed knockdown of *presenilin* in *Drosophila* revealed cellular abnormalities described in vertebrate models and humans. Reductions in mitochondrial size and number, deficits in autophagosome-to-lysosome trafficking, and lipid accumulation were observed. Conversely, knockdown of genes required for HS biosynthesis produced larger mitochondria, increased autophagy flux to the lysosome, and reduced levels of intracellular lipid. Cellular and behavioral abnormalities produced by *presenilin* knockdown were markedly suppressed by simultaneous reduction of HS biosynthetic encoding genes in the fruit fly. HS-mediated regulation of mitochondrial function, autophagy, and lipid metabolism was conserved in human cells.

Transcript analysis revealed a core group of SLC transporters and apolipoproteins that were significantly affected in opposite directions by decreases in expression of *presenilin* and HS. Simultaneous decrease in expression of *presenilin* and HS reverted this core group to near-wild type expression. Our work provides insight into the effects of HS interaction with *parkin*, TDP-43, and *presenilin*, and highlights the role SLC transporters may play in the progression of AD.

1588S **Parkin-null *Drosophila* vulnerable neuron mitochondrial hydrogen peroxide levels are reduced by manganese porphyrin compound** Amber N Juba[1], Riley Hamel[2], Petros P Keoseyan[2], T. Bucky Jones[3], Artak Tovmasyan[4], Lori M Buhlman[1] [1]Biomedical Sciences Program, Midwestern University, Glendale, [2]Arizona College of Osteopathic Medicine, Midwestern University, Glendale, [3]Anatomy, Midwestern University, Glendale, [4]Department of Translational Neuroscience, Ivy Brain Tumor Center, Barrow Neurological Institute

Identification of oxidative stress-initiating events may be key to developing successful therapeutic interventions for neurodegenerative disease. Excessive cellular reactive oxygen species (ROS) levels result from overproduction and/or decreased capacity of a variety of antioxidants. Elucidation of oxidative stress sources presents many obstacles and has wide-ranging implications for neurodegenerative diseases, including Parkinson's (PD). Homozygous loss-of-function parkin mutations cause a rare form of PD that shares hallmark pathophysiology with the idiopathic form. The *parkin* gene is conserved in *Drosophilae* (*park*), and flies have a dopaminergic brain region that is functionally homologous to the mammalian substantia nigra, which selectively degenerates in PD patients. We reported elevated protein oxidation in mitochondria of degenerating, but not non-degenerating, dopaminergic neurons in parkin-null *Drosophila*. We have also reported sustained elevated levels of hydrogen peroxide (H_2O_2) and transiently increased glutathione redox equilibrium (GRE) in vulnerable neuron mitochondria, but not in non-degenerating neuron mitochondria. Here we measured dopaminergic neuron mitochondrial H_2O_2 and GRE in parkin-null flies raised on food supplemented with MnTnBuOE-2-PyP^{5+}, a manganese porphyrin compound (MnP). MnPs are powerful superoxide dismutase mimetics that also catalyze protein cysteine oxidation and S-glutathionylation. MnTnBuOE-2-PyP^{5+} is being tested as a normal tissue radioprotector in clinical trials involving cancer patients undergoing radiotherapy. MnTnBuOE-2-PyP^{5+} improves developmental outcomes and decreases mitochondrial H_2O_2 in parkin-null fly dopaminergic neurons. Restoring redox imbalances may ameliorate parkin loss-of-function pathology and warrants study of MnTnBuOE-2-PyP^{5+} in additional neurodegenerative disease models toward use in clinical trials. There is currently no strategy for slowing PD progression. Despite the obvious implication of oxidative stress in PD models and patient tissue, antioxidant therapies have failed in clinical trial, perhaps because they lack critical target specificity or bioavailability.

1589S **Roles of Secreted Host Signals in Drosophila Tumor-Host Interactions** Kavya Adiga, David Bilder Molecular and Cell Biology, University of California, Berkeley

While tumor growth has been well-characterized, the interaction between a tumor and its host remains understudied. Tumors can have strong effects on the activity of distant organs, and these can be potent drivers for host lethality. Current work tends to focus on understanding the effects of tumor-secreted molecules on the host, but I am interested in how host tissues respond to a tumor. To study this, I use a simple cancer model in Drosophila. RNA sequencing reveals upregulated factors predicted to be secreted from host fat body (the major secretory organ; analogous to human fat and liver) in the presence of a tumor. Comparison of the response to tumor versus that to "chronic" sterile wounding reveals both shared and distinct molecules. Using a lifespan assay as a primary screen, I have identified candidates that when knocked down in the fat body affect cancer-induced host mortality. Some of these factors alter tumor burden and/or progression, while others appear to alter another aspect of host physiology. Further data on how these factors mechanistically impact tumor-host interactions will be presented.

1590S **Uncovering the mechanism of action of small molecules with neuroprotective potential in ALS using proteomics** Yash Kulkarni[1], Rachel A Allen[2], Deborah Cebular[1], Anne M Pruznack[1], Jon Njardarson[2], Daniela C Zarnescu[1] [1]Cellular and Molecular Physiology, Penn State College of Medicine, [2]Chemistry and Biochemistry, University of Arizona

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder with a prevalence rate of 7 cases per 100,000 people worldwide. Cytoplasmic inclusions of hyperphosphorylated and ubiquitinated TAR DNA binding protein (TDP-43) are found in 97% of ALS cases and thus represent a major pathological hallmark of ALS. Although a variety of therapeutic approaches have been designed for ALS or directed against TDP-43 using cells and animal models, success in slowing down the disease has been limited. To address this, we performed an in vivo phenotypic screen aimed at mitigating TDP-43 associated locomotor and survival deficits in a Drosophila model of ALS based on overexpression of wild-type or mutant TDP-43 in motor neurons. Using this strategy, we identified three novel compounds from unique chemistry collections. Through a hit expansion campaign focused on one of these small molecules, we developed over 50 analogs, which afforded a new lead compound with improved activity (RAA-47). Next, we set out to identify the mechanism of action for RAA-47 using proteomics. To avoid the developmental lethality caused by pan-neuronal expression of TDP-43 we used the Elav Gene Switch GAL4 driver

to conditionally express TDP-43 in adults while administering RAA-47 or DMSO as vehicle control. Preliminary results show alterations in mitochondrial and metabolic proteins that we are currently validating. We are also using biotinylated analogs in conjunction with streptavidin pull-downs and mass spectrometry to identify the molecular target(s) of RAA-47. We will present our progress on identifying the molecular target and pathways modified by RAA-47 in flies and human cell lines with TDP-43 proteinopathy.

1591S **A Drosophila model of dementia based on C9orf72 hexanucleotide repeat expansion (HRE) exhibits age dependent axonal degeneration and FTD relevant behavioral phenotypes** Megan A Brennan[1], Brijesh Chauhan[1], Sharon Shaju[2], Keating R Godfrey[3], Daniela C Zarnescu[1] [1]Molecular and Cellular Physiology, Pennsylvania State University College of Medicine, [2]Juniata, [3]University of Florida

G4C2 Hexanucleotide Repeat Expansions (HREs) within the C9orf72 gene can cause the most common inherited forms of Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Dementia (FTD). HREs are transcribed into RNA, transported into the cytoplasm, and translated into DiPeptide Repeats (DPRs) via Repeat Associated Non-AUG (RAN) translation. Both sense and antisense strands can be translated in multiple reading frames, creating several types of DPRs, which just like the G4C2 RNA are linked to neuronal toxicity. The HRE RNA and DPRs can cause neuronal degeneration over time, leading to ALS, FTD, or co-morbid ALS-FTD. In patients with FTD, disinhibition in behavior, becoming emotionally or socially isolated, dementia, and personality changes are common symptoms. Certain variants of FTD have overlapping phenotypes with ALS including brain degeneration, reduced lifespan, and loss of motor coordination. Several Drosophila circuits have similar functionality to human circuits including the Mushroom Body (MB), which regulates working memory and sleep among other behaviors. Here we characterize a novel model of dementia based on C9orf72 expressing either 12 or 44 G4C2 HRs in a subset of Kenyon cells comprising the MB circuit. Morphological analyses using confocal microscopy show evidence of age dependent axonal thinning in flies expressing HRs compared to w1118 controls. We could also detect age and sex associated changes in GFP-tagged DPRs (GR-GFP) generated via RAN translation, that correlate with axonal degeneration. Longevity analyses show that the presence of HRs decreases lifespan compared to w1118 controls, with male flies being more severely affected by the presence of G4C2 repeats than females. Using Drosophila Activity Monitors (DAMs) we also find that both HRs and sex play a role in altering activity and sleep behaviors even in young flies. Current experiments include using a y-maze assay to evaluate age dependent changes in overall movement and alternation, which is considered a measure of working memory. In summary, this model recapitulates several FTD relevant phenotypes which provide a novel model for studying C9orf72-FTD that can be used for future in vivo screening of genetic and small molecule modifiers of neurodegenerative disorders.

1592S **Uncovering the protective role of glycolysis in ALS using genetic and pharmacological approaches in *Drosophila* models of TDP-43 proteinopathy** Sara Gherardi[1], Suvithanandhini C Loganathan[2], Malajah Johnson[3], Daniela C Zarnescu[4] [1]Molecular and Cellular Physiology, The Pennsylvania State University College of Medicine, [2]University of Arizona, [3]The Pennsylvania State University College of Medicine, [4]Cellular and Molecular Physiology, The Pennsylvania State University College of Medicine

Amyotrophic Lateral Sclerosis (ALS) is a progressive and fatal neurodegenerative disease. TAR DNA binding protein (TDP-43) is a DNA/RNA binding protein which typically resides in the nucleus, but mislocalizes to the cytoplasm and forms inclusions, consequentially leading to a nuclear loss of function and a cytoplasmic gain of function. Regardless of etiology, 97% of patients exhibit TDP-43 cytoplasmic inclusions, referred to as TDP-43 proteinopathy. Recent studies have uncovered evidence of metabolic dysregulation in patients and animal models exhibiting TDP-43 proteinopathy; however, this remains poorly understood. Platelet phosphofructokinase (PFK) is the most abundant member of the PFK family of proteins in the nervous system, and catalyzes one of the rate limiting steps in glycolysis. PFK has 2 ATP binding sites, with one acting as an allosteric modulator and the other as a catalytic site. Our lab has previously shown that overexpression of PFK can mitigate ALS-related phenotypes. The goal of this study is to investigate the mechanism of action by which PFK overexpression is protective in *Drosophila* models of TDP-43 proteinopathy, and to identify other key enzymes in glycolysis that can mitigate these phenotypes. To determine whether the catalytic activity of PFK is required for neuroprotection, we generated transgenic flies that can overexpress a variant of PFK harboring a mutation in its ATP binding site required for catalysis (PFK^{ATPbs}). Using the D42 GAL4 driver, we found that overexpression of wild-type PFK (PFK^{WT}) in motor neurons mitigates $TDP\text{-}43^{WT/G298S}$ dependent locomotor deficits. There was also a rescue in survival when PFK^{WT} was overexpressed in the context of $TDP\text{-}43^{WT/G298S}$; however, no rescue was observed with PFK^{ATPbs}, indicating the need for an enzymatically functional PFK to improve TDP-43 dependent phenotypes. We are currently using confocal microscopy to analyze PFK puncta in the ventral nerve cord of third instar larvae. We are also taking pharmacological approaches to identify other enzymes in glycolysis that could mitigate ALS-related phenotypes. Administration of terazosin, a phosphoglycerate kinase 1 agonist, showed a rescue in survival in flies overexpressing $TDP\text{-}43^{G298S}$ in motor neurons. These results identify PFK and glycolysis as a potential therapeutic target and exploring its mechanistic contribution to ALS could lead to the development of novel compounds or diets which can help alleviate ALS patient symptoms.

1593S **Neuronal hyperexcitability and tactile hypersensitivity in a *Drosophila* larvae model of Neurofibromatosis 1** Anneke R Knauss[1], Seth M Tomchik[1,2,3] [1]Neuroscience and Pharmacology, University of Iowa, [2]Department of Pediatrics, University of Iowa, [3]Iowa Neuroscience Institute, University of Iowa

Neurofibromatosis type 1 (NF-1) is an inherited monogenetic disorder caused by the mutation and subsequent dysfunction of the neurofibromin 1 gene (*NF1*), a known tumor suppressor that encodes the neurofibromin protein (Nf1). In humans, the disease is diagnosed early in development and is characterized by the formation of tumors in the nervous system, altered metabolism, decreased stature, and decreased life expectancy. There are no treatments for NF-1, largely due to the complex downstream effects of the dysfunctional protein. The fruit fly, *Drosophila melanogaster,* is a powerful model for studying this disease; in *Drosophila*, the Nf1 protein is ~60% homologous to the human Nf1 protein at the amino acid level. In this well-established animal model, *nf1* mutants display significant decreases in both body size and lifespan. Increases in overall grooming behavior and metabolic rate are also observed. Interestingly, the grooming phenotype relies on proper Nf1 function during the pupal stage of *Drosophila* development; knockdown of Nf1 only in the adult stage does not drive excessive grooming. In *Drosophila* larvae, the reduction of functioning Nf1 induces neuronal hyperexcitability and tactile hypersensitivity; however, the mechanisms for these findings are currently unknown. Using *Drosophila* larvae, we are investigating the neuronal circuitry and cellular mechanisms underlying the developmental necessity of Nf1. Larvae exhibit a sophisticated locomotion repertoire in response to nociceptive stimuli to protect themselves from perceived danger. Previous studies and preliminary data from our lab show an increase in stereotyped escape behavior from *nf1* mutant larvae in response to nociceptive stimulation, a response likely propagated by sensory neurons. Using this behavioral paradigm, we plan to identify the optimal candidate neuronal population for Nf1 study using *Drosophila's* sophisticated genetic toolkit.

1594S **Molecular Dissection of Non-Olfactory Roles of an Odorant Binding Protein** Benjamin Soto, Nichole A. Broderick Biology, Johns Hopkins University

Odorant binding proteins (Obps) are canonically associated with functions in olfaction. Obps are functionally conserved from invertebrates to mammals, but are most well studied in insects. Loss of function studies of several Obps in various models demonstrate that some Obps play no, or minor, roles in olfaction, but have other impacts on host physiology. We previously reported that siRNA knockdown of the Tsetse fly Obp6 and knockout of its ortholog in Drosophila, Obp28a, led to reduced wound healing due to impacts on melanization. As such, these flies had reduced crystal cell populations, phenoloxidase activity, and expression of the crystal cell differentiation factor lozenge. Importantly, diminution of crystal cells is observed in both larvae and adults of both fly species. Collectively, this illustrates that Obp6/28a: a) are functionally conserved across taxa, b) perform functions outside of olfaction, and c) exert their impacts early in development, but with lasting effects across life stages. We will further discuss the mechanism by which Obp28a mitigates wound healing and its additional impacts on host physiology, including Obp28a patterns of expression to understand the epistasis of Obp28a in crystal cell development. Altogether, this work will shed light on the role of Obps in insect physiology outside of their previously hypothesized roles in olfaction.

1595S **Spenito-dependent metabolic sexual dimorphism intrinsic to fat storage cells** Arely V Diaz[1], Daniel Stephenson[2], Travis Nemkov[2], Angelo D'Alessandro[2], Tânia Reis[1] [1]Department of Medicine, University of Colorado Anschutz, [2]Department of Biochemistry and Molecular Genetics, University of Colorado Denver

Metabolism in males and females is fundamentally different. Differences are usually linked to sexual reproduction, with circulating signals (e.g., hormones) playing major roles. In contrast, sex differences prior to sexual maturity and intrinsic to individual metabolic tissues are less understood. We analyzed *Drosophila melanogaster* larvae and found that males store more fat than females, the opposite of the sexual dimorphism in adults. We show that Spenito (Nito), a conserved RNA-binding protein and regulator of sex determination, is required for the metabolic differences intrinsic to the major fat storage tissue, including many differences in the expression of metabolic genes. Nito knockdown specifically in the fat body (FB) abolished fat differences between males and females. We further show that Nito is required for sex-specific expression of the regulator of sex determination, Sex-lethal (Sxl). "Feminization" of fat storage cells via tissue-specific overexpression of the female determinant isoform of Transformer (TraF) in male and female FBs made larvae lean and reduced the fat differences between males and females. Correlating with these reduced fat differences, and consistent with inducing female-like expression in the FB, TraF overexpression shifted the male FB expression of metabolic genes to a female-like expression pattern. At the molecular level, Nito is a component of the N-methyladenosine (m^6A) methyltransferase complex where it plays a role in alternative splicing via m^6A-RNA modification. To test an m^6A-dependent modification requirement for metabolic dimorphism, we knocked down other members of the complex and found that Virilizer, fl(2)d, and Mettl14 are also required for metabolic differences between males and females. We are currently exploring the contributions of different diets to Nito- and m^6A-mediated metabolic dimorphism.

1596S **Understanding the long-term impacts of early-life exercise** Heidi M Johnson[1], Nicole Riddle[2] [1]Biology, University of Alabama at Birmingham, [2]University of Alabama at Birmingham

Exercise is a powerful and accessible therapeutic strategy for preventing or managing many disease conditions such as diabetes and cardiac dysfunction. However, exercise response demonstrates variation between individuals associated with sex and genetic makeup. While it is generally agreed that exercise has benefits as part of a healthy lifestyle, the relationship between exercise and lifespan is poorly understood. Here, we investigate the lifetime impacts of exercise using *Drosophila melanogaster*. We measured lifespan, activity level, body condition, physical ability, and reproductive health to determine how exercise treatments affect resource allocation to activity, somatic maintenance, and reproduction. We found that the impact of exercise on these measures of health is complex, with most responses depending on the interactions of sex, genotype, and treatment. Interestingly, a longer treatment (20 days) did not elicit consistently stronger effects than a shorter exercise treatment (5 days). However, the 20-day exercise treatment was associated with decreased climbing performance compared to controls up to several weeks after treatment ended, suggesting that long exercise treatments have the potential to be detrimental. Together, these results reveal the complexity of factors controlling exercise response, confirm the importance of genotype and sex, and highlight the importance of designing personalized exercise treatments to obtain optimal outcomes.

1597S **Single-cell analysis reveals immune activation in the tumor-host interaction** Hong-Cun Bao Tulane University

Cancer is one of the most feared diseases in our nation; however, the mechanism by which cancer actually takes a life remains to be fully explored. Studies on the mammalian immune system have developed several tools that revolutionized cancer treatment. Nevertheless, the complexity of the mammalian system remains a formidable challenge for researchers. The fruit fly is a relatively simple model organism and provides an opportunity to avoid such complexity. Here we take advantage of fly's simplicity to study tumor-host interactions and how tumors kill files.

We use NICD overexpression salivary gland tumor injection model to study tumor–host interactions. Technically, we allograft the NICD tumor from larval salivary gland into the abdomen of an adult fly host, allowing the tumor to grow in the host for 10 days. Subsequently, we dissect the adult, take out the tumor, and cut it into pieces small enough to perform another round of allograft. This allografting process can sustain the tumor for a maximum of 2 years.

During this period, we collect both the host and remaining tumor tissue for bulk-RNA sequencing or single-cell sequencing. Through gene set enrichment analysis of host bulk-RNA sequencing, we identify innate immune response as the top enriched term. Furthermore, through single-cell analysis of the tumor tissue, we identify two groups of cells that are not tumor cells but hemocytes (marked by Hml and He) and fat body cells (marked by Apolpp and Yp1) from the tumor host. Further data analysis reveals the expression of various immune response genes, such as antimicrobial peptides (AMPS) and peptidoglycan recognition proteins (PGRPs), in these two types of cells, while the tumor cells do not exhibit such expression. In detail, fat body cells exhibit high levels of Attacins, Diptericins, Bomanins, and immune-induced molecules, whereas Cecropins are predominantly expressed in hemocytes. As for the PGRPs, PGRP-SB1, PGRP-SC2, and PGRP-SD are primarily expressed in fat body cells, while Hemocytes express PGRP-LF.

In conclusion, the IMD pathways were activated in the tumor host, as confirmed by DptA-lacZ staining.

1598S **MICOS Complex Effect on Mitochondrial Dysfunction During Aging** Victor Knowles[1], Stephanie Uzordinma Awuzie[1], Mikesha Carter[1], Laura Galvan[1], Madison Raub[1], Angie del Barco[1], Antentor Hinton[2], Blake Riggs[1] [1]San Francisco State University, [2]Vanderbilt University

The cristae are important for driving oxidative phosphorylation in the electron transport chain to generate ATP. The cristae's size and shape are believed to be regulated by the mitochondrial contact site and cristae organizing system (MICOS). MICOS is a protein complex composed of subunits found at the inner membrane of the mitochondria. However, it is unknown how the MICOS complex regulates and maintains the cristae over the life of the mitochondria and if defects in MICOS function contribute to cellular aging. Here, we hypothesize that loss of MICOS complex function over time contributes to mitochondrial defects leading to cellular dysfunction found during aging. To test this hypothesis, we employed an aging assay using Drosophila melanogaster with loss of the components of the MICOS complex. Using the GAL4/UAS system, we used RNAi to inhibit Mitofilin and CHCHD3 in the MICOS complex to measure a decrease in lifespan. Then the flies were transferred to a different vial regularly and dead flies in each vial were recorded. Our data did not reveal a significant difference in lifespan in CHCHD3 and Mitofilin in comparison to our wildtype, however, we did see a longer survivability rate in females as compared to males in Mitofilin and CHCHD3 RNAi, contrary to our control. Quantitative PCR was utilized to measure transcript levels of MICOS subunits and mitochondrial regularity genes across the aging of Drosophila, from the embryonic stage to 75-day-old flies. Our results revealed a small decrease in CHCHD3 and Mitofilin transcription levels in Drosophila aged from embryo to 75-day-old flies. Going forward we plan to conduct qPCR on MICOS RNAi flies to determine the efficiency of mRNA

transcription suppression through the lifespan of Drosophila. We will use immunohistochemistry and confocal microscopy to detect levels of oxidative stress using 8-OHdG as a biomarker. Then we will use Mito-GFP with various MICOS components to image morphology and structure impacts in the heart and skeletal muscle cells of Drosophila.

1599S **Metabolomics and Lipidomics Studies reveal altered nutrient metabolism in the non-obese Nepl15 mutant flies** Surya Jyoti J Banerjee[1], Shahira H Arzoo[1], Soumyadip Kundu[2] [1]Biological Sciences, Texas Tech University, [2]Cell Biology, Mimetas

The Drosophila specific non-catalytic Neprilysin like 15 (Nepl15) is a major regulator of glycogen and glycerolipids storage. Nepl15 knock-out (*Nepl15^{KO}*) adult flies consume same amount of foods, however, the mutant adult male flies store significantly low amounts of lipids and glycogen, whereas mutant adult female flies store slightly less lipids and higher amount of glycogen compared to the control flies. Accordingly, mutant flies have anti-obesity features like extended life-span and ability to remain active at older age. Thus, it is important to take a deeper look at the nutrient metabolic pathways to understand alterations in the cellular mechanisms in these mutant flies. Therefore, we have performed analysis of the primary metabolomics and lipidomics using age-matched mutant and control adult male and female flies. Our preliminary analysis using the Metaboanalyst platform reveals that primary metabolites and lipids are different between the two sexes in the normal, and mutant adult fly groups using the Principal Component Analysis (PCA). Partial differences in the primary metabolites and the lipids are seen between the adult *Nepl15^{KO}* and control male flies, and the adult *Nepl15^{KO}* and control female flies in PCA. However, complete separations of primary metabolites and lipids between the *Nepl15^{KO}* and control male and female flies are evident in sPLSDA and oPLSDA analyses. While considering 1.5 folds change in the *Nepl15^{KO}* flies relative to the controls, we found that the *Nepl15^{KO}* adult males have 20 upregulated and 4 downregulated primary metabolites, and 48 upregulated and 193 downregulated lipids; while the *Nepl15^{KO}* adult females have 17 upregulated and 20 downregulated primary metabolites, and 47 upregulated and 81 downregulated lipids. Our analyses identified changes in the amino acid metabolism pathways between the mutant and control male and female flies. Thus, our data indicates an overall change in the nutrient metabolic pathways between the *Nepl15^{KO}* and control adult flies of each sex. Additional analysis of our data can provide detailed information about the metabolic pathways that are controlled by Nepl15 in future. This information ultimately will be useful to find new strategies to regulate obesity and other metabolic disorders.

1600S **Progress in Development of an Advanced Cancer Cachexia Model** Sofiane GANA, Mardelle Atkins, Morgan Marsh, Oluwapelumi Soyebo, Grace Stegemoller, Ellen Thompson, Logan McDowell Biology, Sam Houston State University

Cachexia is a complex wasting disorder which results in metabolic derangement and rapid loss of body muscle. It affects up to 80% of cancer patients and may be the direct cause of mortality for around 20% of all cancer patients. Yet, diagnostics and therapeutics for this devastating condition are extremely limited. Prior work in murine models have had limited success in translating their findings to the clinic. Thus, we have developed a cachexia model in Drosophila that recapitulates key features of cachexia, but in a more rapid and scalable system. We will present our current characterization of this model as well as novel insights gained.

1601S **Increased dopaminergic release confers neuroprotection against a *Drosophila* model of sporadic Parkinson's disease.** Angeline Claudia Atheby[1], Katarzyna Rosikon[1], Hakeem Lawal[1], Angeline Claudia Atheby[2] [1]Delaware State University, [2]Biological Science, Delaware State University

Parkinson's disease (PD) is a debilitating neurodegenerative disease characterized pathologically by the loss of dopaminergic neurons of the substantia nigra pars compacta. Decades of research have established key environmental and genetic factors as contributors to its etiology although the precise cause of most cases the disease remains unknown. Moreover, despite the advances in our understanding of the possible causes of PD, a viable treatment remains elusive. Rotenone, a potent laboratory model for sporadic PD has been used to uncover important insights into the etiology of the disease. We are interested in developing new disease-modifying therapeutic strategies against PD. Our approach of choice is to test a neuroprotective strategy based on increasing in the physiological release of dopamine (DA). To accomplish this goal, we are testing the neuroprotective capability of the small molecule dacarbazine (which we identified in a previous pharmacological screen) and its structural derivative, 5-Amino-4-imidazolecarboxamide (AICA). Both compounds have been reported previously to increase synaptic activity by potentiating the function of the vesicular monoamine transporter (VMAT, which facilitates the packaging and transport of DA into synaptic vesicles for exocytotic release). In this project, we investigated whether both compounds are capable of conferring organismal and/or neuroprotection against rotenone toxicity. We report that dacarbazine confers a small but reproducible protection against organismal toxicity induced by rotenone exposure in both male and female *Drosophila.* These results are all the more remarkable given that dacarbazine is a chemotherapeutic drug with a toxic potential of its own. Crucially, we report for the first time, that consistent with its published role as a VMAT-dependent drug, AICA protects dopamine (DA) neurons against rotenone-induced neuronal toxicity in an assay in which we combined both a

pesticide (rotenone) and age as risk factors for PD. We also present preliminary results of the effects of both compounds on rotenone-induced increase in oxidative stress. Together, these findings identify a promising new compound against PD and validate the importance of a physiological increase DA release as a viable therapeutics strategy against the disease.

1602S **The Drosophila Covid Resource (DCR) is used to reveal key functional interactions between SARS-CoV-2 NSP8 and host factors.** Margot Mel de Fontenay[1], Annabel Guichard[1], Daniel Bressen[2], Ketta Sneider[1], Shenzhao Lu[3], Oguz Kanca[3], Sara Sanz Juste[4], Shinya Yamamoto[3], Hugo Bellen[3], Ethan Bier[1] [1]University of California San Diego, [2]Universidade Federal do Rio de Janeiro, [3]Baylor College of Medicine, [4]The University of Texas MD Anderson Cancer Center

SARS-CoV-2 infections still represent a significant public health concern, while long Covid remains poorly understood. Development of effective therapies against Covid and long Covid relies on mechanistic knowledge of virus-host interface. Numerous host proteins have been shown to physically bind to individual viral factors, but the functional meaning of such interactions is less understood. We present a comprehensive Drosophila COVID-19 resource (DCR), which consists of publicly available lines for conditional tissue-specific expression of all SARS-CoV-2 encoded proteins, UAS-human cDNA transgenic lines encoding established host-viral interacting factors, and GAL4 insertion lines disrupting fly homologs of SARS-CoV-2 human interacting proteins. We demonstrate how of the DCR can be used to functionally assess SARS-CoV-2 genes and candidate human binding partners. We show that NSP8 engages in strong genetic interactions with several human candidates, most prominently with the ATE1 arginyltransferase to induce actin arginylation and cytoskeletal disorganization, and that two ATE1 inhibitors can reverse NSP8 phenotypes. The DCR enables parallel global-scale functional analysis of SARS-CoV-2 components in various tissues relevant to Covid pathologies.

Park, K.H. Wan, … Bier, E. (2023). A comprehensive Drosophila resource to identify key functional interactions between SARS-CoV-2 factors and host proteins. Cell reports, 42(8), 112842. Advance online publication. https://doi.org/10.1016/j.celrep.2023.112842 PMID: 37480566

1603S **Single-Cell Insights into Aging, Aging-related Disease, and Longevity in Drosophila** Tzu-Chiao Lu[1,2], Ye-Jin Park[1,2,3,4], Hugo J. Bellen[2,3,4], Hongjie Li[1,2] [1]Huffington Center on Aging, Baylor College of Medicine, [2]Department of Molecular and Human Genetics, Baylor College of Medicine, [3]Program in Development, Disease Models and Therapeutics, Baylor College of Medicine, [4]Jan and Dan Duncan Neurological Research Institute, Baylor College of Medicine

Aging, a complex biological process, has profound implications for healthspan and the progression of age-related diseases. In this study, we present a comprehensive analysis of Drosophila single-nuclei datasets, encompassing the Aging, Alzheimer's Disease, and Rapamycin Fly Cell Atlases. Our focus is to elucidate the intricacies of cellular aging, unravel the pathogenesis of age-related diseases, and decipher the mechanisms underlying longevity. We have refined cell type annotations to capture the subtle nuances of aging processes and the rejuvenating effects of rapamycin, a compound renowned for its lifespan-extending properties. Our integrative approach combines data across multiple dimensions—age, sex, genotype, and rapamycin treatment—to construct a detailed view of the cellular aging landscape. Additionally, we have developed a user-friendly, interactive visualization platform, enhancing the accessibility of these complex datasets for a broad range of scientific inquiries. Through this integrative endeavor, we aim to deepen our understanding of the molecular and cellular dynamics of aging and longevity, offering valuable insights into Drosophila aging research.

1604S **Identifying Candidate Genes and Genetic Networks that Influence the Age-specific Ability to Clear an Infection Using a Genome Wide Association Study (GWAS)** Shonda Campbell University of Maryland Baltimore County

The innate immune response is an evolutionarily conserved process that is essential for survival in multicellular organisms. However, as individuals age, immune functions begin to decline, a phenomenon known as immunosenescence, which can vary greatly among individuals. This variation has a genetic component yet the genes that contribute to this variation are widely unknown. Here, we used 183 genetically distinct genotypes of the *Drosophila* Genetic Reference panel (DGRP) to assess their ability to clear an infection at one and five weeks of age, and then carried out a genome-wide association study (GWAS) to identify candidate genes that contribute to differences in immune responses among genotypes at each age. We also carried out a genetic network analysis using the candidate genes identified in the GWAS to identify signaling pathways that contribute to age-dependent variation in immune function. We found that clearance ability varied greatly among genotypes, but on average, the ability to clear an infection declined by 70% with age. We identified 153 genes significantly associated with clearance at 1 week of age, 52 genes significant at 5 weeks of age, and only two genes, *Cc2d2a* and *lipophorin receptor 1* (*LpR1),* significant at both ages. Of the identified candidate genes, 53 were mapped to genetic networks. Gene Ontology Analysis of genes in the networks implicate genes encoding proteins involved in cell adhesion, migration and those associated with the plasma membrane as important contributors to variation in immunity. Network analysis also implicated several

signaling pathways as contributing to genetically based differences in the ability to clear infection. Our results indicate that the genetic basis of naturally occurring variation in immune function changes with age. Future work will focus on how these genes influence immune function to better understand the molecular mechanisms that give rise to age-dependent genetic effects, which will be important for understanding the genetic basis of senescence.

1605S **The effects of phytocannabinoids on *Drosophila melanogaster* midgut, lifespan and locomotor activity** Sandra C Illescas, Alyssa M Vidal, Cristian Rodriguez, Mariano Loza-Coll Biology, California State University, Northridge

Phytocannabinoids, compounds found in the *Cannabis sativa* plant, can activate the canonical CB1/2 endocannabinoid system in mammals, and have garnered increasing attention for their potential health benefits. While numerous studies have explored their effects on mammalian systems, limited research exists on the impact of phytocannabinoids on invertebrate models. *Drosophila melanogaster* does not have CB1/2 receptors, but offers a valuable platform to investigate potential physiological effects of phytocannabinoids via CB1/2-independent, yet well conserved molecular pathways.

Here we present preliminary work aimed at assessing the influence of broad spectrum phytocannabinoid extracts containing cannabidiol, cannabigerol, delta-9-tetrahydrocannabinol and others on *D. melanogaster* midgut homeostasis, locomotor behavior and lifespan. Adult flies carrying an *esg*-Gal4ts>UAS-*gfp* were exposed to phytocannabinoids via dietary supplementation, and immunofluorescence microscopy followed by automated CellProfiler analysis revealed morphological changes in *D. melanogaster* midguts, including alterations in progenitor morphology and the relative proportion of enteroendocrine cells in the intestinal epithelium. We also complemented our analysis of intestinal homeostasis with a standard lifespan assay, as well as climbing assays to determine any differences in locomotor activity. Lastly, we also analyzed whether exposure to phytocannabinoids, which are known to have anti-inflammatory effects in mammals, could protect fly intestinal epithelia from the oxidative stress caused by exposure to Paraquat.

Our preliminary findings suggest that phytocannabinoids have complex effects on midgut morphology, which correlate with broader physiological effects. Further work will be aimed at experimentally manipulating genetic pathways known to serve as non-canonical targets of phyto- and endo-cannabinoids in mammals, and thus explore their potential roles in mediating their effects on flies. Our work will hopefully unveil alternative yet conserved mechanisms that might better inform their administration in the context of human health.

1606S **RNA-Seq analysis starvation selected Drosophila melanogaster** Aavash Adhikari, Allen Gibbs School of Life Sciences, University of Nevada Las Vegas

Obesity is a common, serious and costly disease with 41.9% prevalence in the US. The heritability estimate of obesity is up to 70% indicating a huge role of genetics as its causal factor. Although we know much about the genetics behind obesity, understanding it at the transcriptomic and proteomic levels will further give us some insights into its molecular physiology. Drosophila melanogaster, which has been selected for starvation resistance, develops slower, is larger in size, and has higher lipid content than normal-fed flies. They also have altered physiologies like cardiac dysfunction, reduced sleep performance, and reduced fecundity. We are using those flies as a model for understanding human obesity by analyzing their transcriptome and proteome at the third instar larvae, as previous research has shown that this is the key stage differentiating between starvation-selected and control flies.

Transcriptomic analysis revealed genes that were differentially expressed between selected and control populations. Out of 15094 with nonzero total read count (adjusted p-value < 0.01), 2983 (20%) genes were upregulated and 2029(13%) genes were downregulated. Gene set enrichment analysis revealed functions like ribosome biogenesis, fatty acid metabolic process, carboxylic acid and oxoacid metabolic process were activated in starvation selection flies. In contrast, developmental processes like imaginal disc eversion, leg disc development, and leg disc morphogenesis were suppressed. The results are consistent with our observation of longer development time for starvation-selected flies. We have obtained proteomic data from the same time frame and will analyze them to correlate with the transcriptome data. We hope combining the two data sets will further validate our results and give more information about the physiology of starvation-selected flies.

1607S **The autophagic stem cell loss promotes intestinal inflammation** Kang Han[1], Michael Boutros[2], Jun Zhou[1] [1]Hunan University, [2]German Cancer Research Center

The inflammatory bowel disease (IBD) is a complex and multifactorial intestinal disorder arising from gene-environment interactions. The genetic variants are major causes in IBD pathogenesis, however, only 30% of patients are diagnosed positive for known IBD causative genes. To identify additional IBD risk genes and unravel the disease mechanisms, we performed a large-scale in vivo CRISPR screen detecting IBD-like symptoms in *Drosophila* intestine. We discovered 105 of nearly 2000 tested

CRISPR knockouts develop IBD-like disorders, notably, 47 genes (45%) are previously known IBD causative genes in humans. We identified the ceramide synthase Schlank controls stem cell survival by regulating lipogenesis. The Schlank mutant exhibits a reduced lifespan with IBD-like disorders like intestinal barrier defect, inflammation, and diarrhea. Mechanistically, we showed Schlank knockouts displayed reduced lipid levels and impaired autophagosomal/mitochondria activity in stem cells, leading to stem cell death and organ failure, thereby causing intestinal inflammation. Inhibition of lipolysis and autophagy restores stem cell numbers and barrier function of the intestinal epithelium, prevents intestinal inflammation, and extends the organismic lifespan. We therefore uncover a previously underappreciated role for stem cell maintenance in the pathogenesis of IBD and demonstrate that stem cell revival could be the potential therapeutical strategy for IBD treatment.

1608S **Using Drosophila to Understand the Role of Polyamine Metabolism in Parkinson's Disease** Bedri Ranxhi[1], Zachary M Chbihi[1], Zoya Bangash[1], Zaina Qadri[1], Sokol V Todi[1], Peter A LeWitt[2], Wei-Ling Tsou[1] [1]Pharmacology, Wayne State University School of Medicine, [2]Neurology, Wayne State University School of Medicine

Polyamines play essential roles in various organisms, encompassing multiple physiological functions including cell growth, survival, and are involved in key biological processes, such as the synthesis of proteins and nucleic acids, stabilizing the structure of chromatin, regulating apoptosis, and safeguarding cells against oxidative damage. Polyamine metabolism has also been investigated for yielding disease-specific biomarkers. In a pilot study we identified increases in serum concentrations of three L-ornithine-derived polyamines (putrescine, spermine, and spermidine), each of which showed correlation to Parkinson's disease (PD) progression and its clinical subtypes. Considering the significant physiological roles that polyamines play in our body's functions and their tight homeostatic regulation, we further investigated if the insights gained from our biomarker discoveries could help us gain a better understanding of the biochemical aspects of neurodegeneration in diseases like Parkinson's, and others where proteinopathy is vastly prevalent. We conducted experiments in which we altered the way polyamines are processed in *Drosophila* models of synucleinopathy (knocking down critical polyamine interconversion enzymes). These models involve an excess of neuronal α-synuclein.

We observed substantial alterations in the lifespan and motility of *Drosophila* after suppressing key enzymes of polyamine metabolism (spermine synthase [SMS], spermidine/spermine N1-acetyltransferase 1 [SAT1], spermine oxidase [SMOX], or polyamine oxidase [PAOX]. As polyamine metabolism is vital for maintaining neuronal integrity, we investigated the functional involvement of each polyamine in neuronal homeostasis and their regulation with regard to α-synuclein. In addition, we investigate whether modifying particular polyamine enzymes in our fly model of α-synuclein overexpression would lead to a reduction in the extent of α-synuclein aggregation.Our analysis provides a deeper perspective into the underlying causes of neuronal and systemic changes in polyamine metabolism as it relates to α-synuclein proteinopathy. These findings may offer valuable guidance for designing clinical trials that focus on therapeutic interventions directed at the regulation of polyamine pathways.

1609S ***Drosophila* model of *de novo PHACTR1* variant demonstrates alterations in bristle structure and synapse function** Jonathan Andrews[1], Sharayu Jangam[1], Paige Hall[1], Lauren Briere[2], Shinya Yamamoto[3], David Sweetser[4], Michael Wangler[1] [1]Molecular and Human Genetics, Baylor College of Medicine, [2]Division of Genetics, Massachusetts General Hospital, [3]Baylor College of Medicine, [4]Medical Genetics, Massachusetts General Hospital

Phosphatase and Actin Regulator 1 (PHACTR1) is a member of a family of Protein Phosphatase 1 (PP1) binding proteins which defines the substrate specificity of the Phactr1/PP1 holoenzyme. PHACTR1 is broadly expressed within the central nervous system and is believed to play an important role in the regulation of actin cytoskeletal dynamics, PP1 activity, actin stress fiber formation, cell motility, and cell survival. Multiple *PHACTR1* variants have been previously associated with different human pathologies, including developmental and epileptic encephalopathy, West syndrome, myocardial infarction, melanoma growth, coronary artery disease, and cervical artery dissection. PHACTR1 is orthologous to *Drosophila CG32264*, which is highly expressed in the adult brain, anterior midgut primordium, larval midgut, and posterior midgut primordium. We have identified a human proband with a *de novo* duplication of exon 5 and parts of the surrounding introns who presented with global developmental delay, hypotonia, absent speech, seizures, behavioral problems, mild prominence of ventricles and sulci, and slight dysmorphism of the left hippocampus. Subsequently, we generated a *Drosophila* overexpression model of human PHACTR1 using the GAL4/UAS system to drive the expression of the human gene within specific tissues in the fly. As PHACTR1 is regulated by actin via the presence of RPEL domains, we sought to evaluate its effect on several actin rich or neurologically related structures in the fly model. Overexpression of either the reference or variant human cDNA via a Nubbin-Gal4 driver produced no changes within the wing tissues, and overexpression within the eye by GMR-Gal4 produced only minor changes in eye morphology. Ubiquitous overexpression of the putatively pathogenic variant using either an Actin, Tubulin, or Pannier-Gal4 driver was sufficient to induce forking or abnormal bends in bristles. These changes within the actin-rich bristle structures were not observed in animals overexpressing the reference human cDNA. Likewise, the ubiquitous overexpression of CG32264 showed no alterations in bristle morphology. Ubiquitous depletion of *CG32264* via

two different RNAi lines (*CG32264^{JF02975}* and *CG32264^{HMC05840}*) also failed to cause any changes in bristle morphology. However, the expression of *CG32264^{JF02975}*, but not *CG32264^{HMC05840}*, in eye tissues via GMR-Gal4 produced a rough-eye phenotype. An electroretinogram of the adult fly eye demonstrated significant changes in the on/off transients in animals expressing our PHACTR1 variant compared to both PHACRT1 reference and CG32264 expressing animals. Our initial assessment demonstrates that *Drosophila* is a suitable model for further exploration of *PHACTR1* variants and identifies that duplications of the 5th exon are putatively deleterious and may underly a novel disorder separate from those previously associated with *PHACTR1*.

1610S **Utilizing Trojan Exon Cassettes to observe altered neurodevelopmental and neurodegenerative phenotypes caused by *pex* mutations in *Drosophila*.** Vanessa A Gomez, Sharayu Jangam, Jonathan Andrews, Michael Wangler Molecular & Human Genetics, Baylor College of Medicine

Peroxisomal Biogenesis disorders (PBD) are a group of autosomal recessive disorders caused by loss-of-function mutations of one of the *PEX* genes responsible for peroxisomal formation. Impaired peroxisome assembly causes severe multisystemic failure with patient phenotypes ranging from epilepsy, feeding issues, biochemical abnormalities, and neurodegeneration. To study the neurodevelopmental and neurodegenerative phenotypes seen in patients, we moved to *Drosophila* as a model organism utilizing Trojan Exon Cassettes. Here, we generated a fly line in which the coding sequence of *pex2* has been replaced by the *Kozak-GAL4* promoter trap sequence. This cassette results in a simultaneous knock-out of the *pex2* and knock-in of a *GAL4* driver sequence. After crossing *pex2-Kozak^{GAL4}* lines to known *pex2* null alleles, lifespan analysis showed a significant difference in experimental flies than controls. These results are consistent with our known null alleles, suggesting that *pex2-Kozak^{GAL4}* is also a null. In parallel, we have generated UAS-human cDNA lines to assess the function of *PEX2* variants in *Drosophila* and compare variant function with human rescue. Human rescue will be done by replacing *pex2* with either reference or variant human transgenes and observing differences in phenotype that could suggest a *pex2*-specific effect. Utilizing the *pex2-Kozak^{GAL4}* and UAS-human cDNA lines, functional assays are underway, such as bang sensitivity and climbing assay, to observe and compare loss-of-function variant function with human rescue. Altogether, we hope to utilize these unique *Drosophila* lines to observe the neurodevelopmental and neurodegenerative phenotypes in *pex2* variants and better understand their pathogenicity.

1611S **The glycoprotein 5 of porcine reproductive and respiratory syndrome virus stimulates mitochondrial ROS to facilitate viral replication** wang jiang Henan Agricultural University

Viruses have evolved sophisticated mechanisms to manipulate host cell organelles to serve as niches for persistence and proliferation. In the present study, we aimed to investigate the role of cellular organelles in the replication of porcine reproductive and respiratory syndrome virus (PRRSV). We found that the morphology of mitochondria and the endoplasmic reticulum (ER) were both altered, and the contact between these two organelles was enhanced during PRRSV infection. By the overexpression of PRRSV-encoded open reading frames, we identified that only glycoprotein 5 (GP5) was essential for ER-mitochondria contact. Further investigation revealed that GP5 interacted with the ER inositol 1,4,5-triphosphate receptor (IP3R) and the mitochondrial voltage-dependent anion channel (VDAC1) to promote the Ca2+ efflux from ER into mitochondria. Excessive mitochondrial Ca2+ uptake resulted in mitochondrial dysfunction and substantial mitochondrial reactive oxygen species (mROS) production. Elevated mROS activated autophagy through the AMPK/mROR/ULK1 axis to facilitate PRRSV replication. GP5-induced mROS also triggered the NOD-like receptor family pyrin domain-containing protein 3 (NLRP3) inflammasome. Inhibition of autophagy augmented NLRP3 inflammasome activation and exhibited an anti-PRRSV effect, suggesting autophagy counteracted the NLRP3-mediated innate immune response. Overall, our findings highlighted the importance of cellular organelles in virus-host interactions and provided new insights into the complex interplay between virus replication and innate immune responses

1612S **A potential role of the gut microbiome in promoting age related alcohol tolerance in Drosophila** Patricia Pujols, Kerianalee Rivera, Imilce Rodríguez, Alfredo Ghezzi Biology, Universidad de Puerto Rico, Rio Piedras

Alcohol Use Disorder (AUD) is a medical condition characterized by a limited ability to stop or control alcohol use despite adverse social, occupational, or health consequences. In older adults, the habit of excessive alcohol consumption represents 20% between the ages 60 to 64 years and 11% over 65 years of age, according to the National Survey and Drug Use and Health. Aging can affect the response to alcohol in aspects of sensitivity and tolerance, which puts the elderly at greater risk. Thus, there is an urgent need to characterize the cellular and molecular effects of alcohol consumption in this aging population. Aging has twelve proposed hallmarks but of particular interest for our project is the altered intercellular communication between the animal genome and the microbiome leading to microbial dysbiosis. The human being is home to around 38 trillion bacteria and this collective commensal, symbiotic, and pathogenic microorganisms is known as the microbiota, the majority of which is found in the intestine. Our study aims to understand the effects of alcohol on the bidirectional interaction of the gut microbiome and the brain in aspects of tolerance and sensitivity in young and old animals. We are using *Drosophila*

melanogaster as a model organism as it has homology with humans in alcohol response, intestinal microbiome composition, and displays aging phenotypes. To measure age-related changes in alcohol behaviors, we exposed young (5 days) and old (5 0days) Canton-S female flies to 50% ethanol vapor. We then calculated the time they take to sedate. For sensitivity assays, we measured resistance to alcohol in a first exposure compared to a control group that is exposed to water. While for tolerance we calculated the difference between resistance from a second exposure generated by a previous one. We then measure the changes in the gut microbiome after one or two exposures to alcohol. To do this we dissected the intestine of treated flies and plated the homogenate in selective media for *Lactobacilli*, *Acetobacteria,* and *Enterobacteria* and measure abundance in Colony Forming Units (CFUs). Our data shows that there is an increase in sensitivity and tolerance in old flies. In young and old flies, we find that after one exposure to alcohol, all CFUs increase and then decrease during the second exposure. Young flies treated with antibiotics have a decrease in tolerance. Future studies are focused on finding the molecular mechanism used by specific bacterial species to influence sensitivity and tolerance in flies. We hope to elucidate the underlying causes of neuroadaptation possibly caused by changes in the gut microbiome and to further understand these changes in the aging context.

1613S **Regulation of intestinal stem cells and longevity by the nuclear envelope protein Klaroid (Koi)** Ithan Cano, Carlos Asturias, Courtney Frazier, Mariano Loza-Coll Biology, California State University, Northridge

Multicellular organisms often rely on resident adult stem cells (ASCs) to maintain tissue homeostasis. These oligopotent ASCs undergo self-renewing asymmetric divisions, by which they produce an identical copy of themselves and a differentiating sister that will give rise to any one of a limited range of terminally differentiated cells to replace those lost to injury, disease or normal tissue turnover. The activity of ASCs is governed by pleiotropic master regulator (MR) genes, which exert direct or indirect control over numerous downstream effector genes, most of which remain poorly understood.

Here we report preliminary findings on the role that the nuclear membrane protein Klaroid (Koi), an experimentally validated target of Escargot and dSTAT92E, two well-known and important MR genes in Drosophila intestinal stem cells (ISCs). Previous work by others established Koi's role in repairing double-strand DNA breaks in Drosophila cells in culture and its requirement for attachment of the nucleus to the cytoskeleton in the Drosophila eye. To our knowledge, no previous studies have specifically addressed Koi's role in ISCs.

Here we used ISC-specific genetic manipulations of Koi and immunofluorescence microscopy to determine the effect of over-expressing or knocking-down Koi on the number, morphology and relative abundance of different cell types in the intestinal epithelium, both in young flies and during aging. Since preliminary observations indicated that Koi overexpression might be protective against aging-induced intestinal dysplasia, we also conducted lifespan assays coupled with a Smurf assay to probe for intestinal barrier integrity. Flies with lower Koi expression in ISCs showed a significant shortening in lifespan compared to controls. Surprisingly, flies overexpressing Koi in ISCs had comparable survivorship to controls for approximately 35-40 days, but experienced a sudden and sharp mortality afterwards. We are currently trying to more carefully characterize the effect of Koi manipulations in ISC regulation, and thus identify potential links between the nuclear envelope, ISC biology and their secondary effects on lifespan.

1614S **The Stumble E3 Ligase Induces Interaction Between the SWI/SNF Component BRG1 and Beta-catenin to Promote Wnt Signaling** Kai Yuan[1], Sara Kassel[2], Nawat Bunnag[3], Ben Maines[3], Amber Adams[3], Zachary Spencer[3], Andres Lebensohn4[4], Rajat Rohatgi[5], David Robbins[6], Arminja Kettenbach[3], Ethan Lee[2], Yashi Ahmed[3] [1]Molecular and Systems Biology, Dartmouth College, [2]Vanderbilt University, [3]Dartmouth College, [4]National Cancer Institute, [5]Stanford University School of Medicine, [6]Georgetown University

The Wnt/β-catenin signal transduction pathway is an ancient pathway that regulates cell proliferation and differentiation during animal development. Inhibition or aberrant activation of Wnt/β-catenin signaling causes birth defects and several cancers, particularly colorectal cancer. Although the canonical Wnt pathway has been extensively studied, no FDA-approved drugs targeting the pathway exist. Here, starting with genome-wide forward genetic screens in human haploid cells, we identify an evolutionarily conserved ubiquitin ligase, Stumple, as a novel positive regulator of Wnt/β-catenin signaling. RNAi-mediated depletion and conditional CRISPR-mediated mutagenesis of Drosophila *Stumple* decreased Wnt/β-catenin signaling in multiple tissues. Genetic epistasis analysis showed that Stumple acts downstream of the β-catenin destruction complex. In the presence of Wnt, Stumple interacted with BRG1, a subunit of the SWI/SNF chromatin remodeling complex, and induced BRG1 ubiquitination. Stumple-induced ubiquitination did not affect BRG1 stability nor its association with SWI/SNF components. However, Stumple depletion decreased the interaction between BRG1 and β-catenin, the key transcriptional coactivator in the Wnt signaling pathway. Our findings support a model in which Stumple ubiquitylates BRG1 in the presence of Wnt and promotes its interaction with b-catenin, thereby bringing SWI/SNF to Wnt target genes. Our studies suggest a general mechanism by which cell signaling induces the interaction between BRG1 and pathway-specific transcription factors to

recruit SWI/SNF complexes to their appropriate target genes.

1615S **Protective Role of Exercise-responsive Genes against Chronic Muscle Disuse** Mousumee Khan, Jodi Protasiewicz, Li Tao, Charles Chung, Alyson Sujkowski, Robert J. Wessells Physiology, Wayne State University

Prolonged sedentary state due to medical conditions can cause chronic muscle disuse and lead to physical incapacity and poor quality of life. Here, we described a model of skeletal muscle disuse via enforced restraint utilizing *Drosophila melanogaster* to characterize the effects of sedentary behavior in flies. We found that restraint substantially reduced endurance, climbing speed and longevity in flies. Restrained flies accumulated significantly more polyubiquitin than unrestrained flies, indicating enhanced protein degradation in muscle of restrained flies. However, flies that were restrained for most of their life, but released five times a week to undergo an exercise program significantly ameliorated their endurance, climbing speed and muscle actin integrity accompanied by upregulation of autophagy and phosphorylated AKT (p-AKT). Lastly, we identified three exercise-responsive genes, *Sestrin* (*dSesn*), *Spargel* (*srl*) and *Iditarod* (*Idit*) whose overexpression in muscle provided significant protection against the effects of restraint. Proteins encoded by these genes represent targets that may be leveraged toward therapeutic options for patients with chronic inactivity.

1616S **Comparative Genomics Reveals DNA Elements that Regulate p38Kb in Aging and Stress** Brooke Allen[1], Alysia Vrailas-Mortimer[1,2,3] [1]Biological Sciences, Illinois State University, [2]Biochemistry and Biophysics, Oregon State University, [3]Linus Pauling Institute

Aging is complex process that results in the decline and deterioration of an organism's functions. A number of aging genes have been identified though how they are regulated in the context of aging is not well described. One such aging gene is the highly conserved p38 MAPK (p38Kb), which we have shown to extended lifespan and increased stress resistance when over-expressed in *Drosophila* muscle. Loss of p38Kb results in a shortened lifespan, premature locomotor dysfunction, and increased stress sensitivity. Though much is known how p38 MAPKs are regulated at the protein level, little is known about how p38 MAPKs are transcriptionally regulated. Therefore, we utilized a comparative genomics approach in which we analyzed the upstream region of the p38Kb gene across 22 sequenced species of Drosophila. We identified two conserved transcription factor binding sites in Drosophila species that were more resistant to oxidative stress and had increased levels of p38Kb protein in response to oxidative stress. One site is a predicted AP-1 biding site, while the other is a predicted lola-PT binding site. We found that over-expression of either AP-1 or lola-PT in D. melanogaster, which has both binding sites, was sufficient to induce p38Kb transcription under standard conditions. Only over-expression of lola-PT was able to induce p38Kb transcription under oxidative stress conditions. In order to determine if these binding sites play a functional role in p38Kb transcription during aging and stress, we have generated p38Kb null mutants that have a transgenic version of the upstream region and full gene sequence of the p38Kb gene with either have an intact promotor with both binding sites, a promotor with only the AP-1 site, a promotor with only the lola-PT site, or a promotor with both sites scrambled. Our preliminary findings suggest that the lola-PT site is required for stress response and viability, while the AP-1 site is required for lifespan.

1617S **Changes in immune signaling may mediate different outcomes between mild, repeated TBI and a single, severe TBI** Jorge A Garcia, Daniel Tulchinskiy, Kamden T Kuklinski, Doyinsola Ogunshola, Rebecca Delventhal Biology, Lake Forest College

Traumatic brain injuries (TBIs) are a common neurological disorder, affecting more than 1.5 million people nationwide and often cause hospitalization, long-term disability, and death. However, due to differences in age, sex, and other demographics, it is difficult to compare outcomes of different injury patterns amongst humans, especially because the characteristics of TBIs sustained are often highly variable. To study head injuries in a controlled manner, we used *Drosophila melanogaster* as a model organism to assess the effects of mild, repeated TBI (multi-day, MD) compared to a single, severe TBI (single-day, SD). We wanted to know if different patterns of TBI differ in short- and long-term outcomes. To determine this, we measured acute mortality, lifespan, and climbing. We found that flies given a SD TBI exhibited higher acute mortality, but the surviving flies showed a longer lifespan than flies given a MD TBI. Likewise, flies given a MD TBI showed worse long-term locomotor ability. We hypothesized that different immune responses to MD vs. SD TBI may mediate differences in short- and long-term outcomes. To test this, we measured expression of antimicrobial peptides (AMPs) 4 hours post-TBI and found that AMP expression increased after each day of the MD TBI and was eventually equivalent – if not greater – than expression four hours post-SD TBI. We are currently investigating long-term AMP expression post-TBI. We also measured acute mortality and lifespan of Imd and Toll mutant flies post-MD and SD TBI. We found that loss of Imd led to worse short- and long-term survival in both injury conditions, indicating that Imd signaling is protective in both injury types. Interestingly, while loss of Toll led to worse short-term survival after SD TBI, Toll mutants survived better after MD TBI. When we measured Toll mutants' lifespan post-MD and SD TBI, we saw that loss of Toll did not significantly change the flies' lifespan post-SD TBI but modestly increased the lifespan of flies post-MD TBI, suggesting that Toll signaling is detrimental for both short- and long-term outcomes from a MD

TBI. To understand cell-type specificity in Toll signaling, we are conducting glial and neuronal knockdowns of Toll and testing short- and long-term outcomes. Understanding differences in cellular immune responses to different types of TBI could enable the development of tailored treatments, improving outcomes.

1618S **Mutagenesis of *spastin*: a model for Hereditary Spastic Paraplegia and opportunity for a course-based undergraduate research experience (CURE)** Jerry Ye[1], Claudia Barreto[2], Myra Cai[2], Meera Gangasani[2], Sofia Guerrero[2], Cordelia Hume[2], Qizhou Jiang[1], Taranjit Saggu[2], Letian Wang[1], Nina T Sherwood[2], Emily F Ozdowski[2] [1]Biology, Duke Kunshan University, [2]Biology, Duke University

Locomotor dysfunction and progressive neurodegeneration are hallmarks of Autosomal Dominant-Hereditary Spastic Paraplegia (AD-HSP) patients. Mutations in multiple genes have been implicated, but approximately 40% of AD-HSP cases result from disruption of SPG4 / SPASTIN. The SPAST protein is a member of the AAA ATPase family and has been shown, across different cell types, to regulate the microtubule cytoskeleton. Given that the amino acid sequence is highly evolutionarily conserved, the microtubule interacting and trafficking (MIT) domain and the catalytic ATPase domain were also identified in *Drosophila melanogaster*. To characterize critical protein regions, we mutagenized fruit flies with the chemical, ethyl methane sulfonate (EMS). Point mutations generated in *Drosophila spastin* were isolated and sequenced, while individual fruit fly lines were tested for disruptions of viability and neuromuscular junction morphology. Here we report the results of these new mutations and the allelic series of severity that our data support. When compared to the genetic null, $spas^{5.75}$, this mutational analysis provided a readout of important amino acid residues and was accomplished within a single undergraduate semester. Each student was given an unidentified mutant line of *Drosophila* for characterization. For students, this type of project integrates different levels of analysis from basic genetics and cell biology to the application in human health. It is ideal for an exploratory upper-level lab course, a CURE (course-based undergraduate research experience), in which the students are given more independence and freedom of analysis than in introductory courses. Our course design included a breadth of laboratory techniques (molecular biology, animal husbandry, microdissection, immunofluorescence, and microscopy) and digital tools (DNA sequence analysis with SeqMan Ultra, image analysis with Image J/Fiji, graphing in R, and figure compilation in Adobe Photoshop). The assessments focused on data interpretation and visual science communication with a final poster presentation. The characterization of new mutations could be generalized to other easily screened phenotypes and the use of *Drosophila melanogaster* as the model organism makes the timeline of a single semester possible.

1619S **The prototypical TUB domain protein TUB bipartite transcription factor *Tub* regulates RNA trafficking** Tyler R. Henderson[1,2], Hamza Taufique[1,2], Rieko Niibori[1], Ulrich Braunschweig[3], Benjamin J. Blencowe[2,3], Sabine P. Cordes[1,2] [1]Lunenfeld-Tanenbaum Research Institute, [2]Department of Molecular Genetics, University of Toronto, [3]Terrence Donnelly Center for Cellular and Biomolecular Research

In mice and humans, mutations in the TUB bipartite transcription factor (*Tub*) gene cause maturity-onset obesity, insulin resistance, deafness and retinitis pigmentosa. Furthermore, mutations in *Tub* orthologues present within *Drosophila melanogaster* and *Caenorhabditis elegans* also cause metabolic and sensory deficits. TUB is the founding member of the TUB protein family; in mammals this includes TU-like proteins (Tulps) 1-4. Both Tub and Tulp proteins harbor a carboxy terminal nucleic acid binding domain - the TUB domain. TUB can tether to the inner plasma membrane via a phosphatidylinositol 4, 5-bisphospate (PIP_2) binding domain and translocate primarily into the nucleus upon G-alpha q signaling. As a result, TUB was postulated to be a signal responsive transcription factor; however, this proposed TUB-dependent transcriptional program has remained elusive.

Many of the systems impacted by loss of Tub in mammalian and non-mammalian models are reliant on cilia, antenna-like organelles cells used to sense environmental signals. One of the most striking phenotypes observed in TUB and mammalian TULP3 mutants is the mislocalization of G-coupled protein receptors (GPCRs) to cilia. Indeed, the phenotypes observed in these model systems resemble ciliopathies. How or whether TUB's nucleic acid binding properties are connected to its role in GPCR trafficking has been unknown.

Using affinity purification-mass spectrometry (AP-MS), we discovered that TUB interacts with RNA binding proteins; including ones known to be required for cilia formation and function. We found that TUB binds RNA *in vivo* and by performing individual nucleotide resolution crosslink and immunoprecpitate RNA sequencing (iCLIP-seq) we have identified endogenous TUB target mRNAs in the mouse retina and hypothalamus. Electrophoretic mobility shift assays confirmed TUB's capacity to directly bind target RNAs in vitro and helped define its binding preferences. Consistent with a role in RNA transport, select TUB bound mRNA and their encoded proteins were mislocalized in *Tub* deficient mice. A role for TUB in RNA transport was further supported by the ability of specific TUB-bound RNA sequences to redirect non-ciliary proteins to cilia. Thus, we have uncovered a novel TUB-dependent RNA regulatory program and roles for TUB in RNA transport.

These findings change our understanding of TUB domain protein functions and open new avenues for exploring signal-

responsive RNA localization and its role in appetite homeostasis and neuronal health.

1620S **Glyceraldehyde 3-phosphate dehydrogenase, spermatogenic (GAPDHS) functions as a link between melanoma metabolism and cell morphology** Marelize Snyman[1], Sophie Wix[1], Rachel Walsdorf[1], Lindsey West[1], Juliana Kim[1], Gregory A Hosler[2], Jennifer Gill[1] [1]UT Southwestern Medical Center, [2]Propath

GAPDHS is a spermatogenic enzyme expressed in most human melanomas and functions to limit metastasis in patient-derived xenograft (PDX) melanomas. To understand its role in natural tumor progression, we examined its expression in patient samples ranging from normal melanocytes to benign nevi to advanced melanomas. Using single-cell RNA sequencing data from skin, we determined that GAPDHS expression is actually detectable in normal melanocytes, which was previously not known due to the lack of granularity in bulk RNA-sequencing of skin. We confirmed this expression of GAPDHS in melanocytes at the protein level through immunohistochemistry of human skin samples. GAPDHS expression was maintained in early stages of melanocyte tumor progression from benign nevi to early melanoma. GAPDHS expression was partially or totally lost in more advanced melanomas and metastases consistent with a role in repressing metastasis. Spatial transcriptomics comparing GAPDHS high and low regions of patient melanoma tumors indicated that GAPDHS expression is associated with pigmentation and melanocyte differentiation programs. Phenotypically, lower GAPDHS expression was associated with the loss of melanoma nesting and the acquisition of less pigmented, spindle phenotypes. Knockdown of GAPDHS in melanoma PDX cells led to an increase in the mesenchymal and tumor invasive marker N-cadherin, indicating GAPDHS impacts cell morphology in addition to its previously known effects on metabolism. Additional studies are ongoing to determine whether this morphologic change is essential for its influence on melanoma metastasis.

1621S **Relating mouse and human phenotypes for cross-species translational discovery** Cynthia Smith, Susan Bello, Carol Bult The Jackson Laboratory

Mouse Genome Informatics (MGI) integrates mouse genotype-phenotype datasets from biomedical publications and large-scale projects with genomic, mutation, expression, functional and human disease model data to accelerate correlative discoveries and inform genetic disease etiology and therapeutics. To facilitate cross-species translation of phenotype and disease data between human and mouse we have developed the Human-Mouse: Disease Connection (HMDC) resource. This tool allows for users to pose simple to complex questions and retrieve phenotype and disease data for both human and mouse genes simultaneously. Human data are imported from the Human Phenotype Ontology knowledgebase. Human genes are associated with Human Phenotype ontology (HP) terms mouse genes are associated with Mammalian Phenotype ontology (MP) terms. Mappings between terms in these ontologies are included with the Mouse-Human Ontology Mapping Initiative (MHMI, https://github.com/mapping-commons/mh_mapping_initiative), which aims to collect and standardize the dissemination of mouse-human phenotype mappings and develop a set of best practices for their use. By utilizing these term mappings and relationships, users can enter a phenotype or disease term name from either species in the search, select related terms using a term picker tool, and thus return annotations using matching terms across both species in the HMDC. The results set returned includes genes associated with any of these terms or their descendants. This casts a broad net to bring in data from both species regardless of the ontology used to capture the data. The HMDC accelerates the ability to identify new candidate disease genes in human, support development of improved mouse models, and improve methods to computationally compare model characteristics to particular human diseases or syndromes.

1622S **Investigating Tuberculosis Disease Tolerance versus Susceptibility in a Diverse Murine Model** Alwyn Ecker[1], Kaley Wilburn[1], Marco Tulio Pardini Gontijo[1], Rachel Meade[2], Clare Smith[1], Martin T Ferris[3] [1]Molecular Genetics and Microbiology, Duke University, [2]University Program in Genetics and Genomics, Duke University, [3]Department of Genetics, UNC Chapel Hill

Mycobacterium tuberculosis (*Mtb*), the causative agent of tuberculosis (TB) disease, is currently the leading cause of death by an infectious agent. Clinically, *Mtb* results in heterogenous outcomes where most individuals can contain or 'tolerate' the infection while others will go on to develop an active infection. Research has traditionally focused on identifying host and pathogen resistance pathways in the context of active TB infection. However, there is a growing appreciation for the arm of the host immune defense involved in disease tolerance. Disease tolerance manifests when host resistance mechanisms weaken, or in cases of chronic infections like TB, the host activates alternative protective mechanisms to minimize collateral damage to its tissues, while minimizing harm to the pathogen. Host and *Mtb* mechanisms that allow for individuals to 'tolerate' infection have been relatively unexplored**,** in part due to the lack of a murine model that recapitulates *Mtb*-specific disease tolerance. In published work from our laboratory, we infected over 50 Collaborative Cross mouse strains, and identified specific CC strains that recapitulate distinct TB disease states. One of these strains was CC023/GeniUNC (CC023). We have identified CC023 as a novel murine model of *Mtb*-specific disease tolerance. Upon low dose aerosol infection with ~100 *Mtb* wildtype H37Rv bacilli, CC023 maintains high bacterial burden as well as elevated levels in pro-inflammatory cytokines (i.e. *TNF-α*, IL-17, MIP-1 *α*). To elucidate host genetic factors that contribute to the disease tolerance phenotype in CC023, we have identified candidate host

genes that underlie disease tolerance. Among these genes, a top candidate gene is gasdermin A (*Gsdma*) on chromosome 11. *Gsdma* is part of the gasdermin gene family, and they are implicated in pyroptosis. The role of *Gsdma* has not been elucidated for *Mtb* infection. We infected *Gsdma*$^{-/-}$ mice to see if *Gsdma*$^{-/-}$ would phenocopy CC023's high bacterial burden and cytokine profiles, underscoring its role in CC023's disease tolerance phenotype. Our results demonstrate that *Gsdma*$^{-/-}$ mice have an intermediary *Mtb* phenotype compared to the canonical C57BL/6J (increased bacterial burden, and unique cytokine profile) but does not phenocopy the high bacterial burden and cytokine profile of CC023. These results suggest that CC023's disease tolerance is independent of *Gsdma*, and *Gsdma* may be additive rather than the driver of the disease tolerance in CC023.

1623S **Generating quantitative allelic series in mice by targeting splicing at essential exons.** Bruce A Hamilton, Dorothy Concepcion, Renee Long Cellular & Molecular Medicine, UC San Diego

Efficient modeling of genetic variation requires access to a broader palette of alleles than has historically been available in many organisms, including lab mice. Germline editing with RNA-guided enzymes has allowed construction of custom alleles for nearly a decade, but the cost of generating multiple alleles has often limited the range of alleles examined. We have targeted polypyrimidine tracts, which are essential cis-acting signals for pre-mRNA splicing, at essential exons of several developmentally important genes. Providing repair donor oligonucleotides that vary in degree of predicted splicing disruption as a pool allowed recovery of multiple alleles from each of several small-scale injection experiments. Results from editing at *Cep290* (5 alleles), *Shh* (7 alleles), *Tulp3* (6 alleles), and *Wnt1* (4 alleles) illustrate the utility of this approach to simultaneously generate both null and quantitative hypomorphic variants. Quantitative titration of gene activity allows more precise modeling of biological function, buffering and epistasis, and disease impact.

1624S **Rodent Model Resource Center (RMRC) - An international repository for novel GM rodent strains** Hsin Chih Sandy Hsu, Monica Meng-Chun Shih, Si-Tse Jiang, Hsiang-Ju Lin, Hsian-Jean Chin National Laboratory Animal Center, National Applied Research Laboratories, Taiwan

The Rodent Mouse Resource Center (RMRC) is listed as one of the repositories in the database of International Mouse Strain Resource (IMSR). RMRC is a non-profit repository under the National Laboratory Animal Center (NLAC) founded by the Taiwan government. We collected nearly 450 strains precious rodent strains generated by NLAC and domestic researchers thus far. Despite our small scale, we possess numerous globally unique strains. These unique strains are focused on disease models and tissue-specific Cre strains. These strains contribute to the advancement of research. Here are a few samples as follows,

1. Neuronal field strains
2. Metabolism field strains
3. Humanized strains

Furthermore, we provide biomaterial export/import services to distribute the strains to global researchers in need. We facilitated collaboration involving around 500 strains across more than 100 institutes. These institutes, spanning nearly 15 countries, are spread across Asia, North America, and Europe. We are trying to break through the bottleneck in Australia's exportation

We hope to assist researchers in obtaining the most suitable strains for their experiments, enabling the precious strains to reach their maximum value simultaneously. In addition, we can also accelerate the development of Taiwan's biotech and pharmaceutical industry and align with global trends.

1625S **Combining P301L and S262A tau variants prevents spheroids formation in mice** Camila A Zanella[1], Mel Feany[2] [1]Pathology, Harvard Medical School and Brigham and Women's Hospital, [2]Harvard Medical School and Brigham and Women's Hospital

Increased phosphorylation of the microtubule-binding protein tau is strongly implicated in the pathogenesis of Alzheimer's disease and related tauopathies. Tau is phosphorylated by a range of kinases at many sites. To understand the effects of serine 262 phosphorylation in vivo, we used a transgenic central nervous system (CNS) model of tauopathy. We utilized neonatal delivery of adeno-associated viruses expressing mutant tau (P301L) in non-transgenic mice. We generated full-length 0N/4R human tau constructs in the CTR4 vector, driven by a hybrid chicken β-actin promoter to ensure ubiquitous and long-lasting expression of human tau. We combined the tau variants P301L and S262A and performed behavioral analyses, including open field, novel object recognition, and fear conditioning tests. We confirmed human tau expression in the mouse brain and evaluated neuron numbers via stereology, analyzed glial fibrillary acidic protein (GFAP), and assessed spheroid formation.

Animals were aged up to 10 months. Results were first tested for normality, then analyzed using Kruskal–Wallis one-way ANOVA with Dunn's multiple comparisons test or one-way ANOVA followed by post hoc Tukey's multiple comparisons. Our results show that CNS expression of P301L tau impairs long-term context memory, and preventing S262 phosphorylation shows a trend towards improving context memory. No deficits were observed in short-term memory and locomotion. Stereology did not reveal differences in the total number of neurons in the CA1 region between the tau P301L and control group. No differences were detected in GFAP levels between tau P301L and control group. Pathogenic tau is known to cause axonal degeneration, manifested as axonal swellings or spheroids, which are distinctive neuropathological features in tauopathies. In our P301L mice spheroid was observed in various brain regions, including the thalamus, cortex, and hippocampus. This was rescued when the S262A tau variant was also expressed. Preventing phosphorylation of tau at a single site was able to rescue spheroid formation. These findings enhance our understanding of how specific phosphorylation sites are implicated in tau neurotoxicity.

1626S **Genetic mapping and mediation analysis reveal immune phenotypes underlying genetic susceptibility to severe coronavirus disease in mice** Ellen L Risemberg[1], Sarah R Leist[2], Alexandra Schaefer[2], Kalika D Kamat[1], Timothy A Bell[1], Pablo Hock[1], Colton L Linnertz[1], Darla R Miller[1], Ginger D Shaw[1], Fernando Pardo Manuel de Villena[1], Ralph S Baric[1], William Valdar[1], Martin T Ferris[1] [1]Genetics, UNC Chapel Hill, [2]Epidemiology, UNC Chapel Hill

Coronaviruses have caused three severe epidemics in the 21st century, including SARS and COVID-19, while climate change and increasing human-animal interaction raise the likelihood of future outbreaks. This motivates improved understanding of viral pathogenesis and mechanisms of susceptibility to severe disease. Studies utilizing the substantial number of COVID-19 patients worldwide have identified genomic regions associated with disease severity in humans; however, the specific genes and mechanisms underlying these associations are unclear. To identify disease-associated loci and study underlying mechanisms in more depth, we created a genetic mapping population from an F2 cross between coronavirus-susceptible and coronavirus-resistant Collaborative Cross mouse strains (CC006/TauUnc and CC044/UncJ, respectively). Over 1000 F2 mice were infected with mouse-adapted SARS-CoV, SARS-CoV-2, HKU3-CoV or saline. Weight loss, lung congestion score, viral titer, and immune profiles were measured. We recently reported several loci associated with disease outcome (i.e., weight loss and congestion score) following infection with all three coronaviruses, one of which is homologous with a COVID-19-associated locus in humans. Those initial results suggested that some mechanisms of susceptibility are 1) conserved between mice and humans and 2) shared across multiple coronaviruses, including one (HKU3-CoV) not present in humans. Here, we extend that study to dissect specific mechanisms of genetic susceptibility. We perform an integrative analysis of disease related phenotypes and intermediate immune phenotypes (i.e., viral titer and immune cell concentrations) in both control and infection groups. We apply gene-by-treatment and multi-trait quantitative trait loci (QTL) mapping to identify several loci associated with immune composition at baseline (in control mice) and following infection with mouse-adapted SARS-CoV and SARS-CoV-2. We use mediation analysis to identify causal relationships underlying associated loci, which suggests that infiltration of certain immune cells and failure to control viral replication are mediators of genetically-driven disease risk. This work takes advantage of invasive phenotyping and environmental control not possible in humans to improve our understanding of coronavirus disease susceptibility, which can improve our ability to treat and control current and future outbreaks.

1627S **Characterizing Dominant Noncoding Suppressor Variants of Lethal Thrombosis in the Mouse** Arina Rodionova[1], Marisa A Brake[2], Amy E Siebert[3], Randal J Westrick[4] [1]Biological Sciences, Oakland University, [2]Harvard University, [3]Blood Research Institute at Versiti, [4]Oakland University

Thrombosis is a complex trait characterized by excessive blood coagulation in the circulatory system. Alterations in gene expression can play a prominent role in the modulation of complex traits. In C57BL/6J mice, reducing TFPI expression by 50% *Tfpi*^{tm1Gjb}*/+ akaTfpi*$^{+/-}$*)* results in a perinatal lethal phenotype when on the Factor V Leiden homozygous (*F5*^{tm2Dg}$^{L/L}$ aka *F5*$^{L/L}$) prothrombotic background. We conducted a dominant sensitized whole genome ENU mutagenesis screen to suppress this *F5*$^{L/L}$ *Tfpi*$^{+/-}$ lethality, creating large, multigenerational lines with high penetrance of *F5*$^{L/L}$ *Tfpi*$^{+/-}$ mice. We named these lines Modifier of Factor 5 Leiden (*MF5L*). *MF5L6* is a line with 85 *F5*$^{L/L}$ *Tfpi* $^{+/-}$ offspring exhibiting 72% penetrance. We performed linkage analysis and identified a significant linkage peak on Chromosome 3 (LOD=4.35) in this line, accounting for half of the suppressing effect and containing the tissue factor gene (*F3*). Tissue factor is the main protein initiator of thrombosis. In independent mouse genetic experiments, we showed that a 50% reduction in *F3* gene expression suppresses F5$^{L/L}$ Tfpi$^{+/-}$ lethality, so this became our main candidate gene in this region. To investigate the *F3* candidate in detail, we first performed DNA sequencing on the entire *F3* coding region and found no *F3* coding mutations in *MF5L6* pedigree members. We next hypothesized that a regulatory mutation was responsible for reducing *F3* gene expression in *MF5L6*. To quantify *F3* expression, I performed quantitative PCR on liver, lung, and heart tissues from *MF5L6*. I observed two distinct expression profiles in the lung, vessel, and liver *F3* mRNA of the MF5L6 mice when compared to the wild type (B6) and F3$^{+/-}$, those that had a 50% reduction in F3 expression and those who did not. Interestingly, there was no reduction of expression in the heart tissues of MF5L6, suggesting a regulatory mutation that operates in a tissue specific manner. We performed whole

genome sequencing on 5 MF5L6 pedigree members and identified two prime candidate variants in the 200 kilobase upstream region of *F3*. The mutations are not in known regulatory elements. I am presently analyzing the rest of the MF5L6 line to determine whether these mutations control *F3* expression. Identification of the variant controlling *F3* expression will provide new insights into the regulation of this important coagulation gene and will enable us to identify the variant(s) responsible for the remainder of the thrombosis suppressing effect in MF5L6.

1628S **Identification of a major *Actr2* thrombosis suppressor mutation via a sensitized ENU mutagenesis screen** Adrianna M Jurek[1], Caitlin Schneider[2], Marisa Brake[3], Amy Siebert[4], Linzi Hobbs-Parker[5], Randal Westrick[6] [1]Biology, Oakland University, [2]Michigan State University, [3]Beth Israel Deaconess Medical Center, [4]Versiti Blood Research Institute, [5]Medical Collage of Wisconsin, [6]Oakland University

Thrombosis is a complex genetic trait that occurs when blood clots form inappropriately in the veins. Using a sensitized ENU mutagenesis screen to identify novel thrombosis modifier genes, we identified a mutation in the gene *Actr2* (p. R258G, *Actr2*^{MF5L12}) that restores survival to a perinatal lethal thrombotic phenotype. *Actr2* codes for the protein ARP2, which plays a critical role in actin branching and polymerization. Previous studies showed that while *Actr2+/G* mice did not display any health consequences, *Actr2* homozygous progeny deviated from Mendelian frequencies (12% *Actr2*$^{G/G}$, p<9x10^{-7}) and developed kyphosis around 6 months of age. However, the role of *Actr2*/ARP2 in thrombosis was unknown. We hypothesized that the *Actr2*^{G} mutation suppresses thrombosis via alterations in plasma coagulation factors and/or actin cytoskeletal rearrangement. We performed biochemical and functional thrombosis assays on *Actr2+/G* and *Actr2+/+* mice to test our hypothesis. We analyzed plasma for the prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin generation (TGA) to assess blood coagulation. Platelet aggregometry was used to measure platelet activation. A mouse tail clip assay was used to measure bleeding time and quantify blood loss. To correlate these findings with actin cytoskeletal defects, we analyzed mouse embryonic fibroblasts (MEF). Our results showed that *Actr2+/G* mice had a prolonged PT and aPTT (N>17, p<0.03) and a platelet aggregation defect when compared to their wild-type littermates. There was also a significant reduction in thrombin peak height in heterozygous *Actr2* mice compared to wildtype (N=10; p=0.03). Despite the delayed time to clot formation, *Actr2*+/G mice did not exhibit a bleeding phenotype and showed no significant differences in blood loss from the tail clip assay. The MEF assay showed significant differences in mean cell surface area at 20 minutes after plating, indicating an actin cytoskeletal defect (p<0.05). Our results demonstrate extreme phenotypes in the *Actr2*$^{G/G}$ mice as a result of the profound defects in maintaining the actin cytoskeleton. However, mild coagulation pathway and platelet defects in *Actr2*+/G mice due to impaired cytoskeletal function suggest that ARP2 mediated mechanisms could be antithrombotic drug therapeutic targets that have limited effects on bleeding.

1629S **Identifying Candidate Genes for Neurodegenerative Disorders with Evolutionarily-Informed Generative Models of Protein Sequences** Evan M Cofer, Rose Orenbuch, Dinko Franceschi, Debora Marks Systems Biology, Harvard Medical School

Each individual possesses a plethora of mutations, but distinguishing pathogenic from benign mutations is non-trivial. Missense variants in particular pose a significant challenge, and their interpretation more difficult than variants that totally compromise protein function (e.g. protein truncating variants). This is particularly challenging in rare variant analyses, where we cannot simply rely on allele frequency or other proxy measures of deleteriousness. In this work, we describe the application of popEVE - an evolutionarily-informed generative model of protein sequences that leverages population data to calibrate pathogenicity predictions proteome-wide - to the task of rare variant association studies in large-scale clinical biobanks. In particular, we focus on neurodegenerative diseases such as Alzheimer's Disease, which affect millions of individuals worldwide, and are known to have a significant heritable component. In doing so, we are able to identify numerous genes relevant to neurodegenerative disorders, including many which have not been previously identified through large-scale genome-wide association studies. Many of the top candidates from our study show localized brain-specific expression, or interact with genes known to play an outsized role in the genetics of Alzheimer's Disease. Finally, we investigate specific rare variants that appear to show strong associations, and speculate about how their predicted structural changes may lead to functional changes in individual genes.

1630S **Genotype specific microbiome divergence of humanized APOE 2, 3, and 4 mice after microbiome standardization** Michelle Aries[1], Makayla Cook[1], Hope Gasvoda[1,2], Ashley Gooman[1,2], Tiffany Hensley-McBain[1,3] [1]McLaughlin Research Institute, [2]University of Providence, [3]Touro College of Osteopathic Medicine Montana

Alzheimer's disease (AD) is the leading cause of dementia in the United States. Of the more than 6.5 million people currently living with AD, almost two-thirds are female. Most cases of AD are late onset/sporadic AD (LOAD). Having the apolipoprotein E 4 (APOE4) allele is the greatest known genetic risk factor for LOAD, while the greatest known risk factor is age. The gut microbiome (GMB) is a key essential to health, and bacterial dysbiosis can lead to poorer outcomes for disease states and an increase in microbiota and their metabolites in the peripheral. The intersection of APOE, inflammation, and gut microbiota in

AD is incompletely understood. Previous studies in humans and humanized APOE mice have demonstrated *APOE*-genotype differences in commensal short chain fatty acid producing bacteria. However, these studies were cross-sectional and used methods unable to resolve the bacteria to the genus or species level. It remains unknown if *APOE* genotype is a driver of GMB divergence over time and how GMB changes with age and sex in the context of APOE genotype. In this study, humanized targeted replacement mice with either *APOE 2, 3,* or *4* (APOE-TR) were purchased from JAX. Each APOE-TR male was bred with one of the same two C57BL/6 sisters to standardize microbiomes across lines and monitor diverge based on APOE allele inheritance. Stool samples were collected from the parents at breeder set up and 6 months old, and from heterozygous pups (n=3 per sex) at wean, 7 weeks old, and 6 months old. Stool was also collected from the homozygous F2 generation (n=3 per sex) at wean and 7 weeks old. Stool pellets were assessed via shallow shotgun sequencing to increase the sequencing depth and enable species and strain level taxonomic resolution. The heterozygous pup's microbiome resembled that of their C57BL/6 mother rather than their APOE-TR fathers at wean and 7 weeks old. However, by 7 weeks old, GMB diverged based on sex and APOE genotype, with genotype-specific alterations including changes bifidobacteriaceae and lachnospiraceae. These are the first data demonstrating GMB divergence over time driven by APOE genotype. Future studies will investigate how APOE-specific bacterial species impact inflammatory responses *ex vivo* and *in vivo*. Studying genotype specific changes in GMB and how specific APOE-specific bacteria impact inflammatory responses can aid in understanding and potentially treating some of the underlining mechanisms associated with APOE-related LOAD.

1631S **The Canadian Rare Diseases Models and Mechanisms (RDMM) Network: Connecting novel disease gene discoveries to functional characterization research in model organisms** Philip Hieter[1], Sanja Rogic[1], Paul Pavlidis[1], Phillippe Campeau[2], Kym Boycott[3] [1]Michael Smith Laboratories, University of British Columbia, [2]Department of Pediatrics, University of Montreal, [3]Department of Genetics, University of Ottawa

Advances in genomics has transformed our ability to identify the molecular cause of rare diseases (RDs). Yet for most candidate RD genes, we lack insight into their biological function, how mutations identified in patients affect them, or what therapies could be useful. Model organisms (MOs) represent powerful tools to confirm the pathogenicity of RD gene variants, characterize gene's biological function, and identify potential therapies. For these reasons, the Canadian RDMM Network (http://www.rare-diseases-catalyst-network.ca/) was established in 2014 to catalyze and fund connections between clinicians discovering new disease genes and researchers able to study equivalent genes and pathways in MOs.

The RDMM Network has created a rapid and direct pathway from gene discovery to functional characterization studies in MOs. The central resource of the RDMM Network is a web-based Canadian directory of MO researchers ('the Registry') built to facilitate identifications of suitable collaborators for applying clinicians. As of Oct 2023, 694 MO researchers have registered 16,675 genes of interest. With the aid of the computational inference built into the Registry, this translates to the coverage of 9,802 human genes. RDMM uses a committee process to identify and review potential clinician-MO researcher matches and approve $30,000 CAD in catalyst funding. Since 2014, we have made 120 clinician-MO scientist connections and funded 150 functional characterization proposals. Besides the scientific insights into the molecular mechanisms of rare disease and possible novel therapies, these collaborations also lead to high impact papers, long-term collaborations, external grants.

In 2019, we established international linkages with emerging similar networks in Europe, Australia, and Japan. To facilitate community uptake, we made the RDMM Registry portable, customizable and linkable with other instances, and our committee structures and process freely available. We are willing to assist additional RDMM regional networks as needed, and to further support global collaborations. (https://rdminternational.org/)

In our third round of funding (2022-2027), RDMM expanded the scope of model systems to include the use of human cell models, including primary patient-derived cells, cell lines derived from iPSCs, and organoids. The Canadian RDMM Network will continue to create meaningful collaborations between clinicians and MO researchers and advance RD research locally and globally.

Boycott KM, et al. (2020). The Canadian Rare Diseases Models and Mechanisms (RDMM) Network: Connecting Understudied Genes to Model Organisms. Am J Hum Genet. 106(2):143-152

1632S **Multi-drug Cancer Adaptive Therapy with Deep Reinforcement Learning** Zhaozhi Li[1], Jenna Fields[2], Mohamed Osman[3], Bishoy M Faltas[3,4,5,6], Jaehee Kim[1] [1]Department of Computational Biology, Cornell University, [2]Department of Computer Science, Cornell University, [3]Division of Hematology and Medical Oncology, Department of Medicine, Weill Cornell Medicine, [4]Caryl and Israel Englander Institute for Precision Medicine, Weill Cornell Medicine, [5]Sandra and Edward Meyer Cancer Center, Weill Cornell Medicine, [6]Department of Cell and Developmental Biology, Weill Cornell Medicine

Drug resistance frequently compromises the effectiveness of standard cancer treatments, leading to tumor progression and patient relapse. Optimizing drug dosage, schedule, and sequence is crucial for delaying tumor progression and enhancing

therapeutic benefits. While previous studies on inferring optimal treatment strategies have predominantly focused on single-drug treatments, there is a pressing need to develop a computational framework based on realistic mechanistic mathematical models that can effectively address the complexities of multi-drug settings. One of the major challenges in achieving this goal is the inherent complexity and non-linearity of cancer mechanisms, further complicated by the irregularity and sparsity of clinical data. Clinicians must also adhere to established guidelines and constraints when deciding on the sequence, type, and dosage of therapy for each patient, adding an additional layer of complexity.

In this study, we developed computational frameworks with two main objectives. First, we created a personalized and scalable bio-digital twin of bladder cancer, involving a mechanistic mathematical model that captures the key biological processes driving bladder cancer progression and its response to therapy. This model was integrated into a neural ordinary differential equation, which combines the adaptability of advanced neural networks and ctDNA-derived information to provide insights into patients' genetic alterations and the impact of treatment over time. Second, we focused on inferring optimal cancer treatment strategies involving multiple drugs using deep reinforcement learning (DRL). This included the integration of clinician input to refine DRL action space; the validation of our model against clinical longitudinal ctDNA data from patients throughout their treatment; and an exploration of the interpretability of the DRL-derived treatment strategies. We applied our method to advanced bladder cancer data, demonstrating that it offers interpretable and adaptive treatment strategies for multiple drugs, thereby improving patient survival rates and overall quality of life.

Our work establishes a computational framework for investigating multi-drug cancer therapy using DRL, opening up new possibilities for personalized medicine, improving overall cancer treatment efficiency, and enhancing patient benefits. Additionally, our framework demonstrates how the use of serial ctDNA monitoring can yield valuable insights into drug responses and tumor progression in patients with advanced cancer.

1633S **A cancer variant functionalization platform using genetic interaction mapping in Saccharomyces Cerevisiae** Seevasant Indran[1], Christopher Loewen[2] [1]University of British Columbia, [2]University of british Columbia

A majority of missense variants have no functional interpretations. The remaining accounts of mutations are yet to be discovered and cannot be interpreted using traditional genetics approach. In an era where whole genome sequencing cost is approaching towards $500, this bottleneck limits the diagnostic and usability of sequencing technology. This study aims to develop and improve on a cancer variant functionalization platform using genetic interaction mapping in *Saccharomyces Cerevisiae* by an approach called Sentinel Interaction Mapping (SIM). SIM does not rely on complementation, "humanization of yeast" or human orthologs in yeast, therefore the practical limits of screening human disease associated genes is not limited to these aspects - in contrast to current orthology yeast-based screens. SIM is accomplished by transforming ~ 5000 yeast mutants with the Gene of interest (TP53) using Synthetic Gene Array (SGA) technology which identifies Synthetic Dosage Lethal (SDL) interaction partners. The associated partners termed "Sentinels", are then subjected to fitness-based assay in conjunction with the GOI potentially exposing the functionality of a variant or VUS. Functional variants under the influence of these sentinels report with a synthetic sick fitness phenotype and debilitating variants report with a fitness viable phenotype comparable to Wild Type (WT) Sentinels without the GOI. Here, we report an assay for variant functionalization of TP53 in yeast.

1634S **Quorum Sensing Underlies Viability Resurgence in Chronologically Aged Yeast Cells** Kai-Ching Hsiao, Hsin-Ying Lin, Min-Hao Kuo Biochemistry and molecular biology, Michigan state university

With the continual increase of the elderly population in modern societies, it is crucial to investigate the molecular mechanisms underlying aging in order to maximize the healthspan of the population. Using the budding yeast as the model to study the control of chronological aging, we observed the phenomenon of viability resurgence in quiescent time (VRQT), in which chronologically aged cells divide synchronously in spent medium, resulting in the extension of the population lifespan. VRQT does not require fresh nutrients. Practically all strains that we tested, including haploid and diploids, laboratory and wild strains, show VRQT readily. Progeny cells arising from VRQT repeat this phenomenon when they are old, and do not exhibit growth advantage when put in direct competition with cells that have not gone through this process. Together, these results argue strongly for an innate program that preserves population viability. Moreover, VRQT frequency is heightened by in denser cell suspension, suggesting a quorum sensing-like collective behavior. Indeed, increasing the concentration of quorum sensing molecules (QSMs) in the medium enhances the frequency of viability resurgence. On the other hand, while some cells are able to execute VRQT, there exists another population of cells that remain mitotically capable but do not engage in VRQT. These cells can be revived upon transplanting to fresh medium. Genetically, knocking *GPR1*, one of a G protein-coupled receptors in budding yeast, diminishes the occurrence of VRQT without impacting vegetative growth, suggesting that GPR1p may serve as a potential receptor for VRQT. Together, our data suggest an innate program related to quorum sensing that not only maintains the viability of aging yeast cells, but also expands a population through synchronous division through a harsh time. This

discovery may shed light strategies that enhance lifespan and healthspan.

1635S **Barcode-sequencing screen for modulators of anticancer ruthenium complex sensitivity in *S. cerevisiae*.** Andrew R Chinn[1], Jackson Blackman[2], Pamela Hanson[1] [1]Furman University, [2]UC Irvine

Phenotypes uncovered via pharmacogenomic analyses provide a viable tool for understanding the effects of diverse drugs on cellular pathways. Furthermore, these unbiased genome-wide assays can identify genes with unanticipated and/or previously unknown roles in cellular drug responses. In this study, we analyzed pools of barcoded budding yeast (*S. cerevisiae*) deletion strains to identify genes that alter sensitivity to the anticancer ruthenium complex *trans*-[tetrachlorobis(1*H*-indazole) ruthenate(III)] (KP1019). An analysis of two identical pools of barcoded yeast deletion strains was conducted using next generation sequencing, detecting a total of 3293 unique upstream barcodes representing 69.2% of nonessential deletion strains. A custom Python script was able to recover the majority of mutated barcode sequences with a Levenshtein distance of lev = 1. There was a positive correlation in the log(fold-change) of strain abundance among the two trials used in analysis (R^2 = 0.43, y = 0.61x + 0.026), indicating substantial agreement between biological replicates. GO term analysis revealed significant enrichment of DNA repair pathways amongst strains exhibiting sensitivity in both trials. This result is in line with previous studies showing DNA as a target of KP1019 in both yeast and cancer cells. Additionally, analysis of KP1019 resistant strains uncovered enrichment of the “cytosolic ribosome” GO term. As verification that the drug affects ribosomes, we monitored localization of Rpl7a-GFP. In KP1019-treated yeast, this ribosomal protein accumulates in the nucleolus indicating that the drug impairs ribosomal biogenesis. The screen also identified a number of outliers not associated with enriched GO terms. For example, yeast lacking the polyamine transporter Tpo1 consistently displayed high levels of resistance to KP1019. This result may relate to KP1019’s activation of the oxidative stress response, as published studies previously showed that *tpo1* null mutants are resistant to oxidative stress. While these results offer support for current models of KP1019 action and validate the screen design, additional characterization of novel outliers may help to elucidate the cellular pathways and processes that modulate KP1019 sensitivity. Improved understanding of the genetic factors that alter the efficacy of KP1019 may create opportunities for genetically tailored medicines and combination therapies in the future.

1636S **Suppressor screening in *S. cerevisiae DGA1*Δ *LRO1*Δ mutant reveals insights into yeast aging mechanism** Hsin-Ying Lin, Kai-Ching Hsiao, Min-Hao Kuo Michigan State University

Saccharomyces cerevisiae is a robust model organism to study aging. We reported previously that yeast cells with reduced intracellular triacylglycerol (TAG) content have a shortened chronological lifespan, whereas those with higher TAG content live much longer. Such changes are independent of the canonical function of TAG in providing energy for cells. To understand how TAG maintains lifespan, a TAG-deficient “lean” strain was subjected to high-copy suppressor screening for genes that, upon overexpression, can rescue the early death phenotype. In addition to shortened lifespan, these lean cells show elevated mitochondrial reactive oxygen species (ROS), which likely contribute, at least partly, to the lifespan shortening. Several Live-Long-Again (LiLA) candidates were identified. When cultured with the vector control, these LiLA clones acquire growth advantage when the population grow old, confirming their ability to regain normal chronological lifespan. In one of the LiLA clones that has been investigated further, reduced ROS levels and altered lipid profiles are observed, suggesting that a particular lipid species may control lifespan and metabolic metabolism when TAG is deficient. This LiLA phenotype is linked to a gene that was first described as being associated with wine fermentation in certain but not all laboratory strains. The expression, intracellular localization, and possible molecular functions of this LiLA suppressor will be discussed. In summary, our suppressor screen has unveiled novel pathways for lifespan regulation that will help our understanding and development of measures to preserve achieve healthy longevity.

1637S **Development of a High-Throughput Zebrafish Model of Blood-Brain Barrier Disruption** Sashank Sabbineni[1], Joanna R Thomas[1], William E Frye[1], Robert W Robey[1], Collin T Inglut[1], John Quinlan[1], Andrew C Warner[2], Donna Butcher[2], Jennifer Matta[2], Elijah E Edmondson[2], Alexander Y Mitrophanov[3], Blake Carrington[4], Raman Sood[4], Michael M Gottesman[1] [1]Laboratory of Cell Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA, [2]Molecular Histopathology Laboratory, Frederick National Laboratory for Cancer Research, National Institutes of Health, Frederick, MD, USA, [3]Statistical Consulting and Scientific Programming, Frederick National Laboratory for Cancer Research, National Institutes of Health, Frederick, MD, USA, [4]Zebrafish Core, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA

The blood-brain barrier (BBB) prevents entry of most drugs, including chemotherapeutics, into the brain due to a physical barrier and a chemical barrier. A physical barrier is formed due to tight junctions between capillary endothelial cells and a restrictive chemical barrier is primarily comprised of two major ATP-dependent efflux pumps (ABCG2 and ABCB1), which are expressed on the apical surface of brain microvascular endothelial cells, and function to efflux substrate drugs into the blood, preventing brain penetration. Mechanisms to disrupt these barriers are an effective way of delivering chemotherapeutics and

other drugs to the brain. However, studying these mechanisms in an *in vitro* model is challenging, and mammalian models are low throughput. On the other hand, a zebrafish model has the potential for high throughput studies and has a BBB very similar to humans. We created a zebrafish model of BBB disruption, by expressing the luciferase NanoLuc under the control of the glial-controlled promoter GFAP (glial fibrillary acidic protein) in the brain parenchyma, behind the BBB. Furimazine, a NanoLuc substrate, is unable to pass through the BBB as it is a substrate of the multi-drug efflux transporters human ABCG2 and zebrafish Abcg2a which prevent substrates from entering the brain. By introducing ABCG2 inhibitors, furimazine is able to cross the BBB and interact with NanoLuc to produce a dose-dependent increase in bioluminescence light. Younger larvae (3-5 days old) have higher baseline bioluminescence, indicating a less restrictive developing BBB whereas older larvae (7 days old) have a more restrictive developing BBB. Our future goal is to adapt this assay for high-throughput screening of BBB disruptors, and eventually combine these methods with brain tumor xenografts to assess the delivery of chemotherapeutics to brain tumors.

1638V **Exploring the impact of *S. mutans* and *L. casei* on cell cycle disruptions: insights from *C. elegans* as a model for microbial dysbiosis** Ana M. Cedeno Escobar, Katherine M. Walstrom Div. Natural Sciences, New College of Florida

Mutations disrupting the cell cycle and replication can lead to a cell becoming cancerous. Microbial dysbiosis is the term used to refer to the action of microorganisms interacting with cancerous cells to aid tumor progression and metastasis. These pathogens use their virulence factors to colonize and damage the host's cells. Specifically, the cariogenic bacterium *Streptococcus mutans* utilizes its adherence and acid-tolerant abilities to partner with other bacteria in invading the host's cells. *S. mutans* has been shown to aid the progression of oral squamous cell carcinoma and other extra-oral diseases. On the other hand, the bacterium *Lacticaseibacillus casei* exhibits probiotic properties that have been shown to aid in the treatment and prevention of intestinal cancers. As opposed to *S. mutans*, which generate microbial dysbiosis, *L. casei* could be said to generate microbial homeostasis. When grown together, these bacteria exhibit a competitive relationship where *L. casei* prevents the dominance of *S. mutans*. The intricacies of the relationship between these bacteria has not been fully elucidated. A knowledge gap remains on the effect of each species on cellular mutations having to do with cell cycle disruptions and the molecular pathways via which they act. In the present study, the effects of *S. mutans* and *L. casei* on the nematode *Caenorhabditis elegans* were explored. Two life stage assays were carried out to quantitate the amount of worms in each larval stage. One assay compared the development of worms on *S. mutans vs. L. casei*, using OP50 as a control; while the second looked at whether *L. casei* had a protective effect on the worms. Furthermore, DIC microscopy was used to image *C. elegans* hermaphrodites and eggs. A reduction in the number of offspring produced and a delay in the development of eggs and offspring were observed for worms grown on *S. mutans*. Worm growth on *L. casei* preceding transfer to *S. mutans* did not have a protective effect as evidenced by similar developmental delays and reduced egg and offspring counts. Leveraging the wealth of available information about *C. elegans* enables the correlation of observed alterations with documented changes in the literature. The hope is to introduce *C. elegans* as a model organism for oral cancer and microbial dysbiosis research, and for this study to be a stepping stone for the discovery of the molecules causing cellular aberrations.

1639V **Antizyme Inhibitor (AZIN) displays a nuclear localization in human keratinocytes (HaCaTs)** Shannon Nowotarski Penn State Berks

The polyamines putrescine, spermidine and spermine are small, naturally occurring polycationic molecules that are essential for normal cellular growth and development in eukaryotes. To generate cellular polyamines, the rate limiting metabolic enzyme ornithine decarboxylase (ODC) converts the amino acid ornithine into the diamine putrescine which is subsequently converted to the higher polyamines spermidine and spermine. Antizyme (AZ) is an endogenous inhibitor of ODC and binds to ODC targeting it to the 26S proteasome for degradation. Additionally, ODC is regulated by antizyme inhibitor (AZIN), a protein that closely resembles ODC but does not contain enzymatic activity. AZIN binds to AZ with higher affinity than ODC and therefore negates the effects of AZ on ODC. Very little is known about what other proteins AZIN might interact with in mammalian cells. Thus, the focus of these studies was to determine which proteins interact with AZIN in an attempt to better characterize the involvement of AZIN in the progression of non-melanoma skin cancer. BIOID studies were done and MYH9, or myosin 9, was determined to be a potential binding partner of AZIN. This was extremely interesting because it had recently been reported that an edited form of AZIN binds to myosin 9 in prostate cancer cells. AZIN had previously been thought to localize only in the cell cytoplasm. However, it has been shown in prostate and colorectal cancers that AZIN undergoes RNA editing by adenosine deaminase acting on RNA (ADAR1). The edited version of AZIN is able to translocate to the nucleus. In these studies, we investigated this phenomena in a human keratinocyte cell line (HaCaT) and show that, in our system, AZIN is mainly nuclear. These studies could provide rationale for the use of nuclear AZIN as a chemotherapeutic target because nuclear AZIN has been shown to be associated with more aggressive disease in prostate cancer.

1640V **the role of MYT1L and Piwil2 genes biomarkers in Medulloblastoma development** Mohammed Ali Alshehri Medical genetics, Najran university

Medulloblastoma is the most common childhood's malignant brain tumours which is about 15 – 20%. Mortality due to this disease is high (~40%) and successful treatment is associated with significant neurological and cognitive consequences, making new therapies desirable. Indeed, drivers identification for this devastating tumour will allow development of more precise targeted therapies.

Piwil2 gene as a stem cell maintaining factor that trigger spermatogenesis process has shown to be expressed in different tumour tissues and cell lines. Including, MB primary tumours, in mice. In the other hand, normal tissues showed no expression of piwil2. The tumorigenic effects of piwil2, owing to the activation of STAT3/BclX pathways. This study emphasized that overexpression of piwil2 leads to NIH3T3 highly proliferation and differentiation. However, genomic silencing piwil2 leads to decrease cellular proliferation and differentiation even leads to apoptosis.

1641V **The utilization of *Drosophila melanogaster* as a model organism to investigate the underlying mechanism of Septin11-related axonal sensorimotor polyneuropathy** Farzaneh Larti[1], Ayşe Candayan[1], Taha Akkülah[1], Gülay Kaya[1], Cansu Kocabaş[1], Mustafa Kaan Kozluca[1], Marcel Nos Lorens[1], Onur Can Aydeniz[1], Barış Can Mandacı[2], Esra Battaloğlu[1], Arzu Çelik[1] [1]Molecular Biology and Genetics, Boğaziçi University, [2]Molecular Biology and Genetics Department, Boğaziçi University

Septins are GTPases that make up the fourth component of skeletal proteins. They are found in many eukaryotes and can form a filamentous network alongside microtubules, intermediate filaments, and actin. In *Drosophila melanogaster*, Sep2 and Sep5 are the closest orthologues to Septin11. We analyzed the expression of Sep2 by using a line that expresses Sep2-GFP under the control of the Sep2 promoter. Sep2 is expressed ubiquitously in all tissues, including neuronal cells and larval muscles. Additionally, we observed that Sep2 mutants had a shorter lifespan and decreased survival rates, while about 4% showed wing and notum abnormalities.

Our investigation revealed that the absence of Septins could cause abnormal neuromuscular junctions, mispositioning of myonuclei, and defects in larval locomotion behavior. The neuromuscular junctions (NMJs) pattern in Sep2 and Sep5 mutants showed defects in innervation and misrouting phenotypes. We observed a difference in the number of boutons between Sep2 mutants and control flies, indicating an overgrowth phenotype in the absence of Sep2. We also observed poor development and overgrowth in NMJ boutons, represented by the number of satellite and super boutons. Flies with deletions in Sep2 and Sep5 showed distinctive abnormalities in developing pre- and post-synaptic areas, which implied severe defects in the dynamic localization of DLG protein at the junctions.

Furthermore, we investigated the position of nuclei in larval muscles and found that Sep2 and Sep5 mutants had clustered nuclei rather than evenly spaced nuclei, with differences in nuclear shape and volume. Moreover, the knockdown of Sep2 and Sep5 did not cause an increase in the number of flies with fragmentation in the nerve tract along the L1 vein of the wing at the age of 20 days.

The locomotion behavior of both larvae and adult flies was studied, which showed a significant decrease in the ability of mutants. Using a modified SING assay, Sep2 mutants showed defects in Startle-Induced locomotion and negative geotaxis. The crawling assay showed that the path length in 1 minute significantly decreased in Sep2 mutants. However, inducing the expression of Sep2-GFP in larval muscles could rescue that defect. Furthermore, the two-choice sucrose taste assay showed a delayed response in mutants with both Sep2 and Sep5 deletions, compared to the immediate attraction of controls.

In conclusion, this study highlights the crucial role of Septins in neuromuscular development. Further investigations are underway to assess the expression level of all *Drosophila* Septins in knockout mutants to explore compensation mechanisms. Additionally, humanized flies expressing wild-type and a truncated form of Septin11 will be used to investigate the functional orthology of human and fly Septins. Our research improves the current understanding of the mechanisms that drive neuropathic disorders.

1642V **Tissue Specific Innate Immune Responses Impact Viral Infection** Steven Miller[1], Elisha Segrist[2], Beth Gold[3], Sara Cherry[3] [1]Microbiology, University of Pennsylvania, [2]National Institutes of Health, [3]University of Pennsylvania

All organisms have many pathways to sense and respond to pathogenic challenge. The presence and regulation of these pathways can vary within tissues and cells of the same host. The CDN-STING pathway is antiviral through control of NFkB-dependent gene expression. Viruses infect diverse tissues and we set out to determine in which cell types does STING control infection and whether there are distinct gene expression programs induced in different tissues. We uncovered differences in genes induced by CDN sensing by STING across tissues. And we found that STING is required for the antiviral activity of CDNs in distinct tissues. Moreover, we found that this is important during viral infection as STING is required in particular cell types to control systemic infection. Lastly, we found that genes induced by CDN-dependent STING activation also control infection. These results highlight tissue-specific antiviral activity that likely impacts immunity to viruses with distinct tissue tropisms.

1643V **Metabolic Reprogramming in PIK3CA^{H1047R} Mutated Endothelial Cells** Brandee Rockefeller[1], Qingfen Li[2], Kevin Pumiglia[2] [1]Biology Department, Utica University, [2]Regenerative and Cancer Cell Biology, Albany Medical College

Angiogenesis, the development of blood vessels from preexisting vasculature, involves tight coordination and regulation of endothelial cell functions including migration, proliferation, and differentiation. Activation of the PI3K signaling cascade is essential to the proper formation and function of vasculature. Errors in this development can manifest as vascular malformations, which are structurally abnormal and dysfunctional blood vessel networks that have potential to cause significant morbidity and mortality. Currently, there are no uniform treatment guidelines or targeted therapeutic options as the mechanistic basis remains unclear. Over the last several years genetic profiling data has linked mutations in PIK3CA, the catalytic subunit of PI3K, to the development of vascular malformations in humans. Our goal is to better understand endothelial cell function, and the development and maintenance of PIK3CA^{H1047R} driven vascular malformations. We hypothesize, based on the robust mTOR activation and role mTOR plays in the regulation of cellular metabolism, that these endothelial cells undergo metabolic reprogramming to meet high energy and biosynthetic demands. Using a ribo-tagged lentiviral vector we were able to isolate and quantify mRNA from bead angiogenesis assays *in vitro.* We found several metabolic genes to be differentially regulated following the expression of the "hot spot" activating mutation PIK3CA^{H1047R} suggesting that endothelial cells do undergo metabolic reprogramming.

1644T **The *C. elegans* NuRD chromatin remodeler interacts with the Fanconi Anemia pathway during germline DSB repair** Deepshikha Ananthaswamy[1], Sereen El Jamal[2], Paula M Checchi[3], Teresa W Lee[1] [1]Biological Sciences, University of Massachusetts Lowell, [2]Biology, Marist College, [3]Sanford Burnham Prebys Medical Discovery Institute

All cells encounter environmental hazards that damage DNA and generate toxic double stand breaks (DSBs). Therefore, organisms have evolved overlapping and redundant DSB repair pathways to protect genome integrity, particularly in germ cells. In response to DNA damaging agents like cisplatin and hydroxyurea, the Fanconi Anemia pathway helps repair DSBs. However, since genomic DNA is always packaged as chromatin, DSB repair must be coordinated with local chromatin remodeling. The Nucleosome Remodeling and Deacetylase (NuRD) complex is one complex that repositions nucleosomes, but its role in DSB repair remains unknown. In *C. elegans*, mutations in the catalytic subunit of NuRD, CHD4/LET-418, lead to defective DSB repair and sterility. *let-418* mutants are highly sensitive to cisplatin and hydroxyurea in ways that phenocopy Fanconi Anemia pathway mutants: exposure to these DNA damaging agents causes reduced fertility, more DSBs, and severe chromosome fragmentation. We tested the genetic interaction between Fanconi Anemia mutant *fcd*-2 and NuRD mutant *let-418*, by assessing mitotic and meiotic DSB number, chromosome segregation, and embryonic survival. We find that *let-418* is epistatic to *fcd-2,* indicating that it is necessary for proper germline DSB repair. Our results suggest that nucleosome remodeling mediated by NuRD regulates DNA damage repair during oogenesis, demonstrating the importance of regulating local chromatin environment for preserving genome integrity.

1645T **Characterizing the effects of WEE-1.3 depletion on spermatogenesis in *C. elegans*** Shannon Pfeiffer, Aimee Jaramillo-Lambert University of Delaware

Meiosis, the specialized type of cell division that results in the production of eggs and sperm, is a highly complex process that is tightly regulated. This ensures that these gametes are healthy and capable of producing progeny. Though similar, meiosis in the female and male germ lines are distinct and are differentially regulated. The kinase Wee1/Myt1, which is conserved throughout eukaryotes, is a key regulator of both the mitotic and meiotic cell cycles. Wee1/Myt1 inhibits the CDK1/cyclin B complex, which is required to drive entry into M-phase. Many studies of Wee1/Myt1 during meiosis have focused on oogenesis, while its role and regulation in spermatogenesis are not well understood. Our lab uses *Caenorhabditis elegans* to study meiosis. The *C. elegans* ortholog of Wee1/Myt1 is *wee-1.3*. In *C. elegans* oogenesis, *wee-1.3* knockdown causes chromosome overcongression and premature oocyte maturation. These defects in oogenesis cause infertility, as the oocytes are unable to be fertilized by healthy sperm. In the context of spermatogenesis, *wee-1.3* knockdown had not been assessed due to experimental limitations. However, several gain-of-function (gof) mutations in *wee-1.3* are known to cause primary spermatocyte arrest, while oogenesis is unaffected. The distinct phenotypes of *wee-1.3* mutants suggest that WEE-1.3 is differentially regulated in oogenesis vs. spermatogenesis. Here, we use auxin-inducible degradation to selectively deplete WEE-1.3 from the *C. elegans* male germline. This results in severe chromosome segregation defects, including chromatin bridges and small DNA fragments, during spermatogenesis. These defects negatively impact male fertility; WEE-1.3 depleted males mated with females produce reduced brood sizes with decreased embryonic viability compared to wild type. Future directions include live imaging of spermatogenesis in WEE-1.3 depleted males, which will allow us to determine how these chromosome segregation defects arise. Since WEE-1.3 inhibits CDK-1, future work also aims to examine whether an acute loss of CDK-1 function can ameliorate the segregation defects caused by WEE-1.3 depletion.

1646T **Unveiling the function of a putative IHO-1 homolog in *Caenorhabditis elegans*** Zachary Leydig[1], Marilina Raices[1],

George Chung[2], Judith Yanowitz[1] [1]OBGYN/Reproductive Sciences, MWRI & University of Pittsburgh, [2]Biology, New York University

Meiotically dividing cells rely on the formation of DNA double-strand breaks (DSBs) to initiate crossing over. While this not only ensures genetic diversity by physically shuffling maternal and paternal genes, it also allows chromosomes to segregate appropriately by creating chiasmata between homologs. Spo11 is the enzyme that catalyzes meiotic DSBs and is highly conserved across organisms. However, Spo11 requires the activity of additional proteins to ensure it acts at the right time and in the right place. In yeast, REC114 and MEI4 were found to be essential for DSB formation. In mice, REC114, MEI4, and IHO1 form a pre-DSB complex. However, the degree to which these auxiliary proteins are conserved across multiple organisms is unknown. While homologs have been found for REC114 and MEI4 in the worm (DSB-1/2 and DSB-3, respectively), an ortholog for IHO1 remains elusive. We recently identified a putative homolog of IHO-1 in the worm using degenerative amino acid alignments. We removed the coding sequence with CRISPR to create a null allele. Unlike DSB gene mutations which confer a HIM phenotype and show univalents in diakinesis oocytes, *iho-1* mutants show DNA fragments and fusions, consistent with a repair defect and not a DSB defect. Yeast two-hybrid further revealed no interactions with worm DSB proteins supporting the conclusion that the worm homolog is functionally divergent. We will present these results and further studies on the function of this protein in the worm germ line.

1647T **Characterization of the double-strand break machinery in C. elegans** Marilina Raices[1,2], Fabiola Balmir[3], Wei Li[3,4], Nicola Silva[5], Judith Yanowitz[2,6] [1]Ob/GYN, Magee-Womens Research Institute, Pittsburgh, [2]University of Pittsburgh, [3]Magee-Womens Research Institute, [4]Tsinghua U. Medical School, [5]Masaryk University, [6]OB/GYN, Magee-Womens Research Institute

Crossing over between homologous chromosomes during meiosis promotes genetic diversity by creating new combinations of alleles over generations. Crossovers (CO) create physical connections between the homologs that promote their proper alignment on the meiotic spindle and subsequent apposite segregation. Defects in CO formation can trigger errors in the correct number of chromosomes in the gametes. Recombination initiates with a double-strand break (DSB) introduced by the conserved topoisomerase-like enzyme SPO-11 but the timing, placement and number of COs depend on the activity of accessory factors. In fact, SPO-11 works in concert with at least 10 other proteins to ensure the proper timing and placement of breaks (and COs). While these proteins have been well characterized in budding yeast, our understanding of the conserved complexes that regulate SPO11 are still poorly understood.

In C. elegans, dsb-1, him-17, mre-11, and rad-50 are required for DSBs formation. xnd-1 and him-5 influence DSB formation mainly on the X chromosome. dsb-2 impacts breaks on all chromosomes and becomes essential in older animals. rec-1 influences CO placement and cep-1, lin-35, and parg-1 contribute to break induction. We are investigating the relationship between these DSB factors in order to uncover the regulatory events that promote DSB formation. To this end, we are taking a multi-pronged approach using genetic epistasis with partial loss-of-function alleles, rescue with ectopically expressed transgenes, yeast-2-hybrid analyses, and co-immunoprecipitation. These studies are allowing us to construct a model for the timely recruitment and activation of SPO-11 that is revealing remarkable conservation across evolution.

1648T **HP1 recruits the chromosomal passenger complex to the chromosome for acentrosomal spindle assembly in meiosis** Siwen Wu[1], Manisha Persaud[1], Keara Greer[1], Kim McKim[2] [1]Rutgers University, [2]Genetics, Rutgers University

Chromosome segregation fidelity during female meiosis is critical for maintaining genome integrity, with aberrations causing infertility, miscarriages, and severe congenital anomalies. At the heart of this process, the chromosomal passenger complex (CPC), comprising the inner centromere protein (INCENP), Borealin, Survivin, and Aurora B kinase, functions as a central regulator of spindle assembly and ensures accurate bi-oriental chromosome segregation during meiotic cell division. In Drosophila oocytes, the CPC is required for microtubules recruitment to chromosomes, facilitating acentrosomal spindle formation post-nuclear envelope breakdown and managing kinetochore-microtubule attachments during meiotic metaphase I. However, the mechanics behind CPC's recruitment to the chromosomes and its interaction with spindle microtubules remain elusive. INCENP is a scaffolding protein providing the platform for CPC assembly. It encompasses several essential domains, including a N-terminal domain responsible for binding Borealin and Survivin, the STD and SAH domains known to interact with microtubules (MTs), and a heterochromatin protein-1 (HP1) binding domain. From previous study, we hypothesized that HP1 recruits the CPC to the chromosomes to initiate acentrosomal spindle assembly. To test this hypothesis, we developed HP1 RNAi reagents and generated INCENP mutants with deletion of HP1 binding sites. In HP1 RNAi oocytes treated with Binuclein 2 (BN2), an Aurora B inhibitor, we found no CPC recruitment to chromosomes. This observation indicated that HP1 is required for CPC's chromosomal recruitment. Interestingly, while INCENP mutants deleting the HP1 binding regions exhibited spindle formation, many HP1 RNAi oocytes did not, suggesting that HP1 is required for spindle assembly but its interaction with INCENP isn't essential for this function. Both HP1 RNAi and INCENP mutants displayed chromosome biorientation defects, indicating that HP1-INCENP interaction is critical for chromosome biorientation. Although bipolar spindle is being formed,

there must be defects in how the kinetochore and microtubules interact. Because a HP1-INCENP interaction is not required for spindle formation, a more complicated regulatory system for spindle assembly, possibly involving multiple INCENP domains or Borealin, may be required. Together, our findings shed light on the intricate dynamics of CPC-HP1, enriching our understanding of bipolar spindle organization and meiotic chromosome segregation in female meiosis.

1649T **Effects of B Chromosomal Dosage on Longevity Outcomes in *Drosophila melanogaster*** Tristan E Young[1], Rachel Ferris[2], Nicole C Riddle[1] [1]Biology, University of Alabama at Birmingham, [2]University of Alabama at Birmingham

Sex-specific longevity is poorly understood across the animal kingdom, with some species having one sex live longer than the other and some species having no sex-based differences in longevity. In humans and many other mammal species, females tend to live longer. This trend is also seen in many strains of *D. melanogaster.* There is, however, no known reason for this variation in sex-based aging differences. One molecular pathway of interest in aging research is heterochromatin maintenance. The heterochromatin loss model of aging was first proposed in 1997 by Villeponteau. This model suggests that chromatin maintenance is lost with age, leading to genomic instability, negatively impacting lifespan. Furthermore, this model suggests that altering the amount of heterochromatin might impact lifespan. One way to test heterochromatin's roles in aging and longevity is by exploiting non-essential B chromosomes, which are small chromosomes comprised primarily of large amounts of heterochromatin. A small percentage of eukaryotes, such as *D. melanogaster,* can carry B chromosomes, making them an ideal model organism for testing heterochromatin dosage roles in longevity. We utilized *Drosophila* strains with and without B chromosomes to perform a longevity study. Preliminary data suggest a positive association between B chromosome dosage and longevity in both sexes. On-going experiments investigate measures of genome stability in these strains to determine if differences in heterochromatin maintenance might explain the lifespan increase seen in the B chromosome strains. Investigating heterochromatin dosage effects in *D. melanogaster* will inform the roles of heterochromatin in aging and lifespan across animal species.

1650T **The Role of Drosophila Rif1 and CtIP in DNA Double-Strand Break Repair** Makenzie S Thomas, Gautham Pillai, Margaret Butler Human Science, Georgetown University

Double-strand breaks (DSBs) are genotoxic DNA lesions that must be accurately and efficiently repaired to maintain genome integrity. DSBs are largely repaired through non-homologous end-joining (NHEJ), homologous recombination (HR), or single-strand annealing (SSA). Rif1 and CtIP are conserved proteins implicated in DSB repair pathway choice through their potential redundant roles in DNA end resection required for homology-directed repair. To elucidate the role of Rif1 and CtIP in error-free HR repair, the DSB reporter assay, Direct Repeat of white (DR-white) was performed in Drosophila melanogaster. Our work demonstrates a ~20% decrease in HR in DmCtIPΔ mutants and ~7% decrease in HR in DmRif1Δ mutants compared to heterozygous controls. Similar to DmCtIPΔ mutants, DmRif1ΔCtIPΔ double mutants experienced a ~20% decrease in HR compared to heterozygous controls. Tracking across Indels by DEcomposition (TIDE) molecular analysis was utilized to assess the role of DmRif1 and DmCtIP in DSB repair pathway choice via NHEJ. These results revealed a ~30% increase in NHEJ for DmCtIPΔ mutants (with a proportional decrease in HR) and no difference in NHEJ for DmRif1Δ mutants. Once again, compared to the DmCtIPΔ mutants, DmRif1ΔCtIPΔ double mutants experienced a similar increase in NHEJ of ~30% (with a proportional decrease in HR). Interestingly, while we show a ~30% decrease in SSA for DmCtIPΔ mutants using the P{wIw} SSA assay, there was no difference in SSA repair for DmRif1Δ mutants, which may suggest a more extensive end resection function for CtIP. Future directions will include SSA analysis of DmRif1ΔDmCtIPΔ double mutants to elucidate potential redundant roles of Rif1 and CtIP in extensive end resection, ultimately impacting DSB repair pathway choice.

1651T **Fanconi Anemia Protein FANCD2 Promotes Homologous Recombination Repair in Drosophila** Caroline Worrell, Sara Martin, Anna Joseph, Mitch McVey Tufts University

The Fanconi Anemia pathway is made up a group of proteins that work together to repair interstrand crosslinks (ICLs) and protect stalled replication forks. Mutation of any of the Fanconi Anemia (FANC) genes results in Fanconi Anemia, a harmful human disease that impacts bone marrow development and causes predisposition to various types of cancer. The FANC proteins have also been shown to interact with other types of DNA damage repair processes, and recent published research has shown interaction between FANCD2 and DNA polymerase theta. Polymerase theta is the main protein involved in alternative end joining, an error-prone repair mechanism used to repair DNA double-stranded breaks. Given this observed relationship, the goal of this project is to investigate whether two FA proteins, FANCD2 and FANCI, also play a role in alternative end-joining repair. To test this, a transposon-based site-specific double-strand break repair assay was performed in order to observe the effects of mutations in these two proteins on the frequency of homologous recombination and alternative end-joining repair. The results of this assay showed an increase in alternative end joining and a decrease in homologous recombination repair in the *fancd2* mutants. In addition, we observed a high level of male sterility in *fanci* mutants experiencing transposon-induced breaks. Currently, we are conducting experiments to more clearly define the role of FANCD2

in homologous recombination and to characterize other independent functions of FANCI that promote genome stability in Drosophila.

1652T **An Extended D-loop or a Migrating Bubble? A DNA Gap Repair Assay Based on APOBEC-Induced Mutational Signature to Assess D-loop Dynamics** Mohamed Mahmoud[1], Jeff Sekelsky[2] [1]Department of Genetics, University of North Carolina at Chapel Hill, [2]Department of Biology, University of North Carolina at Chapel Hill

Revealing gap repair mechanisms is not only important for our understanding of genome integrity maintenance, but it is also important for optimizing applications such as Cas9 gene drive and genome editing. Different aspects of gap repair require more investigation, including strand invasion dynamics. Two models have been hypothesized to explain D-loop dynamics: an extended D-loop model and a migrating bubble model. Moreover, it has been hypothesized that gap repair involves several rounds of resection, strand invasion, and synthesis. To fill this knowledge gap, we will use the ebony gene locus as a target sequence for Cas9 cutting and we will use a template sequence on the homologous chromosome. We built different templates, representing different gap lengths. we will use APOBEC3A-mediated mutagenesis to determine where ssDNA is during the repair. Using long-read sequencing, we will analyze target and template sequences to detect APOBEC3A-induced mutations, their patterns, and what model they support. Furthermore, mutations in sequences flanking the target sequence will indicate the extent of resection. Finally, we will carry out experiments in mismatch and base excision repair mutant flies as APOBEC3A mutations leave behind genomic uracil and mismatches that can be fixed by base excision repair (BER) and mismatch repair (MMR), respectively.

1653T **New Insights into the structure and formation of the *D. melanogaster* B chromosome** Shania Kalladanthyil[1,2], Stacey L Hanlon[1,1,2] [1]University of Connecticut, [2]Institute for Systems Genomics, University of Connecticut

Comparative studies between closely related species reveal that genomes are constantly undergoing changes to their chromosome composition; however, these species can be separated by millions of years of evolution, obscuring the context of how new chromosomes form. The supernumerary, non-essential B chromosomes that arose less than 20 years ago in *Drosophila melanogaster* are a newly established model system that has the potential to provide valuable insights into how new chromosomes form and change in real time. The current model of how these B chromosomes arose is through a centromeric misdivision event on chromosome 4 that led to the fusion of the heterochromatic arm fragments to produce an isochromosome. Genomic analysis of the B chromosome centromere shows that it is from chromosome 4, however there is no structural signature that is indicative of a centromeric misdivision event. To further investigate the structure of the B chromosome, we performed fluorescent in situ hybridization (FISH) on metaphase chromosome spreads in larval neuroblast tissue using probes that bind specifically to the chromosome 4 centromeric island *Lampedusa*. Consistent with our genomic data, we found that *Lampedusa* was enriched on the B chromosomes compared to chromosome 4 within the same metaphase spread. These results lead us to propose an alternative model of B chromosome formation that is a result of a double stranded breakage event distal to the centromere to produce an isochromosome with two centromeres. To test this model, we are taking advantage of advances in ultra-long-read (ULR) sequencing technology to create a *de novo* assembly of the B chromosome. We are currently setting up a reliable workflow for extracting high molecular weight DNA from *Drosophila* embryos for ULR resequencing, followed by a pipeline to assemble these long reads into a genomic map of the B chromosome. Our goal is to use this map to confirm the presence of two centromeric islands on the B chromosome, pinpoint the location of the original breakage event, and reveal the genomic context that enabled this break to occur. The B chromosomes are an emerging model system for the empirical study of *de novo* chromosome formation, ultimately leading to a deeper understanding of how new chromosomes arise and evolve across all life.

1654T **In vivo studies of the *Drosophila melanogaster* AP endonuclease 1 ortholog Rrp1** Alyssa Persano, Sara Martin, Mitch McVey Tufts University

Critical for maintaining genomic integrity, loss of DNA repair proteins can have major implications for cellular and organism health. One such protein is the mammalian apurinic/apyrimidinic endonuclease 1 (APE1) which primarily functions in the base excision repair (BER) pathway. In response to damage often caused by reactive oxygen species, a glycosylase removes the damaged base, leaving an AP site. APE1 then primes DNA synthesis by cleaving the sugar-phosphate backbone. While APE1 has been well-characterized in BER, embryonic lethality in APE1 knockout mice has made it challenging to examine the molecular targets of APE1. Although APE1 can be embryonic lethal, the *D. Melanogaster* homolog for APE1, recombination repair protein 1 (Rrp1), has been shown to be viable through embryonic development. Preliminary experiments in *D. Melanogaster* reveal *Rrp1* null mutants have an average hatching rate around 86.78%, which is comparable to wild-type hatching rates. Given this unique viability of Rrp1 mutants and overall significance of APE1 in mammalian disease pathology, *D. Melanogaster* is a strong candidate to help elucidate crucial APE1 mechanisms. Following mammalian models, the first step is to test if *Rrp1* mutants are sensitive to DNA damaging agents that cause base damage, such as methyl

methanesulfonate. We hypothesize that *Rrp1* mutants will be deficient in BER and therefore hypersensitive to DNA damaging agents. Sensitivity assays, which measure the relative survival of *Rrp1* mutants treated with DNA damaging agents, are in progress. In addition to mutagen sensitivity, APE1 has been hypothesized to impact the intracellular redox state which is important in neurodegeneration as neurons are especially vulnerable to oxidative damage. Given the implications of APE1 in neuronal genomic integrity and the high expression of Rrp1 in the *D. Melanogaster* nervous system, we further hypothesize that *Rrp1* mutants will display neurologic phenotypes. To test this hypothesis, we will use behavioral assays and brain histology to evaluate climbing ability and brain tissue health in *Rrp1* deficient flies With these assays, the role of Rrp1 in *D. Melanogaster* BER and neurodegeneration can be more clearly understood, potentially revealing a novel avenue by which to explore crucial neurologic disease pathology and AP endonuclease activity.

1655T **Performance, Modifications and Tuning: Post-translational modifications on Corolla, a meiotic synaptonemal complex protein** Adam Bomar, Katie Billmyre Genetics, University of Georgia

Post-translational modifications (PTMs) greatly increase the diversity and functionality of proteins encoded by the genome. They can affect the shape of a protein, how it interacts with other proteins, and protein synthesis. One process that is heavily dependent on PTMs is meiosis. Meiosis is a multi-stage process during which germ cells go through two rounds of division to split into gametes (e.g. eggs and sperm) containing half the amount of genetic information. Specific proteins are needed at different stages to ensure the cell cycle is proceeding correctly, and chromosomes are separating accurately. Improper chromosome segregation can lead to a number of genetic syndromes and infertility. The lab is currently studying PTMs of a multi-protein structure, the synaptonemal complex (SC) that holds DNA together during early meiosis. The SC forms between the arms of homologous chromosomes during early meiosis and is necessary for the proper segregation of chromosomes. In mice and *C.elegans*, disruption of cyclin dependent kinase (CDKs) activity leads to a loss of functional SC. However, in Drosophila melanogaster we have very little information about SC regulation during meiosis. Here we focused on a central element protein called Corolla. On Corolla, we identified three putative CDK binding sites located near potential phosphorylation sites. To investigate these putative sites, we used CRISPR to create flies lacking them. Corolla^{3xCDK} females did not properly assemble the SC and contained polycomplexes, large aggregates of SC proteins.

Currently, we are characterizing other aspects of meiosis such as double-strand break formation and recombination in these mutants. Additionally, we are taking a two-pronged approach to determine what CDKs/cyclins are active during meiosis. First, we are examining the SC in flies where specific CDKs/cyclins have been knocked down in the germline using RNAi. Second, we are using yeast 2-hybrid to look for physical interactions between CDKs/cyclins and SC components. This work will increase our understanding of what regulates SC assembly and maintenance.

1656T **Not Always Precise: CRISPR/Cas9 Utilizes Multiple Mechanisms of Homology Directed DNA Repair Including Novel Models and Some Detrimental Outcomes** Evan Dewey, Reese Perini, Jeff Sekelsky Genetics, University of North Carolina-Chapel Hill

Accurate understanding of homology directed DNA repair (HDR) non-crossover and mitotic crossover mechanisms is critical to genetic disease prevention. Precisely regulated HDR specifically avoids crossovers to promote non-crossovers, avoiding loss of heterozygosity and genetic disease. We have the unique ability to accurately interpret HDR mechanisms by preserving single nucleotide polymorphisms to define heteroduplex DNA that is key to analysis within crossover and non-crossover products through complete mismatch repair knockout in *Drosophila*. Using this tool, we have identified mechanisms of several independent Cas9 induced mitotic crossover and non-crossover events, including some novel and detrimental outcomes. We see bias toward one pattern of double Holliday Junction (dHJ) cleavage (resolution) in mitotic crossovers, as well as crossovers not predicted by traditional dHJ resolution models, suggesting novel mitotic crossover models. We also find heteroduplex DNA resulting from synthesis is longer on the 5' side of the double strand break (DSB) site in both crossovers and non-crossovers, indicating preference for synthesis in the 5' direction over 3'. We hypothesize this 5' synthesis preference stems from persistent binding of Cas9 to the plus strand after cutting, inhibiting that strand from invading the template, favoring minus strand invasion, and thus facilitating the 5' synthesis bias. In some non-crossovers we see detrimental outcomes such as transposable elements aberrantly inserted near the DSB, large (>50 bp) deletions, and small (4-10 bp) deletions caused by DNA polymerase theta-mediated end joining. We hypothesize these stem from repeated Cas9 cutting, underscoring the importance of caution when employing CRISPR/Cas9 gene editing, as very efficient guide RNAs can cause detrimental outcomes. Our work enhances knowledge of HDR mechanisms, expanding how mitotic crossovers lead to genome instability, and providing better understanding of beneficial HDR utilization in CRISPR/Cas9 genome editing.

1657T **Genomic studies investigate how DNA replication regulates histone incorporation in the *Drosophila* male germline** Jennifer Urban[1], Daniel Ringwalt[1], John Urban[2,3], Brendon Davis[1], Wingel Xue[1], Wai Lim Ku[4], Ryan Gleason[1], Keji Zhao[4], Xin Chen[1,3] [1]Biology, Johns Hopkins University, [2]Carnegie Institution for Science, [3]Howard Hughes Medical Institute, [4]National Heart, Lung, and Blood Institute

As a multicellular organism develops, DNA replication in a mother cell duplicates the genome, followed by mitosis to generate two daughter cells with identical genetic information. How this cell division process contributes to diverse cell types is a fundamental question in developmental biology. It is well known that epigenetic mechanisms play a role in cell fate determination. For example, histones and their post-translational modifications influence chromatin structure to help define cell identity.

We hypothesize that asymmetric cell division contributes to cell diversity through differential inheritance of epigenetic information like histones. To support this, we discovered distinct inheritance patterns for histones during asymmetric cell division of *Drosophila* male germline stem cells (**GSC**s). While pre-existing histones are retained in the self-renewing stem cell, newly synthesized histones are enriched in the differentiating daughter. Further studies demonstrate that at individual DNA replication loci, old histones recycle to the leading strand while the lagging strand incorporates new histones. As leading and lagging strands switch at replication initiation and termination zones, it is unclear how local replication fork asymmetries produce sister chromatids enriched for either old or new histones.

My research tests the question, "how does DNA replication contribute to histone asymmetries that influence cell fate?" Before addressing this, I must first define the epigenetic and DNA replication landscapes in GSCs. However, genomic approaches are challenging in heterogenous tissue with low cell numbers. Using a *Drosophila* testis tumor to increase GSC number, I adapted a chromatin immunocleavage (ChIC) assay to define chromatin features for germline versus somatic gonadal cells. Information on H3K4me3-, H3K27me3-, and H3K9me2/3-enriched regions was integrated with cell type-specific RNA-seq to compare how chromatin relates to cell-specific transcriptional output. Additionally, I performed nascent DNA profiling (Repli-seq) to understand how replication progresses through different chromatin landscapes of each cell type. All three data sets are compared with each other and between cell types to address my hypothesis that a distinct replication program in GSCs contributes to their unique chromatin landscape and cell fate. Altogether, my research aims to address how DNA replication-coupled histone incorporation establishes global histone asymmetries in the *Drosophila* male germline.

1658T **Combinatorial effect of environmental heavy metals on genome stability** Tin Tin Su[1], Elle Mcdonald[2], Barbara Frederick[2] [1]University of Colorado, [2]UNIVERSITY OF COLORADO, BOULDER

Environmental heavy metal contamination poses significant health risks to communities near industrial sites, typically those with lower-income populations. Due to past and current mining activity, the state of Colorado contains several contaminated sites. One such site is in Pueblo, Colorado, where lead (Pb), arsenic (As) and cadmium (Cd) are major heavy metal contaminants in surface soil. Pb replaces essential metals in the body to inhibit the function of enzymes including those used to reduce reactive oxygen species (ROS). As binds sulfhydryl groups and can replace phosphorous, thereby impeding enzymes including those used for DNA repair. Cd has been shown to catalyze ROS production. ROS can damage DNA and lead to genome instability. Indeed, exposure to Pb, As and Cd is associated with an increased risk of various types of cancer including lung and brain cancers. Historically, studies of the genotoxic effect of heavy metals have typically focused on one metal at a time. In contaminated environments, however, these metals appear in combination. Available data show that pollutant combinations, for example Pb and Black Carbon, can synergize in ROS production and DNA damage, with the resulting effect greater than the sum of the effect of each agent. Yet, the genotoxic effects of Pb, As and Cd in combination have not been studied systematically. To fill this knowledge gap, we are assessing the effect of combinations of heavy metals on the genome in two experimental models, human epithelial cells and *Drosophila* larvae. In *Drosophila*, we are quantifying lasting genomic changes in terms of Loss of Heterozygosity (LOH), using fluorescent reporters we described in recent publications (Brown et al., 2020, PLoS Genetics, PMID: 33075096 and Brown et al., Genetics, 2023, PMID: 37214983). In human cells, we are using comet assays and antibody staining to gamma-H2Ax to monitor the level of DNA damage. Results from these studies will be presented.

1659T **Investigating the influence of the *TM3, Sb Ser* balancer chromosome on the female meiotic drive of B chromosomes in *D. melanogaster*** Ryan M Gado[1], Stacey L. Hanlon[1,2] [1]Molecular and Cell Biology, University of Connecticut, [2]Institute for Systems Genomics, University of Connecticut

According to Mendel's Law of Segregation, the meiotic segregation of a genetic element should be random, resulting in a 50-50 pattern of inheritance. Selfish genetic elements, such as the supernumerary, nonessential B chromosomes, can violate Mendel's law and exhibit preferential transmission during female meiosis, a phenomenon known as meiotic drive. The B chromosomes recently discovered in *D. melanogaster* are not themselves selfish, however the genetic background they arose in enables them to exhibit selfish behavior during female meiosis and be preferentially transmitted from one generation to the next. Their progenitor stock carries a null allele of *matrimony* (*mtrm*^{126}) held over the *TM3, Sb Ser* (*TM3*) balancer, both of which are necessary but not sufficient to induce robust meiotic drive of the B chromosomes. Since it is currently unknown how *TM3* contributes to this drive, we hypothesize that one or more of the ten inversion breakpoints on *TM3* interrupt a gene that confers drive suppression, allowing for a stronger degree of drive when *TM3* is present. *TM3* carries five large

inversions that interrupt seven genes, such as the well-known tumor suppressor gene *p53*, one intergenic region, and two unknown regions. To explore our hypothesis, we used a screening assay to monitor the segregation of chromosome 4 that serves as a proxy for B chromosome segregation as both chromosomes exhibit biased transmission in a drive-permissive genetic background. Preliminary screening of the candidate drive suppressors revealed that a reduction in *p53* contributes to biased chromosome segregation, indicating it may be a suppressor of drive. To confirm this result, we are assessing the B chromosome transmission in a *p53/mtrm*^{126}mutant background to determine if *p53/mtrm*^{126} females can recapitulate the high level of drive seen in a *mtrm*^{126}*/TM3* background. Ultimately, this work will provide the starting point for uncovering the mechanism in which the *TM3* balancer chromosome enables the robust drive of the B chromosomes.

1660T **A Cytological F1 RNAi Screen for Defects in *Drosophila melanogaster* Female Meiosis** William D. Gilliland Biological Sciences, DePaul University

Genetic screens induce mutations, make the mutated chromosomes homozygous, and then assay those homozygotes for the phenotype of interest. When screening for genes required for female meiosis, the phenotype of interest has typically been nondisjunction from chromosome segregation errors. As this requires that mutant females be viable and fertile, any mutants that are lethal or sterile when homozygous cannot be recovered by this approach. To overcome these limitations, our lab has screened the VALIUM22 collection produced by the Harvard TRiP Project, which contains RNAi constructs targeting genes known to be expressed in the germline in a vector optimized for germline expression. By driving RNAi with GAL4 under control of a germline-specific promoter (*nanos* or *mat-alpha4)*, we can test genes that would be lethal if knocked down in all cells, and by examining unfertilized metaphase-arrested mature oocytes, we can identify defects associated with genes whose knockdown results in sterility or causes other errors besides nondisjunction.

We screened this collection to identify genes that disrupt either of two phenotypes when knocked down: the ability of meiotic chromosomes to congress to a single mass at the end of prometaphase, and the sequestration of Mps1-GFP to ooplasmic filaments in response to hypoxia. After screening >1450 lines of the collection, we obtained multiple hits for both phenotypes, identified novel meiotic phenotypes for genes that had been previously characterized in other processes, and identified the first phenotypes to be associated with several previously uncharacterized genes.

1661T **Comprehensive Tissue-Specific Somatic Mutation Profiling via RNA-seq in Diverse Mice** Alexis Garretson[1,2], Beth L Dumont[1,2] [1]Genetics, The Jackson Laboratory, [2]Tufts University

Somatic mutations are genetic alterations that occur in non-germ cells and are thus not passed on to offspring. However, somatic mutations can be transmitted to the progeny of mutated cells and disrupt normal cellular processes, leading to dysregulation or oncogenesis. Indeed, somatic mutational loads are associated with cancer, aging, neurodegeneration, autoimmune diseases, and many other genetic diseases. Tumor whole-genome sequencing has led to the identification of characteristic mutation signatures associated with distinct tumor types, but somatic mutation profiles have been far less extensively studied in healthy tissues. To address this gap, we leverage multi-tissue RNA-seq data from genetically diverse mouse strains to comprehensively identify somatic mutations in 10 tissues. We define tissue-specific mutation rates, spectra, and signatures that reveal associations with gene expression levels, chromatin states, and metabolic phenotypes. For example, we identify higher mutation rates in islet cells of mice maintained on a high fat diet and demonstrate that increased mutation rates in this context are associated with a mutational signature of dietary exposure to aflatoxin, a common fungal pathogen of grains. In addition, we find that voluntary exercise is positively associated with increased mutation rate in skeletal muscles and linked to a mutational signature driven by reactive oxygen species. Our findings reveal tissue-specific patterns of somatic mutations and shed light on the relationships between metabolic and molecular phenotypes in healthy tissues, prior to tumorigenesis. We are currently extending our somatic mutation calling method to a large, outbred population of mice for which we have RNA-seq data from multiple tissues. This unique resource will allow us to use QTL mapping to identify genetic loci influencing somatic mutation profiles and rates in healthy mammalian tissues for the first time.

1662T **Meiotic chromosome segregation in the holocentric pantry moth *Plodia interpunctella* can occurs through multiple mechanisms dictated by crossover position** Leah F. Rosin[1], Elissa P. Lei[2] [1]National Institutes of Health, NICHD, [2]National Institutes of Health, NIDDK

Precisely regulating chromosome dynamics during meiosis is essential for reproductive success across species. Errors in meiotic chromosome segregation can lead to reduced fertility, miscarriages, or chromosomal disorders, such as Down Syndrome or Turner Syndrome. Yet, the mechanisms underlying meiotic chromosomal events such as homolog pairing and chromosome segregation are not fully understood in most species. Furthermore, even in species where meiotic chromosome dynamics are beginning to be elucidated, whether or not mechanisms are conserved across species is unclear. Here, we employ Oligopaint DNA FISH to investigate mechanisms of meiotic homolog pairing and chromosome segregation in the

holocentric pantry moth *Plodia interpunctella* and compare our findings to our previous studies in the silkworm moth, *Bombyx mori*, which diverged from *P. interpunctella* over 100 million years ago. We find that like *Bombyx*, meiotic pairing during *Plodia* spermatogenesis is initiated at gene-rich chromosome ends. Additionally, both species form cruciform-like bivalents at metaphase I. However, unlike the telokinetic chromosome segregation mechanism observed in many holocentric species such as *Bombyx* and *Caenorhabditis elegans, Plodia* employ a novel "monokinetic" mechanism of meiotic chromosome segregation, where either telomeres or chromosome middles can act as a kinetochore-recruitment site during meiotic divisions. This monokinetic segregation is uniquely influenced by crossover position, where central kinetochore formation is likely achieved by the unusual formation of multiple chiasmata per chromosome despite the small size of *Plodia* chromosomes. Together, our data reveal conserved mechanisms of homolog recognition and pairing initiation but diverged mechanisms of chromosome segregation, and possibly crossover regulation, across Lepidopteran insects.

1663T **The role of dual histone methylation readers ZCWPW1 and ZCWPW2 in PRDM9 dependent meiotic recombination** Dawn Watkins-Chow[1], Mohamed Mahgoub[2], Sherry Ralls[1], Melania Bruno[1], Jada Gonzales[1], Meghan Yamasaki[3], Florencia Pratto[4], Todd Macfarlan[1] [1]NICHD, NIH, [2]Washington University in St. Louis, [3]NICHD Reproductive Endocrinology and Infertility Training Program, NIH, [4]NIDDK, NIH

Successful meiosis is an intricate process requiring the pairing and segregation of homologous chromosomes. Errors during meiosis can result in aneuploidy, a leading cause of pregnancy loss. Synapsis, the process that forms a physical linkage between homologous chromosomes is facilitated by the repair of DNA double-strand breaks (DSBs) that initiate homologous recombination. The location of DSBs on homologous chromosomes is determined by the DNA binding methyltransferase, *Prdm9*, one of the fastest evolving genes in the mammalian genome and the only known mammalian speciation gene. PRDM9 methylates histone H3 on lysines 4 and 36 which is essential for DSB formation and subsequent homology-directed repair, which can result in crossovers or smaller gene conversion events at PRDM9-initiated hotspots. We have identified two genes, *Zcwpw1* and *Zcwpw2,* encoding dual histone methylation readers that co-evolved with and are tightly co-expressed with PRDM9 during spermatogenesis. The two paralogous genes share conserved zf-CW and PWWP histone binding domains and both ZCWPW1 and ZCWPW2 bind dual methylated (HeK4me3 and H3K36me3) peptides. *In vivo* knockout of either *Zcwpw1* or *Zcwpw2* results in azoospermia and complete infertility, confirming the two genes are not functionally redundant during spermatogenesis, and loss of either paralog results in defective pairing of homologous chromosomes during synapsis. Characterization of the DNA double strand break landscape in *Zcwpw1* or *Zcwpw2* mutants suggests that ZCWPW2 and ZCWPW1 play distinct roles in DNA double strand break formation and repair, respectively. Work is ongoing to identify interacting proteins to further explore the mechanism of ZCWPW1 and ZCWPW2 in meiotic recombination. Collectively our data suggests that *Zcwpw1* and *Zcwpw2* provide previously unknown components of the machinery required for PRDM9-mediated recombination hotspots.

1664T **Characterization of a *RAD23* knock down UV resistance phenotype in *Tetrahymena Thermophila*** Emma J Liimatta[1], Emily M. Schmoll[2], Joshua J Smith[1] [1]Biomedical Sciences, Missouri State University, [2]Forensic Lab, St. Louis County Police Crime Laboratory

Xeroderma Pigmentosum (XP) is a recessive genetic disorder with defective Nucleotide Excision Repair (NER) caused by mutations in the XP proteins. When NER is nonfunctional the risk of skin and eye cancer increases >1000 fold because DNA adducts caused by UV radiation are unable to be repaired. There are currently no treatments or cures for the source of XP, just the presentation which is skin cancer. The NEF2 complex, composed of XPC and HR23A/B, recognizes DNA adducts and attracts NER repair proteins. XPC is widely researched yet there is little research on HR23A/B which functions to stabilize, decrease degradation, and increase efficiency of XPC. When a homolog of *HR23A/B, RAD23* (TTHERM_00013290), was knocked down in *Tetrahymena thermophila* a surprising 3-fold increase in UV resistance was observed in the *rad23* knockdowns as compared to wild type strains. This is the first time *rad23* has been studied in *T. thermophila* and previous *rad23* knockdowns in other organisms have shown UV sensitivity rather than resistance. In this study, *rad23* knockdown was confirmed by qRT-PCR, and UV resistance was confirmed by UV survivability assays. CPD dot blot immunodetection techniques assessed levels of DNA damage in UV treated *rad23* knockdown cells. TUNEL assays assessed the effect of *rad23* knockdown on apoptosis in UV treated cells. Characterization of this *rad23* knockdown UV resistance phenotype could reveal new roles that RAD23 provides in the cell. This research contributes to the current knowledge of Nucleotide Excision Repair and the molecular consequences of NER's absence in Xeroderma Pigmentosum patients. Advancing knowledge of NER, XP and RAD23 will eventually lead to the development of treatments for this genetic disease.

1665T **Cytogenomics uncovers novel rearrangements in frogs of the genus *Xenopus*** Martin Knytl[1,2], Barbora Bergelová[3], Nicola R. Fornaini[3], Halina Černohorská[4], Svatava Kubíčková[4], Tereza Tlapáková[3], Jiří Vávra[3], Vladimír Krylov[3], Ben J. Evans[5] [1]Department of Biology, McMaster University, [2]Department of Developmental Biology, Charles University, [3]Charles University, [4]CEITEC - Veterinary Research Institute, [5]McMaster University

Whole genome duplication by allopolyploidy is preceded by hybridization between two ancestral species, and is often followed by genomic rearrangements and speciation. Allopolyploid genomes have genomic compartments called subgenomes, that each derived from a different lower ploidy ancestor and frequently do not recombine with one another. Here we investigated genome structure of two allotetraploid frogs, *Xenopus borealis* and *X. laevis*, and one diploid species – *X. tropicalis*. *Xenopus* laevis is a commonly deployed model for developmental biology. Using cytogenetic approaches and chromosome-scale genome assemblies for each species, we identified inversions (i) within both L and S subgenomes that are shared by both *X. borealis* and *X. laevis* (and that occurred prior divergence of their common ancestor); and (ii) unique inversions within the L and S subgenomes in either *X. borealis* or *X. laevis*. Inversions that are specific to each subgenome of *X. borealis* or *X. laevis* suggest more recent genomic restructuring, i.e., after divergence of the most recent common ancestral lineage. Using cytogenetic approaches, we additionally identified a population-specific, female-specific inversion on the W sex chromosome of *X. borealis*. This female-specific inversion is consistent with the hypothesis that suppressed recombination surrounding sex-determining genes may be favored by natural selection. Taken together, our efforts provide a chronology of genomic restructuring following allopolyploidization in *Xenopus* and shed light on previous hypotheses regarding asymmetric subgenome evolution in this genus.

1666T **Leveraging deep mutational screening to uncover dominant Rev3 alleles as a novel synthetic lethal therapeutic strategy** Peter Stirling[1], Ecaterina Cozma[2] [1]Terry Fox Laboratory, University of British Columbia, [2]Biochemistry, University of British Columbia

Synthetic lethal (SL) therapies can exploit genome instability present in rapidly dividing cancer cells by targeting key DNA damage repair pathways. Clinically successful SL therapies, such as PARP inhibitors, act by 'trapping' the PARP protein at DNA damage sites, creating persistent cytotoxic protein-DNA lesions and limiting accessibility by redundant repair mechanisms. While PARP trapping is an effective SL therapeutic approach, it is difficult to identify inhibitors de novo with trapping properties. Cancer cells come to rely on error-prone mechanisms like translesion synthesis (TLS) for chemoresistance, making TLS polymerases a high-value cancer therapeutic target. We have leveraged high-throughput mutagenesis techniques to screen for missense variants in DNA polymerase Z (REV3) that cause dominant negative growth phenotypes. Dominant Rev3 variants in the Rev7 and Pol31 interaction interfaces have been identified and will be characterized for altered DNA binding kinetics and protein-protein interaction strength. Additional analysis of this Rev3 variant library and its effects on fitness, genetic interactions and mutation signatures are ongoing. The identification of Rev3 domains mutable to dominant forms may help to guide rational inhibitor development to selectively kill cancer cells dependent on TLS.

1667T **Coevolution of kinetochore protein Cbf2 and budding yeast centromeres** Patrick C Hecht[1], Mai Nguyen[1,2], Tia Peterson[1], Jennifer F Garcia[3], Sara J Hanson[1] [1]Molecular biology, Colorado College, [2]Computer science, Colorado College, [3]Biology, University of New England

The kinetochore is a protein complex that assembles on chromosomes at a location called the centromere, which ensures correct segregation of chromosomes during mitosis. Identifying the centromere for kinetochore assembly is an essential part of this process. Unlike other organisms, budding yeast have developed two different ways of identifying the centromere. Some species such as Saccharomyces *cerevisiae*, have a point centromere that binds to the kinetochore protein Cbf2 which then signals for kinetochore assembly. It is believed that in species with regional centromeres, kinetochore assembly happens independently of any Cbf2 function. Using bioinformatics, we identified Cbf2 homologs in a diverse range of yeast species, including those with regional centromeres. Our goal is to test the conservation of Cbf2 function in yeast with regional centromeres. We are establishing a protein-DNA binding assay that will test the ability of Cbf2 proteins in regional centromere species to bind the centromere of S. cerevisiae. In addition, we are testing the ability of these Cbf2 proteins to complement the loss of S. cerevisiae Cbf2. Through these experiments, we aim to better understand the co-evolution of centromere and kinetochore structure and function.

1668T **Inner kinetochore compositions across diverse centromere types in budding yeasts** Mai Tien Nguyen[1], Jennifer Garcia[2], Sara Hanson[1] [1]Molecular Biology, Colorado College, [2]University of New England

The kinetochore, a multiprotein structure, links centromeres to microtubules during eukaryotic cell division, ensuring accurate chromosome segregation. Centromeres are specific chromosomal regions that serve as platforms for kinetochore assembly. While functionally conserved, kinetochore composition and centromere organization exhibit diversity in eukaryotes. In budding yeasts (subphylum Saccharomycotina), centromeres vary from short, sequence-specific point centromeres to larger regional centromeres. To inventory inner kinetochore compositions in budding yeasts with varying centromere types, we developed "mign", a tool written in Python, to automate the homolog identification of 20 inner kinetochore proteins in 338 species. During the homolog identification process, certain inner kinetochore proteins in budding yeasts exhibit greater similarity to fission yeast *Schizosaccharomyces pombe*, as opposed to *Saccharomyces cerevisiae*. The resulting inventory

reveals that proteins previously recognized to be linked with point centromeres are also present in species featuring regional centromeres. Additionally, the inner kinetochore inventory in the Saccharomycodaceae family positions it as a candidate for centromere type research, given the limited knowledge of centromere types within this family. Understanding inner kinetochore compositions in relation to centromere types offers insight into the coevolution of centromeric DNA sequences and associated proteins. The data obtained here provide directions for future wet lab projects.

1669T **The role of topoisomerases in circularized chromosome strains of *Saccharomyces cerevisiae*** Mara J Stout, Melissa Mefford Department of Biology and Chemistry, Morehead State University

The genome of eukaryotic cells is characterized by multiple linear chromosomes rather than a single circular chromosome that prokaryotes typically have. Maintenance of telomeres at the end of linear chromosomes requires the ribonucleoprotein complex telomerase. Our lab is particularly interested in understanding why eukaryotic cells evolved telomeres and telomerase. To investigate the role of linear chromosomes in eukaryotes, we have successfully engineered budding yeast, *Saccharomyces cerevisiae*, with individually circularized chromosomes. In haploid strains undergoing mitotic division, the circularized chromosome strains have no obvious phenotypes compared to wildtype. However, the chromosomes must be segregated differently than wildtype strains due to the large structural difference. We propose segregation of circular chromosomes will require topoisomerases, which are important nuclear enzymes that engage in DNA replication, transcription, chromosome segregation, and recombination. To test this hypothesis, we deleted the non-essential topoisomerase I (TOP1) and III (TOP3) genes in wild-type and circularized chromosome strains of *S. cerevisiae*. Our preliminary data indicates that deletion of TOP1 and TOP3 produces growth defects for certain circular chromosomes under various conditions. To further test our hypothesis, we are growing yeast in the presence of a topoisomerase inhibitor, doxorubicin, which should mimic the effects of topoisomerase gene deletion. Together, our data will shed light on how chromosomal architecture influences chromosomal segregation and cell proliferation. In the future, we also plan to study meiotic division, hopefully elucidating that linear chromosomes are better able to undergo the vital crossing-over process in meiosis and sexual reproduction.

1670T **Characterizing the mechanism of mutagenesis in Rad5 variants in *S. cerevisiae*** Kate Jiang[1,2], Xanita Saayman[3], Jiayue Wu[4], Nicolo Tellini[3], Gianni Liti[3], Grant W Brown[1,2] [1]Biochemistry, University of Toronto, [2]Donnelly Centre for Cellular and Biomolecular Research, [3]Université Côte d'Azur, [4]University of Toronto

Mutagenesis promotes both genetic diversity and disease progression. One of the sources of mutagenesis is translesion synthesis (TLS), where lesions that block DNA replication are bypassed in an error-prone manner, allowing completion of DNA replication at the cost of introducing incorrect base pairs. *In S. cerevisiae*, the DNA repair protein Rad5 is involved in both error-prone TLS and error-free template switching, and a natural variant of *RAD5* causes increased mutation rate as a result of TLS. The mutational outcomes of Rad5-mediated TLS across the entire genome, as well as how Rad5-mediated TLS contributes to genetic diversity, remain to be understood. We performed a mutation accumulation experiment with strains carrying a template-switching deficient *RAD5* mutant, which reveals a genome-wide mutational spectrum distinct from that of WT, with the *RAD5* mutant containing more transversions. Furthermore, analysis of 2,000+ *RAD5* sequences found in wild yeast isolates revealed distribution of natural variants across the protein and conservation of functional Rad5 domains. A portion of the Rad5 ATPase domain showed presence of common variants, while the rest of the ATPase domain was largely under negative selection, suggesting different functional requirements within the same protein domain. Overall, our results highlight the importance of Rad5 in contributing to genetic diversity through both mediating the repair pathway choice and specifying distinct mutational outcomes.

1671T **Discovery of a Novel Gene that Regulates Cohesins** gurvir singh, Robert V Skibbens Biological Sciences, Lehigh University

Cohesins play essential roles in nearly all aspects of cell and development biology. First, cohesins tether together the sister chromatids in close coordination with the DNA replication fork. Second, cohesins promote high fidelity DNA repair in response to DNA damage. Cohesins also promote both chromosome condensation and gene transcription, each of which depends on cohesin ATPase-dependent DNA looping or extrusion activity.

Cohesins are regulated by at least 2 mechanisms. Eco1/Ctf7 in budding yeast (EFO1/ESCO1 and EFO2/ESCO2 in vertebrates, ESO1 in fission yeast), represents a highly conserved family of essential acetyltransferases that locks cohesins on DNA. On the other hand, Rad61 (WAPL in vertebrates) drives the dissociation of cohesins from DNA. Even though Eco1 is essential for cell viability, cells deficient in both Eco1 and Rad61are viable, but only within a very narrow temperature range. Previously, a spontaneous suppressor screen performed in *eco1 rad61* double null cells identified a number of isolates that 'revert' to robust growth at a wide range of temperatures. Whole genome sequencing of these revertants revealed a small number of gene mutations including within the open reading frame of *FDO1*. To validate that mutation of *FDO1* is the suppressor

of *eco1 rad61* double null temperature sensitive growth, we recreated both partial and full *FDO1* knockouts in the parent *eco1 rad61* double mutant strain. The results confirm that deletion of *FDO1* rescues the temperature sensitivity otherwise exhibited by *eco1 rad61* cells. This is the first report that links Fdo1 to cohesin regulation.

Fdo1 was originally identified as directing the direction of recombination during mating type switching in budding yeast. A 2 hybrid and biochemical studies further revealed that Fdo1 interacts with Fkh1 (Forkhead 1), a FOX-type transcription factor that similarly promotes donor-site preference during mating. Surprisingly, the deletion of *FKH1* had no effect on the *eco1 rad61* double null cells, nor did deletion of the FKH1 ortholog, *FKH2*. We then tested a model that Fdo1 inhibits FKH1 activity, but the overexpression of FKH1 (or FKH2) failed to revert eco1 rad61 double null cells to grow at elevated temperatures. Here, we report on additional findings that link Fdo1 to a separate transcriptional pathway and that regulates cohesion functions.

1672T **Mapping the phenotypes of single amino acid variants of the cytidine deaminase APOBEC3C with deep mutational scanning** Shamitha Aravind[1,2], Grant Brown[1,2] [1]Department of Biochemistry, University of Toronto, [2]Donnelly Centre for Cellular and Biomolecular Research

The apolipoprotein B mRNA editing enzyme catalytic polypeptide-like 3 (*APOBEC3*) family consists of seven paralogous cytidine deaminase genes (A – D and F – H). Cytidine deaminases cause cytidine to thymidine transition mutations when left unchecked by DNA repair mechanisms. Members of the *APOBEC3* family support innate immunity by hypermutating viral and/or retrotransposon DNA. In addition to acting on pathogens and mobile elements, some APOBEC3 proteins deaminate genomic DNA. Emerging evidence implicates *APOBEC3C* (*A3C*) in roles outside of innate immune support; however, the multiple functions of this protein have not been comprehensively investigated. Wild-type A3C has relatively less deaminase activity compared to a naturally occurring variant, $A3C_{S188I}$, which dimerizes more readily. The existence of a protein variant that is less frequent and more active than wild-type A3C reflects the value of phenotyping a large pool of A3C missense mutants in an unbiased manner. I am characterizing the sequence-function relationships for A3C through deep mutational scanning (DMS) in the budding yeast *Saccharomyces cerevisiae*. DMS probes protein function through the analysis of all possible single amino acid variants, allowing the construction of high resolution structure-function maps. By subjecting a library of A3C missense protein variants to multiple assays, I will identify residues that are critical for the cellular function and dimerization of A3C. My approach will provide key insights into the structural characteristics of A3C that underlie its functions.

1673F **The sexually dimorphic recombination landscape in *C. elegans* meiosis coordinates with sex-specific germline gene expression** Zachary Bush[1], Alice S Naftaly[1], Devin Dinwiddie[1], John S Conery[2], Kenneth Hillers[3], Diana E Libuda[1] [1]Biology, University of Oregon, [2]University of Oregon, [3]Biological Sciences, California Polytechnic State University, San Luis Obispo

Crossover recombination events repair DNA damage, create genetic diversity, and ensure the accurate segregation of chromosomes during meiosis in most organisms. In many species, the genomic distribution of crossovers is nonrandom and varies between sexes. While many species evolved kilobase-scale “hotspots” where crossover events are more likely to form, the *Caenorhabditis elegans* genome lacks such hotspots and crossovers are biased to form across megabase-scale domains on the terminal thirds of each chromosome. Further, genetic and cytological experiments indicate *C. elegans* spermatogenesis exhibits higher crossover frequencies in comparison to oogenesis, however, the mechanisms that lead to this sexually dimorphic crossover regulation are poorly understood. To define and analyze these sexually dimorphic recombination landscapes at high resolution across the entire genome, we performed whole-genome sequencing and high-resolution recombination mapping of single worms with recombinant chromosomes from individual meiotic products of either spermatogenesis or oogenesis. We find that the fine-scale distribution of crossovers is sexually dimorphic on chromosomes I, II, and III, and that the rate of crossing over is elevated in spermatocytes. The rate of double crossover events is 4.7 times higher in developing sperm and regulation of inter-crossover distance appears less stringent. The frequency of double crossover events, however, is not shared between all chromosomes, as spermatocyte chromosomes vary from 1.5-7.6% on the autosomes. Further, we define the sequence-level genome annotations and sex-specific chromatin environments associated with the sexually dimorphic crossover distribution. Among our findings, we identify a strong association of ncRNAs, promoters, enhancers, and untranslated regions (UTRs) of genes in genomic regions with sexually dimorphic crossover frequencies. We also detect an enrichment of crossovers in genomic regions associated with actively expressed genes in the male versus hermaphrodite germline. Overall, these studies provide a framework for high-resolution crossover mapping in individual *C. elegans* genomes and reveal potential regulators of the sexually dimorphic crossover distribution.

1674F **Transgenerational Screening of Intrinsically Disordered Proteins for Genes Involved in Meiosis in the Nematode *C. elegans*** yvan doctorovich[1], William McFadden[2], Judith Yanowitz[1] [1]Magee-Womens Research Institute, [2]Department of Pediatrics, Emory University School of Medicine and Children’s Healthcare of Atlanta

Intrinsically disordered regions (IDRs) play critical functions in proteins without having a fixed structure. Unlike most proteins,

which fold into specific conformations to carry out their functions, IDRs are flexible and dynamic, lacking a fixed structure even in the absence of molecular interactions. Despite this, IDRs have specific amino acid compositions and properties that are essential for protein function. At the same time, they have different evolutionary constraints on them because they need only retain charge and not a specific amino acid composition. In this regard, they may appear to be rapidly evolving while in fact retaining function. Our lab has worked on several meiotic proteins that are highly disordered, leading us to consider whether this class of proteins may reveal novel germline functions.

To test this hypothesis, we compiled a comprehensive list of the highly disordered proteins in the worm model, *Caenorhabditis elegans*. We learned this way that they tend to be basic and nuclear, which could support their function as transcription factors. We then knocked them down individually using RNA interference (RNAi) and analyzed effects on fertility by examining the subjects' phenotypes *in vivo* over three generations and DAPI staining the adults after three generations of exposure to look for abnormalities *ex vivo* in the gonadal or embryonic development. This screen was realized on the RNAi sensitive strain *lin-35(ea86)* and the positives were confirmed in the wild-type strain N2.

25 of the 110 genes analyzed caused a reproductive phenotype. The results of this study highlight the significance of these understudied proteins and their potential importance in reproduction in *C. elegans*. It also emphasizes the importance of continued research into IDRs, which could lead to the discovery of novel targets for therapeutic intervention in human infertility.

1675F **Natural variation in mutagen tolerance among *C. elegans* wild isolates** Sophia Tintori, Matthew V Rockman New York University

All living cells are continuously challenged by exogenous, endogenous, and spontaneous DNA damage. While conserved DNA damage response keeps organisms safe broadly, natural variants in these mechanisms can carry profound consequences for cell biology, health, and evolutionary genomics. In this study we use wild nematode strains to study the mutagen tolerance and DNA repair variants that exist in natural populations, and the cell biological and mutagenic consequences of those variants.

We have developed a highly sensitive assay to identify which wild strains are naturally more or less tolerant to different DNA damaging agents during chronic exposure over multiple generations. We have applied this assay to 35 strains across two species: *C. elegans* strains that were previously collected from around the world, and *O. tipulae* that we collected from the Chornobyl Exclusion Zone, a radioactive landscape that we hypothesized may have already selected for mutagen tolerance. We have tested these strains for their diverging sensitivities to a range of DNA damaging chemicals, and have identified phenotypic outlier strains. We have performed bulk segregant analyses with hybrid populations of these outlier strains, identifying alleles of interest for mutagen tolerance phenotypes.

1676F **Pink1 represses apoptosis and allows proper morphogenesis after exposure to ionizing radiation in *Drosophila melanogaster*** Lauren M Orr, Hannah Golding, Ellie O›Brien, Joshua Siauw, Tin Tin Su Molecular, Cellular and Developmental Biology, University of Colorado Boulder

There is accumulating evidence of a direct relationship between the DNA Damage Response and autophagy, but the overall picture lacks clarity. To elucidate this relationship, we conducted a focused RNAi screen for autophagy regulators in the context of ionizing radiation (IR). Using morphological disruption of the compound eye of *Drosophila melanogaster* as a readout, we identified two genes of interest: ref(2)P (*Drosophila* p62/SQSTM1) and Pink1. Both genes are necessary for successful mitophagy, a subset of macro-autophagy. We found that RNAi knockdown of these genes resulted in defective eye morphogenesis when larvae were irradiated in the 3rd instar and the resulting adult eyes were examined. Cell biological analysis showed that Pink1 knockdown did not alter cell proliferation or cell cycle checkpoints after irradiation but increased apoptotic activity post-IR in 3rd larval instar eye discs. This result was reproduced with Pink1^{5} loss-of-function mutants that showed a more pronounced effect on apoptotic activity, specifically in the G1 arrested cells of the morphogenetic furrow. These results suggest that mitophagy might be important for cells in G1 to resist IR-induced apoptosis and ensure proper eye morphogenesis during recovery from radiation damage.

1677F **An Unbiased Screen for Vulnerabilities of Cells with Centrosome Amplification** Jane E Blackmer, Erin Jezuit, Ruth Montague, Archan Chakraborty, Don Fox Duke University

Centrosomes are microtubule organizing centers in animals, coordinating bipolar chromosome segregation during mitosis. Centrosome amplification (CA), a common cancer phenomenon, can pose a problem to the dividing cell as this drives multipolar division, aneuploidy, and often cell death. Usually, cells can compensate for CA by clustering extra centrosomes to two spindle poles. In the cancer therapy field, treatment with anti-clustering agents have attempted exploit CA in cancer and promote multipolar division-induced tumor cell death. However, anti-clustering agent treatment has proven to be

only moderately effective in cancer, suggesting that additional, clustering-independent mechanisms operate in cells with CA. *Drosophila* rectal papillar cells serve as an excellent system to study multipolar division with extra centrosomes, as these cells seldom cluster centrosomes and are highly tolerant of CA and multipolar division.

To identify factors that enable papillar cell survival of multipolar division, we performed an unbiased EMS screen in the *Drosophila* papillae. Our screen examined 642 recessive lethal mutations that we used to generate homozygous mutant clones in developing papillae through mitotic recombination. Our screen exploited the lethality of animals with compromised papillae to a high salt diet, as papillae are required for ion balance. Upon generating mitotic clones in papillar tissue, we screened for mutations that resulted in high salt diet lethality in combination with experimentally induced CA. From this screen, we have identified 26 mutant lines that reproducibly decrease papillar cell survival upon CA. Follow up analysis has placed two of these lines in a complementation group, suggesting our screen approached saturation. At my poster, I will reveal the identity of the gene in this complementation group, which encodes a protein that is orthologous to a target of an FDA approved seizure drug. Our screen is uncovering novel mechanisms of cell survival after CA and promises to identify novel cancer therapy drug targets.

1678F **Unveiling of Meiotic Aneuploidy through Targeted Ovarian Genes** Sarah Abrahem, Brianna Miller, Huda Zaman, Jessica Fellmeth Millersville University of Pennsylvania

The leading genetic cause of infertility is aneuploidy. Aneuploidy is when a cell has too many or too few chromosomes. When this occurs in gametes such as sperm or egg, it can result in infertility or birth defects. In somatic cells, aneuploidy is a hallmark feature of most cancers. Fertilization is where the haploid sperm and the egg fuse together to form a diploid zygote which contains the egg and sperm chromosomes. Then the zygote undergoes mitosis to develop the embryo. Meiosis is a special two-part type of cell division used to create gametes. The first part of meiosis (MI) is the origin for many of these chromosome errors, and this occurs more frequently in eggs than in sperm. These errors happen through nondisjunction of homologous chromosomes in meiosis (MI) in females. It occurs when two homologous chromosomes are pulled toward the same pole by spindle fibers rather than being separated creating an aneuploid egg that gives rise to an aneuploid embryo. The widely accepted source of these errors is the “Long Prophase Pause” which occurs only in oocytes (immature eggs). When females are born, all their oocytes are arrested in the early stages of prophase I of meiosis, this pause lasts until the egg is ovulated which can be 14-40 years later. All the proteins that are on the chromosomes during this period undergo an aging affect which can result in problems with chromosome segregation later.

This project is part of a larger screen attempting to identify new genes involved in meiotic chromosome segregation. Target genes were selected based on expression data from FlyAtlas2 and availability of RNAi stocks from TRiP. I aimed to use these shRNA’s to investigate eight distinct genes that are highly expressed in Drosophila ovaries. According to our preliminary studies, one of the strains has an increased amount of aneuploidy indicating a possible meiotic function. The gene targeted by this shRNA is CG7794 which is a putative protein coding gene on chromosome 3. It is predicted to be a structural component of the cytoskeleton and involved in organization of the spindle in mitosis. It’s role in cell division has not been studied and we look forward to collecting more data regarding the function of this gene in chromosome segregation.

1679F **How chromosomal inversions suppress meiotic recombination: Testing the breakpoint interference hypothesis in *Drosophila melanogaster*** Spencer A Koury Department of Biological Sciences, Auburn University

Recombination suppression in chromosomal inversion heterozygotes is well-documented but poorly understood. In *Drosophila melanogaster*, recombination suppression extends far outside inverted regions where there are no intrinsic barriers to normal chromosome pairing, synapsis, double-strand break formation, or segregation of crossover products. Even though formation of dicentric chromosomes via anaphase I bridges is often invoked to explain suppression inside inverted regions, empirically this mechanism only accounts for 10-20% of the chromosome-wide recombination phenotype in *D. melanogaster*. Thus, 80-90% of the fundamental phenotype of inversion heterozygosity remains unexplained a century after its first discovery. The breakpoint interference hypothesis addresses this knowledge gap by proposing heterozygous inversion breakpoints induce local discontinuities in the synaptonemal complex and, therefore, possess chiasma-like properties. This hypothesis predicts recombination suppression extends from breakpoints in a process analogous to crossover interference, which is qualitatively consistent with suppression extending to both inverted and uninverted chromosomal regions. Here, I develop quantitative predictions for this hypothesis building upon probabilistic models of crossover interference with gamma-distributed inter-event distances. Using *D. melanogaster*, I test these predictions with my own experimental data (>40,000 meioses) on crossing-over outside 4 inversions of the 3rd chromosome. Next, I test predictions for inside inverted regions with published data (>100,000 meioses) from 5 different inversions embedded in metacentric compound X chromosomes. Finally, I compile recombination data for 17 inversions occurring along acrocentric X chromosomes (>300,000 meioses) to test anecdotal claims that distal inversions are stronger crossover suppressors. The results demonstrate that the breakpoint interference hypothesis

accurately predicts suppression outside inversions, substantially improves predictions of suppression inside inversions, and reveals distal inversion are indeed stronger suppressors due to systematic variation in crossover interference. In sum, the breakpoint interference hypothesis provides a mathematical framework for integrating distance-dependent effects of structural heterozygosity on crossover distribution and highlights the potential for integrating statistical theory with biophysical models of crossover patterning along the chromosome.

1680F **Meiotic Crossover Designation and Interference in Drosophila Involves ATR-Dependent Phosphorylation of Mei-218** Susan McMahan, Colette Anikwue, Jeff Sekelsky University of North Carolina at Chapel Hill

The mechanism of crossover interference has been a mystery since Sturtevant described it in 1913. Meiotic recombination begins with DNA double-strand breaks (DSBs), then repair in the context of the synaptonemal complex (SC) culminates with most DSB sites becoming noncrossovers but at least one per bivalent or chromosome arm being selected to be a crossover. If more than one becomes a crossover, they are widely spaced. The discoveries that SC has liquid-like properties and that meiotic RING finger proteins move within the SC and accumulate at sites designated to become crossover led to a model in which coarsening (Ostwald ripening) of RING finger proteins leads to one site or widely separated sites being fated to become crossovers.

A key question is how RING finger protein accumulation can promote crossover repair. We propose that in Drosophila this involves stabilization of the mei-MCM complex to block the anti-crossover activity of Blm helicase, allowing the meiotic Holliday junction resolvase to make a crossover. We propose that stabilization involves phosphorylation by Mei41 (ATR kinase, which we previously showed to be required for interference). Mei218 has an intrinsically disordered region (IDR) in the N-terminus that is under positive selection. We identified putative ATR phosphorylation sites and mutated them the endogenous gene from S/T to A (non-phosophorylatable) or D (potentially phosphomimetic) in numerous combinations, then measured crossovers and interference. A striking finding not previously reported is that in a *mei-218* null mutant, where crossovers are reduced >90%, there is high negative interference (far more double crossovers than expected). Changing a cluster of 3 S/T residues near C-terminus of unstructured region to A made a null allele, though each singly change had no effect. Changing the 5 more N-terminal residues created a hypomorphic allele, and changing all 8 made a weaker hypomorph. Changing these sites to D also produced a series of different allele strengths, with 3D, 5D, and 8D having progressively stronger (though not null) phenotypes.

Our results support the hypothesis that phosphorylation of Mei218 by Mei-41 regulates both crossover designation and interference but suggest that dephosphorylation may also play a role and different sites may have different effects.

1681F **A mutation in the CAL1 binding site of CENP-C shows that CAL1 is not necessary for prometaphase function of CENP-C in meiosis** Eve Jeffries-Walters[1], Jadyn Koser[1], Brandi Wolfinger[1], Madison Holmes[2], Kim S McKim[3], Jessica Fellmeth[1] [1]Biology, Millersville University, [2]Millersville University, [3]Genetics, Rutgers, The State University of New Jersey

Aneuploidy is the leading genetic cause of female infertility. These errors largely originate from nondisjunction (NDJ) of homologs in meiosis I (MI). Female meiosis is uniquely error prone due to a long pause in prophase. Females are born with their oocytes arrested in prophase of MI and the chromosomes don't segregate until ovulation some 14-40 years later. CENP-C, which acts as the bridge between the centromere (chromosome) and the kinetochore (machinery for segregation), is one protein necessary for maintaining chromosome structure through this pause. Previous work from our lab has shown that CENP-C activity during the pause is dynamic and loss of this movement results in aneuploidy. This activity is distinct from mitosis and therefore of special interest. We have created a HA-tagged CENP-C mutant (CENP-C^{FR}) that has a single base pair substitution in the CAL1 binding site. CAL1 is a CENP-A chaperone necessary for CENP-A and CENP-C recruitment to centromeres. We have previously shown using CAL1 RNAi that CAL1 isn't necessary for the dynamic prophase loading of CENP-C. Using tissue specific promoters, we expressed CENP-C^{FR} in *Drosophila* oocytes before or during the pause. We hypothesized that the latter group will appear normal at metaphase I, but the former will exhibit defects. As expected, we observed increased aneuploidy in oocytes expressing CENP-C^{FR} before the pause, similar to a loss of CENP-C. However, flies expressing CENP-C^{FR} after the pause were completely sterile. This does not support our hypothesis, but is similar to the phenotype observed when wildtype CENP-C is expressed with the same promoter. The wildtype-expressing oocytes have been shown to be completely normal at metaphase I, so we believe the defect is during embryogenesis. If this holds true for CENP-C^{FR}, we expect to see a wildtype phenotype at metaphase I. When expressed only in early prophase, the CENP-C^{FR} mutant oocytes displayed levels of NDJ higher than CENP-C knockdown oocytes indicating a possible dominant effect. Cytological studies are ongoing as well as studies using a similar promoter with reduced expression to hopefully avoid the sterility phenotype. This data supports the conclusion that CENP-C activity during the prophase pause is independent of CAL1 which is a completely novel activity for CENP-C. Our aim for this study is to continue to shed light on the mechanisms of CENP-C function during meiosis. Allowing a deeper understanding of the behavior of the centromere, kinetochore, and chromosomes

during the long prophase pause in female meiosis.

1682F **Whole-genome approaches to understanding meiotic recombination mechanism and regulation** Carolyn Turcotte, Jeff Sekelsky Genetics and Molecular Biology, University of North Carolina at Chapel Hill

During meiosis, crossovers between homologous chromosomes ensure proper chromosome segregation. Crossovers are formed by repairing double-strand DNA breaks (DSBs) via homologous recombination (HR). The number and spatial arrangement of crossovers ("crossover patterning") is tightly regulated, and failures in this regulation can lead to aneuploidy and miscarriage. The mechanism behind this regulation and the primary defects that contribute to aneuploidy remain poorly understood. I use a two-pronged approach to study these phenomena in *Drosophila*: 1) mapping recombination events in progeny derived from aneuploid oocytes, and 2) finely analyzing HR products using whole-genome sequencing.
In the first approach, I use a genetic trick to exclusively collect progeny derived from diplo-*2* oocytes (oocytes that experienced chromosome *2* nondisjunction). Preliminary data from whole-genome sequencing of these progeny indicate that many nondisjunction events are the result of failure to properly segregate sister chromatids in MII. Intriguingly, all crossovers observed in progeny thus far were single crossovers that occurred in the middle of chromosome arms, which is typical of normal crossover patterning in *Drosophila*.
In the second approach, I analyze heteroduplex DNA (hDNA), double-stranded DNA in which each strand comes from a different DNA molecule, to better understand recombination mechanism. The classical meiotic HR model indicates that a crossover is formed via a double Holliday junction (dHJ), a structure in which two DNA molecules are linked via criss-crossing of their strands at two adjacent sites. In this classical model, ligated dHJs give rise to all crossovers and generate one of two possible hDNA signatures by being cleaved on all four strands. The model predicts that both signatures are equally likely, yet only one of the hDNA signatures has been observed experimentally. Our lab has mapped hDNA at recombinants of a test locus in Drosophila melanogaster, but redefining the meiotic recombination model requires much more extensive analysis of hDNA than is possible with this methodology. To overcome this obstacle, I am pioneering "hetSeq", a whole-genome sequencing technique to detect hDNA from meiotic products, to continue redefining this model. Shedding light on HR mechanism and crossover patterning is critical to our understanding the factors that contribute to proper chromosome disjunction.

1683F **Control of D. mel Centromere Effect: Genetic or Spatial?** Nila M Pazhayam[1], Jeff Sekelsky[2] [1]Genetics and Molecular Biology, UNC Chapel Hill, [2]Biology, UNC Chapel Hill

Crossing-over between homologous chromosomes is a critical part of meiosis that promotes proper chromosome segregation, thereby forestalling miscarriages and chromosomal disorders such as Down syndrome. Meiotic crossovers (COs) are formed from programmed double-strand breaks (DSBs) that undergo homologous recombination. Although DSBs are distributed throughout the chromosome, CO placement is intricately patterned. One such patterning event is the centromere effect (CE) which ensures CO exclusion in pericentromeric regions. Although crucial to the meiotic cell, the mechanisms driving the CE are poorly understood. To address this gap in knowledge, I am studying the CE using *Drosophila melanogaster* as a model system.

The pericentromeric region of *D. melanogaster* isn't homogenous, instead consisting of two distinct types of heterochromatin; highly-repetitive alpha heterochromatin and less-repetitive beta heterochromatin. A previous study from our lab has shown that the CE is distinct in the two types of heterochromatin, with a complete suppression of COs observed in alpha heterochromatin while beta heterochromatin/proximal euchromatin display a distance-dependent suppression. To further characterize CO control in these regions, I will be mapping proximal COs to either alpha or beta heterochromatin in two classes of mutants - genetic and structural – that have previously been shown to weaken the CE. Genetic mutants include mutants such as *mei218* and *rec,* and structural mutants include genes important for heterochromatin formation such as *Su(var)309* and *Su(var)307*. As the question of whether the CE is under genetic or structural/spatial control remains unanswered, this project aims to investigate how centromere-proximal CO formation differs in different classes of mutants. It is possible that in the *Su(var)* mutants being used in our study, we observe COs in the highly-repetitive alpha heterochromatin - where meiotic crossing-over has never been observed before – while proximal COs in the genetic mutants are limited to beta heterochromatin/proximal euchromatin. Ultimately, whatever pattern of proximal CO formation we observe in the two types of heterochromatin in these mutants will shed light on the mechanisms of CO control that are at play in the pericentromere, thereby providing insight into the *Drosophila* centromere effect.

1684F **Elucidating the role of Polo kinase regulation in suppressing drive of the B chromosomes** Kaylah B Samuelson[1,2], Ryan Gado[1], Allison Gardner[1], Stacey L Hanlon[1,2] [1]Molecular and Cell Biology, University of Connecticut, [2]Institute for Systems Genomics, University of Connecticut

Recently, B chromosomes were discovered in a single stock of *D. melanogaster* that carries a null mutation in *matrimony* (*mtrm*^{126}) held over a third chromosome balancer (*TM3, Sb Ser*). This genotype enables the B chromosomes to be transmitted through female meiosis at a higher-than-expected frequency, a phenomenon known as meiotic drive. Mtrm

normally works with Polo kinase (Polo) in a 1:1 genetic ratio to regulate chromosome segregation, leading us to speculate that the maintenance of this ratio is important to suppress the drive of the B chromosomes. To test this, we genetically altered the ratio of *mtrm* and *polo* using null alleles and found that B chromosome transmission frequencies decrease as the genetic levels of Mtrm increase relative to Polo, suggesting that a high Polo:Mtrm ratio is necessary to promote drive of the B chromosomes. Since the direct interaction of Polo and Mtrm has been previously shown to be essential for proper chromosome segregation, we also tested if this interaction is necessary to suppress the drive of the B chromosomes. We found that B chromosome transmission is still high in a $mtrm^{126}/TM3$ background that expresses a mutant transgene of Mtrm that cannot bind Polo ($mtrm^{T40A}$), indicating that the direct interaction of Mtrm and Polo is necessary to suppress drive. Our results show that the regulation of Polo by Mtrm promotes drive suppression, leading us to explore if other pathways that regulate Polo influence the drive of the B chromosomes. We are currently assessing B chromosome transmission in a $mtrm^{126}/TM3$ background that expresses a hypermorphic transgene of Greatwall (Gwl), a meiotic and mitotic kinase that antagonizes Polo. Overall, our investigation will illuminate how the regulation of Polo kinase influences the meiotic drive of the B chromosomes.

1685F **Homologous Recombination during CRISPR-Induced DNA Double-Strand Breaks** Reese L Perini, Evan Dewey, Jeff Sekelsky Biology, UNC Chapel Hill

Homologous recombination repair (HR) is a vital DNA repair mechanism essential for organismal growth and survival. Misregulation of HR can lead to loss of heterozygosity (LOH) in tumor suppressor genes, potentially facilitating the development of genetic diseases such as cancer. LOH occurs when a functional tumor suppressor allele on one homologous chromosome is lost, resulting in homology for a nonfunctional tumor suppressor. Homologous loss of tumor suppressor function promotes cancerous transformation. Most DNA double-strand breaks are resolved into noncrossover (NCO) genetic products by HR. Double-Holliday junction (dHJ) resolution, a type of HR with an intermediate DNA configuration called a dHJ, leads to rarer crossover (CO) products. COs formed during mitosis can lead to dangerous exchanges between homologous chromosomes and LOH. In order to test proposed models and decipher precise mechanisms of dHJ resolution, we reconstructed CRISPR/Cas9 DNA repair products in *Drosophila melanogaster* using PCR and Oxford Nanopore sequencing. Our findings support proposed models of dHJ cleavage. We also found products that are not readily explained by current models. These unique products characterize exceptions to our proposed models of dHJ cleavage, helping us to better understand this recombination mechanism. Results also provide insights into how COs form in general, and how HR works in a CRISPR/Cas9 context, which can lead to more efficient and successful gene-editing strategies.

1686F **Usage of Clamps during Homologous Recombination Repair of Large Gaps in Drosophila** Meaghan Dineen, Bridget Walker, Daniel P. Kane Le Moyne College

Proper repair of DNA damage events is necessary to prevent genomic mutations and the development of diseases and disorders. DNA double-strand breaks (DSBs) are problematic, compared to single-strand breaks, as template for recovery of any lost sequence is not immediately evident. Repair by end joining is error-prone and can result in loss of flanking sequence to the break site. More accurate repair by the homologous recombination (HR) pathway involves synthesis of new DNA to recover any lost information after template invasion, using a sister chromatid or homologous chromosome, and D-loop formation. In Drosophila, the $P\{w^a\}$ assay uses the excision of a transposable element to generate a single 14-kilobase gap, thereby requiring a large amount of nascent synthesis for full recovery. With this assay, we have previously shown that both replicative and translesion synthesis DNA polymerases compete in the repair process, with replicative polymerases being utilized in longer synthesis tract lengths and translesion polymerases in shorter repair synthesis. In our current research, we hope to determine how the selection of these different polymerase types for utilization at sites of DSBs is coordinated. Roles of polymerase clamps are best known in replication and some repair processes, but are not as clear for homologous recombination in gap repair. By examining *hus1* mutants (part of the 9-1-1 clamp complex) and *PCNA2* mutants we hope to elucidate upstream coordination of polymerase-type choice for this nascent DNA synthesis at HR D-loops. Preliminary analysis suggests that, like polymerases, different clamps are utilized for short versus long synthesis tract lengths, demonstrating the need for clamps to recruit and aid polymerase processivity in large-gap HR repair.

1687F **Mechanism of Somatic Chromosome Pairing in *Drosophila melanogaster*** Makenna Johnson, Kent Golic University of Utah

The ability to pair homologous chromosomes in meiosis is fundamental to sexual reproduction and is achieved through various strategies, such as induced double-strand breaks and recombination. *Drosophila melanogaster* and other Diptera are unique in their ability to pair and maintain pairing in somatic cells, even without recombination. The means by which pairing initiates and is maintained has been of intense interest, but definitive models have yet to emerge. Current models hypothesize that initiation can happen in one of two ways: 1) random interactions of the chromosomes, or, 2) initiation at specific sites, such as telomeres, centromeres, or “pairing sites”. After initiation occurs, these homologous sequences are then proposed to ‘zipper’

together until full homolog pairing is achieved. To investigate the mechanism of somatic chromosome pairing we developed a method that uses heterozygous inversions to measure the degree of homolog pairing. *X* chromosome inversions generated by FLP-mediated recombination revert at a high rate in the presence of FLP, a process that requires pairing with an un-inverted homolog. Inversion loop pairing brings inversion breakpoints into close proximity to facilitate recombination and reversion. By deletion analysis we identified a locus in polytene division 11 on the *X* chromosome that acts as pro-pairing sites and a separate locus that acts as anti-pairing site. These sites do not affect autosomal pairing, indicating that they are likely acting structurally, rather than encoding genes involved in pairing. Additional analysis and results suggest that there are many pro- and anti-pairing sites along the length of the chromosome that either initiate or maintain homologous pairing in somatic cells.

1688F **Loss of *Nemp1* triggers oocyte loss by activating DNA Damage Pathway** Bilal A Hakim[1], Yonit Tsatskis[2], Won Ha[2], Andrea Jurisicova[2], Helen McNeill[1] [1]Developmental Biology, Washington University School of Medicine, [2]Lunenfeld Tanenbaum Research Institute, Mount Sinai Hospital

NEMP1, a conserved protein located in the nuclear envelope, is crucial for the process of oogenesis across various species such as flies, worms, fish, and mice. During oogenesis, a developmentally competent female gamete goes through a series of morphological and functional phases from the primordial to the ovulatory follicle. The ovarian lifespan, and ultimately the fertility of an individual, is in part determined by the quantity of primordial follicles in the ovarian reserve. This reserve possesses all the oocytes an individual will have during their reproductive lifespan. *Nemp1*^{KO} mice are viable, but females are severely subfertile with drastically reduced ovarian reserve. The remaining oocytes have poor developmental competence with defects in chromatin organization. Examination of P10 *Nemp1*^{em1Hmc} ovaries revealed an extensive loss of primordial follicles, which was also detected at the P1-P4 stages. Excessive cell death was observed in the P1-P4 ovaries compared to the P10 ovaries, suggesting the reduced ovarian reserve of *Nemp1* mutants may be caused by apoptosis. Embryonic mouse ovarian surface spreads at E17.5 showed 36% *Nemp1* mutant oocytes have a broad patch of □H2aX as compared to 11% in the WT type. Increased incidence of aneuploidy was also observed in pachytene-stage *Nemp1* mutant oocytes. Analysis of meiotic stages at P0 also demonstrated a delay in Meiotic I progression in *Nemp1* mutant oocytes. Since NEMP1 has a conserved role in fertility, we believe Drosophila can be helpful for studying these NEMP1-specific defects. As reported earlier from the lab, Drosophila Nemp null animals are also sterile, with a significantly reduced ovary size and severe germ cell loss. Closer examination of ovaries upon Nemp knockdown revealed phenotypes consistent with activation of DNA damage response (DDR). To investigate the role of the DDR in the absence of Nemp, we used RNAi knockdown of DDR pathway components such as Tefu (Atr, Chek1, Chek2, and p53. Remarkably, loss of ovary size and egg laying caused by germline expression of Nemp RNAi was partially rescued by simultaneous reduction of Tefu or Chek2, demonstrating that a DNA damage checkpoint was triggered upon Nemp loss. The ovarian reserve in *Nemp1*^{KO} mice was also partially rescued in *Nemp1*^{KO}*Chek*^{KO} double mutants, indicating *Nemp1* loss activates a DNA Damage checkpoint in mammals.

1689F **Uncovering the effect of ZMPSTE24 deficiency on genome integrity** Alannah DiCintio, Alan Waldman University of South Carolina

Restrictive Dermopathy (RD), is an autosomal recessive rare genetic disorder that is neonatal lethal. If children are liveborn, they usually do not make it through the first week of life due to pulmonary insufficiency. RD is commonly caused by insertion mutations that produce premature termination codons in both copies of the *ZMPSTE24* gene. Interestingly, ZMPSTE24 levels are also believed to decrease naturally during the aging process. ZMPSTE24 is a protease that plays a key role in the post-translational processing of lamin A, an essential protein in a structure called the nuclear lamina that plays a critical role in a variety of nuclear functions. The form of lamin A produced in the absence of ZMPSTE24 is permanently farnesylated and methylated. Previous studies from our lab and other groups have shown that other mutant forms of lamin A that are incompletely processed disrupt the repair of DNA double-strand breaks (DSBs) and cause a decreased ability to maintain genomic integrity. Changes in DNA repair have also been associated with the normal aging process. To enhance our understanding of both the biology of aging as well as RD, we are investigating the effects of ZMPSTE24 deficiency on DNA repair and damage accumulation. To do so we have stably transfected a DSB repair reporter substrate into the genome of a HeLa cell line that expresses ZMPSTE24 and into a second HeLa cell line in which ZMPSTE24 expression had been knocked out by CRISPR/Cas9. A DSB can be induced within the substrate through exogenous expression of endonuclease I-SceI, and DSB repair events occurring via either homologous recombination (HR) or non-homologous end-joining (NHEJ) are recoverable by genetic selection. Repair by HR is an accurate and templated form of repair, while NHEJ is an error-prone non-templated rejoining of DNA ends that may lead to deletion or insertion mutations. Our work aims to reveal the impact of ZMPSTE24 deficiency on repair pathway choice. We are also investigating DNA damage accumulation in cells that express ZMPSTE24 and ones that do not by directly visualizing γH2AX foci using immunofluorescence approaches. Results to date indicate increased damage in the absence of ZMPSTE24. We present our ongoing studies using our model system to investigate the effects of ZMPSTE24 deficiency on genome integrity.

1690F **The DNA structural landscape at the centromere and pericentromere** Lydia Gutema, Jitendra Thakur Biology, Emory University

Centromeres are chromosomal loci that bind to spindles to facilitate chromosome segregation and ensure faithful inheritance of genetic information in daughter cells. Issues during centromere formation can result in the gain or loss of genetic material in daughter cells, which can have deleterious effects on human health. DNA sequences at the endogenous centromeric locus are highly repetitive, and while there is some sequence similarity, centromeric sequences at different chromosomes are distinct from each other. Despite the lack of conserved sequences, centromeric proteins are recruited to correct site during each round of cell division. How centromeric DNA encodes the centromere in the absence of conserved sequences is not well understood. Additionally, when there is a loss of the endogenous centromeric sequences, ectopic centromeres can form to maintain inheritance of the chromosome, and these mislocalized centromeres can be seen in cancers and developmental disorders. Ectopic centromeres have a non-random distribution across the genome, which raises interesting questions about how centromeres are assembled at these sites. However, conserved features of the DNA or chromatin at ectopic centromeres and at the endogenous centromeres have not been discovered yet. We hypothesize that DNA structures help play a role to specify the sites of centromeres formation. Our early data shows a distinct change in patterns of certain DNA structures within the active centromeric region and the surrounding inactive pericentromeric regions. Our future work will assess how these differences contribute to centromere specification and how proteins at the centromere and pericentromere establish distinct changes in the structural landscape. This work will allow us to address longstanding questions in the field about how the localization of centromeres is determined in humans, and better understand how unique DNA structures play a role in cellular function.

1691F **Characterization of the Overexpression of RecA Homologs *DMC1* and *RAD51* in *Tetrahymena thermophila*** Jianna M. Cox, Joshua J Smith Biomedical Sciences, Missouri State University

Two RecA homologs, *DMC1* and *RAD51*, work to repair DNA double-strand breaks (DSBs) within the cell through the recombination of homologous sections of DNA. While *DMC1* works to repair programmed DSBs through meiotic recombination, *RAD51* functions to repair both meiotic and non-meiotic DSBs, the latter being repaired through the repair process of homologous recombination. Double-strand breaks can occur through various endogenous and exogenous agents, and when not repaired can cause harmful genomic rearrangements and mutations. Chemotherapeutics are an exogenous agent that work to form DSBs in cancer cells, attempting to inhibit the cells from further spread. However, a hyper-recombinant phenotype is often seen in cancer cells due to the overexpression of *RAD51*. This leads to drug resistance, the persistence of cancers, and an overall poor patient outcome. To work to prevent this issue, further research is being conducted on the function of *RAD51*. In the model organism *Tetrahymena thermophila*, an amacronuclear phenotype is observed only at high temperatures, such as 35 °C, when *RAD51* is overexpressed. Further evidence shows that this phenotype is more affected from the change in temperature rather than only the temperature itself. This is due to a complication in the elongation of the macronucleus, and due to the continuation of DNA synthesis, results in a macronucleus containing up to 5 times the normal genetic content. When *DMC1* is overexpressed, no notable phenotype is observed. When studying the relationship between the mutation and survivability of cells when treated with UV and MMS, no strong correlation was observed.

1692F **DNA double-stranded break and new telomere formation during *Ascaris* programmed DNA elimination** Brandon Estrem[1], Jianbin Wang[1,2] [1]Biochemistry & Cellular and Molecular Biology, University of Tennessee Knoxville, [2]UT-ORNL Graduate School of Genome Science and Technology, University of Tennessee Knoxville

Organisms must maintain the integrity and the full complement of their genome in all cells. However, some organisms undergo a process of DNA loss known as programmed DNA elimination (PDE). In metazoans, PDE often occurs during early embryogenesis in all pre-somatic cells, generating a reduced somatic genome. The human and pig parasitic nematode, *Ascaris*, is a model for studying PDE. In *Ascaris*, DNA double-strand breaks (DSBs) are generated at 72 specific genomic loci, fragmenting the 24 germline chromosomes into 36 somatic chromosomes. Broken ends are healed with *de novo* telomere addition to protect the new chromosome ends. Furthermore, about 1000 germline-expressed genes are lost during DNA elimination, providing an ultimate gene silencing mechanism in the somatic cells. Genomic analysis of the telomere addition sites in an *Ascaris* population revealed a 3-6 kb chromosomal break region (CBR) where telomeres can be added. These CBRs are not associated with motif sequences, common histone marks, or small RNAs, suggesting the break recognition process is sequence-independent. However, all CBRs exhibit more accessible chromatin during DNA elimination, indicating specific mechanisms are involved in this process. To further characterize the DSBs, we used END-seq to identify DNA break sites, end resection, and telomere addition. Using embryos across 11 time points of the 4-8 cell stages, we found that DSBs are introduced before mitosis. Our data also revealed long 3' overhangs are generated after DSB formation, suggesting an extensive end resection process occurs after the initial break. Each breakage site›s resection pattern is unique and may be influenced by the local sequence, nucleosome, and chromatin features. We further observed telomere addition occurs

close to the DNA breakage site. In contrast to the retained ends, we found telomeres rarely heal the eliminated ends of the DNA breaks. We also observed that eliminated ends undergo more resection, suggesting a selective mechanism involved in processing retained vs. eliminated ends. This mechanism is likely associated with the micronuclei formation that engulfs the eliminated DNA, preventing telomere addition. In addition to the 72 CBRs, END-seq revealed 28 alternative break sites within the eliminated DNA. These break sites may provide a fail-safe mechanism to ensure PDE occurs. Overall, our results provide insights into the DNA break and telomere healing processes and lead to new questions in *Ascaris* PDE.

1693F **Understanding the function of the C-terminus of Mms21 in genome stability** Yee Mon Thu[1], Nkechinye Baadi[2], Samuel Li[1] [1]Colby College, [2]Biology, Colby College

MMS21 and its human homolog NSMCE2 have various functions in DNA damage repair and response pathways, which play a vital role in defense against genetic diseases and disorders. Mechanistically, Mms21 functions as an E3 SUMO (small-ubiquitin like modifier) ligase which conjugates SUMO peptides to target proteins with the help of E1 and E2 SUMO ligases. We generated mms21Δ22 mutant in S. cerevisiae, a mutant in which the C-terminus is absent, to approximately mimic the human mutation found in a rare genetic disorder. We observed that a mutant of RAD5 (key regulator of the damage tolerance pathway) and the mms21Δ22 mutant exhibit a negative genetic interaction in the presence of methyl methanesulfonate (MMS), a DNA alkylating agent. This data suggests that Rad5 and the pathway regulated by the C-terminus of Mms21 operate in parallel to counteract MMS-induced DNA damage. Rad5 can function as an E3 ubiquitin ligase to initiate the template switching pathway. In addition, the helicase activity of Rad5 modulates fork regression when the replication fork encounters impediments. To further understand this intricate and essential network of DNA damage response and repair pathways, we will determine if the mms21Δ22 mutant genetically interacts with the rad5 helicase mutant or the rad5 E3 ubiquitin ligase mutant. In addition, we are performing an experiment to understand if the human MMS21 gene, NSMCE2, can functionally rescue the lack of yeast MMS21 gene using the plasmid shuffling assay. In this assay, wild type cells are first transformed with MMS21 on a high copy plasmid. This allows us to knock out the endogenous MMS21, which is essential for cellular survival. Cells with the episomal copy of MMS21 are then transformed with the plasmid carrying NSMCE2. Resulting cells with episomal copies of MMS21 and NSMCE2 will then be grown in the presence of a toxicant (5-FOA) that would force cells to lose the plasmid containing MMS21, while retaining the plasmid with NSMCE2. Growing mms21Δ cells with the episomal copy of MMS21 in 5-FOA led to lethality, confirming the feasibility of the approach. We are currently generating all appropriate strains to determine if the human copy can functionally complement the yeast gene. If such a system is successful, we will characterize cellular and molecular significance of additional NSMCE2 mutations associated with human genetic conditions using this approach.

1694F **The BUDdy System: investigation of GEF and GTPase function in the mitotic exit network in*S. cerevisiae*** Nathalie Merisca, Jennifer Madu, Daniel Sullivan, Anupama Seshan Biology, Emmanuel College

The mitotic exit network, or MEN, in budding yeast, is a Ras-like signaling pathway that governs the cell cycle transition from the end of mitosis into G1. MEN activation is coupled to proper chromosome segregation, and more specifically to the entry of the daughter spindle pole body (dSPB) into the bud. The GTPase Tem1 acts at the top of the pathway and is activated in late anaphase. Tem1 is localized to SPBs and SPB localization is required for its activity. The kinase Kin4 inhibits MEN by preventing Tem1 from localizing. The protein Lte1 inhibits Kin4 and is localized to the daughter cell cortex from S phase to late anaphase. Lte1 prevents Kin4 from binding to the dSPB and in this manner acts as an indirect activator of Tem1. However, Lte1 contains N-terminal and C-terminal guanine nucleotide exchange factor (GEF) domains. These domains are important for Lte1 localization, but we hypothesized that these GEF-homology domains are also important for Lte1 to directly activate Tem1. In this study, we analyzed the impacts of amino acid substitutions within predicted Helix B of Lte1's C-terminal GEF homology domain, which we hypothesized to be important for Lte1 function based on homology modeling with two known GEFs, Sos and RasGRF1. We found that the majority of substitutions (20 out of 25) produced stable protein. We also found that the localization pattern of the Helix B mutants corresponded with their functionality. However, one mutant, I694A, was well localized but still unable to promote mitotic exit. Two other mutants, I683A and N687T, were localized normally, but are only partially functional in promoting mitotic exit. These are the first alleles of *LTE1* where localization does not correlate with functionality. We further investigate how these alleles of *LTE1* impact the localization and activation of Tem1. Our research indicates that budding yeast can be a useful model to study signaling pathway paradigms.

1695F **Genetic interaction studies to understand the function of the C-terminus of Mms21 in genome stability** Cheung Li[1], Lindsey Kim[1], Aleksandra Avramenko[1], Yee Mon Thu[2] [1]Colby College, [2]Biology, Colby College

Sumoylation of proteins coordinates various cellular mechanisms responsible for ensuring genome integrity. Sumoylation is carried out by E1, E2 and E3 SUMO ligases, which facilitate the covalent linkage of small ubiquitin-like modifiers (SUMO) peptide to target proteins. The importance of sumoylation in genome integrity is underscored by genetic disorders associated

with mutations in the SUMO pathway. Truncation mutants of Mms21, an E3 SUMO ligase, have been observed in a rare genetic condition. To characterize how one of these mutations may affect the function of Mms21, we generated the mutant in *Saccharomyces cerevisiae*. This mutant, *mms21Δ22*, lacks the last 22 amino acids of the protein but does not affect the residues in the E3 ligase domain. *mms21Δ22* mutants exhibit negative genetic interaction with *rad5* mutants, suggesting that the C-terminus of Mms21 regulates DNA damage response pathways acting in parallel with the template switching pathway. However, *mms21Δ22* mutants show little or no genetic interaction with *slx4* or *mms4* mutants. These data imply that processes modulated by the Mms21 C-terminus work in tandem with DNA repair pathways that utilize structure specific endonucleases. We found that the SUMO-interacting motif within the C-terminus is not responsible for the phenotype observed. Since the error-prone translesion synthesis functions in parallel to the template switching pathway, we are examining the mutagenic potential of *mms21Δ22* mutants in response to DNA damaging agents. In addition, we are currently performing a dosage suppression screen to uncover which genes cooperate with the C-terminal regulation of Mms21.

1696F **Determining the role of lysine residues in the regulation and function of the DNA mismatch repair protein Msh6.** Kalila Daveron[1], Kayla Carmichael[2], Joanna Haye-Bertolozzi[2] [1]Biology, Xavier University of Louisiana, [2]Xavier University of Louisiana

The DNA Mismatch Repair (MMR) system functions to protect the integrity of the genome in living organisms. Defects in the DNA MMR process can result in increased mutation rates, which in humans can result in Lynch syndrome and increased cancer susceptibility. The initial step of MMR, mismatch recognition, is performed by the protein complex MutSα (Msh2/Msh6). Previous research showed that absence of the lysine acetyl transferase General Control Nonderepressible (Gcn5) results in the increased stability of Msh2. It is also known that Gcn5 acetylates certain lysine residues in Msh6. Additionally, absence of the ubiquitin ligase Modulator of Transcription (Not4) resulted in increased Msh2 protein levels. Our aim is to establish the role of Gcn5 in the regulation of MutSα. We hypothesized that lysine residues in Msh6 may be acetylated by Gcn5, stabilizing the complex. To test our hypothesis we mutated lysine residues, potential Gcn5 acetylation sites, in Msh6 singly and in combination. Lysine residues targeted were primarily in the N-terminus of Msh6 and were changed to alanine, arginine, or glutamine. Using the *CAN1* forward mutation assay, the Msh6 lysine mutants were tested for impact on MMR function in the yeast *Saccharomyces cerevisiae*. Initial analysis of lysine residues shows varying effects on MMR in the mutants tested. We have identified other lysine residues in Msh6 that will be altered to test the effect of mutagenesis on Msh6 protein function.

1697F **Investigating the origin and nature of half-crossover cascades in *Saccharomyces cerevisiae*** Camryn Schmelzer, Ruth Watson, Juan Lucas Argueso Environmental and Radiological Health Sciences, Colorado State University

A half-crossover (HC) cascade is a mutagenic sub-pathway of homologous recombination (HR), where a singular DNA double-stranded break (DSB) is able to trigger the formation of multiple chromosomal translocations. When a DSB is formed but only one of the two broken ends is captured to engage in HR, the repair will proceed through Break-Induced Replication (BIR). In BIR, the single-ended DSB invades a homologous donor sequence and uses it to initiate DNA replication that extends through the end of the template chromosome. Failure of BIR initiation and/or irregular processing of BIR intermediates can lead to half-crossover (HC) formation, in which the single-ended DSB is healed through a translocation, breaking the donor molecule in the process, leaving it with only one DNA end to engage in HR repair. This futile repair attempt may spawn another half-crossover, thus resulting the “cascading” nature of the mechanism. HC cascades can lead to cycles of translocations until BIR occurs to end the series of rearrangements. Structure Selective Endonucleases (SSEs) have been implicated in HC formation. Generally, SSEs cut residual DNA joint molecules, such as D-loops and Holliday Junctions, to conclude HR repair. However, the premature activation of SSEs, such as Mus81 and Yen1, during BIR may generate deleterious HCs. Additionally, Pol32 is an accessory subunit of Poldand largely required for BIR; cells deficient for Pol32 are likely predisposed to HC cascade formation. We have constructed an experimental system in *Saccharomyces cerevisiae* designed to phenotypically identify clones that specifically experienced a cascade of HCs followed by one BIR event that heals the chromosome. We are investigating the roles of Mus81, Yen1, and Pol32 in HC cascade formation, measuring the frequency of HC cascades, and characterizing the resultant rearrangements through Pulse Field Gel Electrophoresis (PFGE) and targeted long-read sequencing across translocation junctions. We postulate HC cascades result from an imbalance between BIR initiation and SSE activation.

1698F **CRISPR is a source of genotoxic stress, even in the absence of gRNA** Stephan C Baehr[1], Samuel Perez[1], Adalyn Brown[1], Alyssa Cenzano[1,2], Katelyn Hancock[1], Lea Patrick[1], Michael Lynch[1] [1]Biodesign Institute, Mechanisms of Evolution, Arizona State University, [2]ASU Preparatory Academy Polytechnic High School

CRISPR is a gene editing platform with seemingly endless applications, from engineering to science and medicine. The excitement of CRISPR’s potential has lead to hundreds of clinical trials aimed at treating human genetic diseases. However, the field is aware that CRISPR’s promise is not entirely without risk; CRISPR by its nature modifies the genome, and may have off-target effects. No enzyme or machine is perfect. Researchers have diligently sought to quantify mutation risk, by testing a specific locus, or set of loci. However, to date, we are unaware of any experiment using the most sensitive detection methods

of evolutionary biology, which can detect error rates that may occur one in a trillion bases per cell division. We demonstrate a mutational hazard of expressing Cas9 to an untargeted locus of yeast, *S. cerevisiae*, which demonstrates a dose-response relationship with increasing Cas9 expression. We find a modest 1.2-fold to 2.7-fold increase in mutation rate, as quantified by fluctuation test. We demonstrate that gRNA appears to increase the mutagenicity of CRISPR, be it Cas9, Cas14, or an Adenine Base Editor (ABE). We note that if indels are the primary means of mutation mechanism in Cas9, the indel rate may be 10-fold higher in our high-expression yeast lines relative to WT controls.

1699F **Checking Set1 activity to ensure meiotic progression** Jayne E Steitz[1], Yasmin Mourad[1], Alexa Sirchio[2], Michael Law[1] [1]Biology, Stockton University, [2]Biological Sciences, Fordham University

Cell fate determination requires faithfully integrating external environmental signaling cues with internal genetic and epigenetic status. Mistakes in signal interpretation can lead to developmental defects or cancer. While the genetics of dividing and differentiating cells are identical, the epigenetics of the cells must be reprogrammed to accommodate distinct fates. In diploid cells of the budding yeast Saccharomyces cerevisiae, mitosis is stimulated in rich growth conditions while meiosis is induced during nutrient depletion. In yeast, many epigenetic regulators are dispensable for mitosis but are essential for meiosis, highlighting the importance of reprogramming the epigenome during this process. Meiosis has several distinct events including pre-meiotic S phase, homologous pairing and recombination, and two rounds of cell division which yield four haploid gametes. Prior to these events, several checkpoint pathways are in place to ensure mistakes are not made prior to cell division. Using a genetic approach, recent work from our laboratory demonstrated that the histone H3 Lys4 methyltransferase, SET1, is essential for progression through homologous recombination and meiosis I, suggesting a key role in satisfying the checkpoints that survey these processes. Surprisingly, Western blot analyses indicate that Set1 is degraded during meiosis, which contradicts its essential behavior for meiosis I. To determine the requirement of Set1 for advancement through meiotic checkpoints, we utilized chemical treatments that induce checkpoint arrest and measured myc-Set1 levels by Western blotting analyses. Yeast harboring myc-Set1 were induced to enter meiosis and treated with 1) hydroxyurea (HU) or 2) nocodazole. HU treatment causes DNA damage, which will arrest cells prior to pre-meiotic S-phase. In contrast, nocodazole results in tubulin depolymerization and will induce the spindle assembly checkpoint prior to meiosis I. We predict Set1 degradation should be initiated following its supportive role in executing the important early meiotic hallmarks of homologous recombination and meiosis I. These experiments will pinpoint when Set1 activity is necessary for cells to efficiently execute the meiotic program.

1700F **Investigating the Role of Mismatch Repair in Promoting Trinucleotide Repeat Expansions in *Saccharomyces cerevisiae*** Katherine M Casazza, Gregory Williams, Lauren Johengen, Maxwell Keller, Brett Irwin, Samantha Phelps, Natalie Lamb, Jennifer A Surtees Biochemistry, University at Buffalo

Mismatch repair (MMR) is an important DNA repair mechanism that protects genomic stability through correcting polymerase errors at the replication fork. In most eukaryotes, including *Saccharomyces cerevisiae* and humans, MMR is initiated by MutS homolog (MSH) complexes, Msh2-Msh3 and Msh2-Msh6, recognizing and binding misincorporations and insertion/deletion loops, respectively. MSH-DNA complexes recruit and activate the latent endonuclease activity of downstream MutL homolog (MLH) complexes, Mlh1-Pms1 and/or Mlh1-Mlh3, to nick the DNA and recruit downstream repair factors. A third MLH complex, Mlh1-Mlh2, lacks endonuclease activity and acts as an accessory factor for both Msh2-Msh3- and Msh2-Msh6-mediated MMR. Deficiencies in the MMR system can lead to Lynch syndrome, a predisposition to cancer and microsatellite instability. While MMR is critical for protecting the genome by preventing mutagenesis, components of the MMR system have been implicated in promoting trinucleotide repeat (TNR) expansions. TNR expansions are the cause of over 40 neurodegenerative and neuromuscular diseases such as Huntington's disease and myotonic dystrophy which are caused by *CAG* and *CTG* repeats respectively. In stark contrast to their function in promoting replication fidelity, components of the MMR system exhibit a pathogenic role through promoting TNR expansions. Using an *in vivo* TNR assay to measure expansion frequencies in *S. cerevisiae*, we previously demonstrated that Msh2-Msh3 can promote genome instability through both *CAG* and *CTG* expansions *in vivo*. This is consistent with work in mice and humans as well as GWAS studies that identified Msh3 as a genetic modifier of expansions. Our work aims to elucidate mechanistic details of Msh3 promoted expansions of threshold length TNR tracts and their distinctions from Msh3-mediated repair. We have demonstrated that Msh3 specific DNA binding is not sufficient for TNR instability. Additionally, we highlight the involvement of all three MLH complexes in promoting tract expansions *in vivo*. Our data demonstrate the importance of an active, albeit aberrant, MMR pathway in promoting TNR expansions. We also report distinct MSH-DNA binding between MMR and TNR structures, *in vitro*. We propose a model in which the TNR DNA structure directs allosteric changes within Msh2-Msh3 that promote a pathogenic Msh2-Msh3-mediated MMR that ultimately leads to TNR expansions.

1701F **Size *Does* Matter: The characterization of telomere function in germ cell development in *Danio rerio*** Jessica MacNeil[1], Sophie Chaviari[1], Cheyenne Petrino[2], Amelia Babb[2], Kellee Siegfried[2] [1]Biology, University of Massachusetts, Boston, [2]University of Massachusetts, Boston

Infertility is a growing problem worldwide and according to the WHO, 48 million couples across the globe suffer from it, so many couples turn to Assisted Reproductive Technology (ART) to become pregnant. A main readout of successful ART can be telomere integrity because telomeres are necessary in aiding the movement of chromosomes during meiosis so that the segregation of chromosomes happens correctly. Telomeres are well known for their role in aging; however, they play an important and understudied role during meiosis. In meiosis, telomeres attach to the nuclear envelope (NE) via a protein chain spanning the NE that interacts with cytoplasmic motor proteins. Through this interaction, chromosomes are shuffled within the nucleus to facilitate homologous chromosome pairing. If this process does not proceed normally, aneuploid gametes may be produced leading to infertility or congenital defects in offspring. Through studying the necessity of telomere length using *telomerase reverse transcriptase* (*tert*) mutant zebrafish, I aim to tease apart the functions of telomeres during gamete development. The *tert* mutant phenotype includes decreased telomere length, aberrant germ cell development, and infertility. I hypothesize that the gonad defects are in part due to problems in meiosis resulting from the shortened telomeres. I found that the meiotic cells in the testis are more sensitive to telomere shortening than non-meiotic cells. By analyzing germ cells undergoing meiosis at 5 months of age, I found an increase of spermatocytes in the leptotene stage of meiotic prophase I, which is when telomeres attach to the NE, suggesting that telomeres of appropriate length are required for meiotic progression. I also found there to be an increase in yH2ax staining in mutant pachytene nuclei, suggesting problems in resolving DSBs necessary for recombination. To get a complete picture of how meiosis is disrupted by shortened telomeres, I am assaying for telomere-NE attachment, homologous chromosome pairing and synapsis, and recombination in fish of different ages. Overall, I will learn how different aspects of meiosis can be affected by shortened telomeres and the importance that telomeres have not only on aging, but in meiosis and overall fertility.

1702S **Formation and stabilization of crossover compartments during *C. elegans* meiosis** Celja Uebel[1], Anne Villeneuve[2] [1]Developmental Biology, Stanford University, [2]Developmental Biology and Genetics, Stanford University

Crossovers (COs) are required to ensure proper segregation of homologous chromosomes during meiosis I in most eukaryotes, yet CO formation is a tightly restricted process. Many organisms designate only a single CO site per chromosome pair or per chromosome arm, despite a substantial excess of the double-strand DNA breaks (DSBs) that serve as the initiating events of recombination, with the majority of DSBs being repaired as non-COs. This restriction of CO formation necessitates that each site designated to become a CO must reliably mature as a CO. Prior research led to a working model in which: 1) A distinct architecture of recombination factors and the formation of a spatially-separated CO-specific repair compartment protects and stabilizes CO intermediates, and 2) Positive feedback involving CDK-2/COSA-1-mediated phosphorylation and scaffold-like properties of the C-terminal tail of MutSγ component MSH-5 combine to promote full recruitment and activity of CO-promoting complexes within the CO-specific repair compartment, thereby conferring robustness to CO designation and maturation. We will expand on this model through our analysis of COSA-2 (CO-Site Associated-2), a new factor identified in an updated genetic screen for mutants defective in meiotic chromosome segregation.

COSA-2 is essential for CO formation, and it becomes abruptly localized to six bright foci per nucleus at late pachynema, colocalizing with other recombination factors at the single CO-designated site per chromosome pair. Moreover, COSA-2 is not required for loading of recombination factors during earlier stages of meiotic prophase, but is specifically required for retention/accumulation of pro-CO factors at late-pachytene CO sites. Super-resolution microscopy reveals a dynamic sub-localization of COSA-2 within CO-site compartments relative to the positions of factors previously inferred to interact with underlying recombination intermediates. The COSA-2 protein contains charged patches and is intrinsically disordered, hallmarks of hub proteins with the potential to bind multiple partners or act as central scaffolds for large multi-protein assemblages. Together these features suggest that COSA-2 may function as “molecular glue”, serving as a hub protein to organize/stabilize the spatially separated compartments that promote CO factor accumulation and architecture of CO-designated sites, thus ensuring formation of a single CO event per chromosome pair.

1703S **Comparison of meiotic proteins REC-1/HIM-5 in *Caenorhabditis elegans* and *Caenorhabditis briggsae*** Michelle Scuzzarella, Judy Yanowitz MWRI, Magee-Womens Research Institute

DNA double-strand breaks (DSBs) are highly deleterious, yet necessary for exchange of genetic material during crossover (CO) formation in meiosis. CO formation is required for the physical connection and proper alignment of homologs to prevent nondisjunction of chromosomes during meiosis I.

In *C. elegans,* most chromosomes receive a single CO on the recombinogenic and less gene-dense chromosome arms, while avoiding the more gene rich chromosome centers. In this organism, the *rec-1* gene is responsible for maintaining normal CO distribution. The number of CO events remains unchanged in *rec-1*mutants, while the location of crossovers is altered. The *him-5* gene plays a role in maintaining normal crossover distribution, while also promoting DSB formation on the X chromosome. When both genes are mutated, more severe defects in DSB formation are observed with nondisjunction of

autosomes also occurring.

Prior studies showed that the *rec-1* and *him-5* genes are distantly related paralogs with a single ancestral gene in other *Caenorhabditis* species. The gene coding for REC-1 is in a synteny block on LG I that is conserved in order and orientation in at least six other *Caenorhabditis* species but the genes in the *rec-1* position show greater sequence similarity with *C. elegans him-5*, which is found on LG V. This evidence, as well as their redundant roles in meiosis suggest that *rec-1* and *him-5* are distantly related paralogs.

We have used the CRISPR/Cas9 gene editing system to create a knockout mutant in the *Caenorhabditis briggsae* paralog of these two genes, *cbg25171*, with the intention of exploring the evolution of these genes and the effect on meiosis in a closely related species. The presence of males in this population has been observed, as well as an increased number of univalents at diakinesis, which indicates an increase in nondisjunction. Based on preliminary data, we hypothesize that *cbg25171* plays a similar role in *C. briggsae*meiosis as both *rec-1* and *him-5* do together in *C. elegans* despite low sequence similarity. Further functional analysis of the *C. briggsae* mutations of the *rec-1/him-5* paralog will be presented.

1704S **Characterization of mutations that affect sex-specific thermotolerance of the synaptonemal complex in *C. elegans* germ cells** Nicolas Lee, Cori Cahoon, Diana Libuda University of Oregon

Meiosis is a specialized form of cell division carried out by sexually reproducing organisms to produce haploid gametes, such as sperm and eggs. Various facets of meiosis are sexually dimorphic which impacts how each sex responds to environmental stressors, such as temperature. Unlike oogenesis, spermatogenesis is extremely sensitive to changes in temperature with heat exposure strongly linked to male infertility, increased DNA damage, and cancer. Although the mechanisms behind this heat-induced male infertility are not clearly defined, our recent data suggests that sexual dimorphisms in the synaptonemal complex (SC), a meiosis-specific chromosome structure, may contribute to the heat sensitivity of spermatocytes in *Caenorhabditis elegans*. The SC is essential for fertility in both sexes, but is highly sensitive to acute heat exposure only in developing sperm. Heat stress of the SC in spermatocytes prompts early SC disassembly and the shortening of the *C. elegans* germline. To determine the proteins that render the SC temperature sensitive, specifically in sperm, we performed a fluorescent-based forward genetic screen. The ongoing genetic screen has identified 26 mutants that alter the SC response to heat by enhancing or suppressing the heat induced SC defects, or displaying other sperm-specific SC defects such as a complete loss of the SC. To identify the causal mutations behind each mutant phenotype, we are utilizing whole genome sequencing and SNP-based recombination mapping. From this analysis, we are generating a candidate list of genes from the genomic region linked to the causal mutation. With established computation pipelines, we are characterizing the candidate genes to uncover the proteins contributing to the temperature sensitivity of sperm. Overall, these studies will reveal the molecular mechanisms by which each mutant alters SC heat sensitivity providing insights into the processes causing heat-induced male infertility.

1705S **The sex specific function of CLS-2 during male sperm meiosis in *Caenorhabditis elegans*** Allen M Ramsey, Sebastian Gomez, Cuc Huynh, Vanessa Cota San Francisco State University

Roughly 1 in 6 people will struggle with infertility, with male factors contributing to 50% of all cases. We know that anucleate or aneuploid sperm can fertilize an oocyte leading to chromosomal abnormalities in embryos. Utilizing Caenorhabditis elegans (*C. elegans*) as a model organism, we aim to elucidate the mechanism of chromosome segregation during sperm meiosis.

The machinery driving faithful chromosome segregation is integral in avoiding chromosomal abnormalities. The central spindle and centrosomes are the primary structures that drive the movement of chromosomes during cell division. Sperm only have centrosomes, unlike oocytes and mitotic cells. The CLS-2 kinetochore protein plays a key role in mediating the attachment of centrosomes to chromosomes. In *C. elegans*, we see a sperm specific localization of CLS-2 surrounding the chromosomes, a distinct difference from other types of cell division. In both mitosis and oocyte meiosis CLS-2 generates the central spindle while localized to the midzone and dissipates as soon as the central spindle has formed, whereas we see CLS-2 stay localized to the chromosomes throughout the entire meiotic process in sperm. We hypothesize that chromosome segregation in sperm meiosis is driven by the centrosomes and that CLS-2 mediates centrosome association of sister chromatids during bi-orientation at metaphase II. The change in localization and persistence of the CLS-2 supports a more integral chromosome-associated function during sperm meiosis. The primary ability of CLS-2 as a microtubule stabilizer suggests that throughout the two segregations seen in sperm meiosis there is a more dynamic machinery involved compared to mitosis and oocyte meiosis.

To test this, we will utilize 3-D reconstruction of live imaged *C. elegans* with three endogenous fluorescent reporters allowing for the visualization of CLS-2's localization in relation to chromosomes and microtubules. We expect to see a similar velocity between centrosome and chromosome dynamics supporting centrosome driven segregation. We will also compare chromosome and centrosome dynamics alongside CLS-2 localization with that of a CLS-2 protein depleted worms utilizing the Auxin Induced Degron Pathway. This will allow for clear characterization of deleterious phenotypes with the expectation of

failed chromosome biorientation and a longer time between each phase of meiosis when CLS-2 is depleted.

1706S **Investigating B chromosome dynamics during female meiosis in *Drosophila melanogaster*** Mengjia Lin[1,2], Stacey Hanlon[1,2] [1]Molecular and Cell Biology, University of Connecticut, [2]Institute for Systems Genomics, University of Connecticut

B chromosomes, which are extra, non-essential chromosomes, were recently discovered in a single mutant laboratory stock of *D. melanogaster.* This mutant background promotes meiotic drive of the B chromosomes in females, resulting in their biased transmission to progeny. The arrangement of B chromosomes at the metaphase I arrest is abnormal and is associated with elevated B chromosome transmission, but it is unknown if the B chromosomes also display abnormal behavior prior to this arrest (in prometaphase I) or after the arrest during the meiotic divisions. Using fluorescent *in situ* hybridization (FISH) and immunofluorescence (IF) to visualize the B chromosomes and the meiotic spindle, respectively, we first examined the arrangement of B chromosomes in prometaphase I when chromosomes are forming attachments to the meiotic spindle and are highly dynamic. We aim to present our findings that will show where the B chromosomes are before settling into a single DNA mass at the metaphase I arrest. We have currently shifted our investigation to visualizing B chromosome dynamics during the meiotic divisions by collecting freshly laid eggs that are in late-stage meiosis since the meiotic divisions rapidly occur as the egg is moving through the oviduct. Our goal is to observe the location of the B chromosomes at each division stage and elucidate how they are taking advantage of the asymmetry of female meiosis to promote their own transmission. Understanding B chromosome dynamics during female meiosis will provide novel insights into how non-essential, newly formed chromosomes can be transmitted with bias, promoting their maintenance in a population over many generations.

1707S **Maintenance of genomic integrity in the male germline of *Drosophila melanogaster*** Kate Lemons, Kent Golic University of Utah

The germline is integral to survival of a species. To maintain genome integrity in the germline there must be effective and rigorous systems to eliminate cells with DNA damage, such as unrepaired double strand breaks (DSBs). The DNA Damage Response has been well studied and defined in somatic cells: at its core, the protein kinase Chk2 phosphorylates the transcription factor P53 ultimately leading to apoptosis of the cell. Previous research has shown that, in the germline, Chk2 is necessary to eliminate cells with DSBs but P53 is not. We further examined the role of Chk2 in maintaining germline integrity. We found that each of Chk2's functional domains are required for its function. Critically, the necessity of the kinase domain indicates that it acts by phosphorylating a downstream target. However, since P53 is not involved in eliminating cells with damaged DNA in the germline, there must be an alternate target. In some systems Chk2 has been shown to phosphorylate and inactivate String (Stg, aka Cdc25), a positive regulator of cell cycle progression. We found that overexpression of stg^{+} mimics the phenotype of *chk2-null*. This strongly suggests that Chk2 phosphorylates Stg to halt cell cycle progression, and that this is the mechanism used to eliminate germline cells with unrepaired DNA damage.

1708S **Mechanism of natural variation in double-strand break repair:** Shahrzad Hajiarbabi, Erin Kelleher Biology and Biochemistry, University of Houston

DNA repair is critical to maintaining genome sequence fidelity in the face of endogenous and environmental mutagens, yet individuals in natural populations often differ in their capacity to repair different forms of DNA damage. We previously mapped natural genetic variation in wild-type *Drosophila melanogaster* in sensitivity to double-stranded breaks (DSBs) to a large locus near the 2nd chromosome centromere. Mutagen-sensitive flies are extremely sensitive to DSB caused by X-ray irradiation and *P*-element transposition, however, the DNA damage response or repair pathways whose reduced function explains these mutagen-sensitive phenotypes remains unknown. Persistent DSBs will lead to the activation of kinases which are responsible for the phosphorylation of downstream genes involved in the induction of cell cycle arrest, repair, and eventually apoptosis. DSBs in *D. melanogaster* are preferentially repaired through homologous recombination repair (HR); however, canonical non-homologous end joining (c-NHEJ) and alternative end joining (alt-EJ) pathways are also used to repair DSBs. To uncover the mechanism of mutagen sensitivity, I am comparing mutagen-sensitive and tolerant alleles with respect to 1) sensitivity to a panel of mutagens that lead to DSBs and 2) repair products of DSBs. Unique sensitivity to particular classes of mutagens can be diagnostic of specific repair deficiencies. Similarly, differences in repair products can be diagnostic of repair processes whose function is reduced.

We discovered that sensitive alleles exhibit dominant and strong sensitivity to Nitrogen mustard, which causes interstrand crosslinks, as well as weaker recessive sensitivity to Hydroxyurea. In contrast, sensitive alleles do not differ from wild-type flies in their response to mutagens such as Camptothecin, Etoposide, and Methyl methanesulfonate. While interstrand crosslink repair remains poorly understood, evidence suggests it requires homologous recombination. Future examination of repair products will reveal any differences in homologous recombination between mutagen-sensitive and tolerant flies. Together, my experiments will point to why individuals differ with respect to sensitivity to DNA damage.

1709S **In *Drosophila melanogaster*, survivors of Blm-deficient development exhibit a neurodegenerative phenotype that includes sleep and circadian rhythm disruption** Tesla Presnell, Ava Hasenoehrl, Brayden Graves, Abigail Brown, Sara Hathaway, Jayden Youngren, Eric Stoffregen Lewis-Clark State College

DNA damage caused by a lack of maternally loaded Blm protein during early embryonic development in *Drosophila melanogaster* results in significant embryonic lethality. It is unknown, however, how this DNA damage affects normal physiologic processes in the few surviving individuals. We investigated whether this developmental abnormality (Blm-deficiency induced DNA damage) causes neurologic dysfunction in adult survivors. We hypothesized that DNA damage exposure in early development would cause increased neurodegeneration and disrupt normal circadian and sleep patterns. Circadian rhythms are the internal body clocks that cycle approximately every 24 hours and regulate many daily behaviors and physiological processes, including sleep. To test our hypotheses, we collected adult progeny from Blm^{-} mothers crossed to Blm^{+} fathers and from the reciprocal cross, Blm^{+} mothers crossed to Blm^{-} fathers. In both crosses, the progeny were heterozygous for *Blm*, but one set developed with maternally loaded Blm protein and one without. We used a climbing assay to measure motor function and saw a significant decrease in climbing ability at multiple ages in adult flies that developed without maternal Blm, suggesting increased neurodegeneration. We investigated sleep and circadian rhythms using a continuous activity monitor. Our data suggests abnormal circadian patterns and disrupted sleep in flies that developed without maternal Blm protein. Each of these phenotypes has been associated with aging in flies. However, we did not detect an increase in protein aggregates in flies that developed without maternal Blm, suggesting our phenotypes are not a result of accelerated aging in these flies.

1710S **Maternal effect of RNASEH2C loss in *Drosophila melanogaster* during embryogenesis** Sara K Martin[1], Mitch McVey[2] [1]Tufts University, [2]Biology Department, Tufts University

RNASE H2 is a three subunit enzyme that resolves RNA-DNA hybrids and cleaves at incorporated ribonucleotides (rNMPs) in the genome to maintain genome integrity. In mammals these functions are vital to DNA replication and knockout mice for the RNASE H2 are embryonic lethal. Hypomorphic mutations in the three subunits cause an autoinflammatory disease in humans Aicardi-Goutières syndrome. While RNASEH2A is the catalytic subunit, loss of the accessory subunits B or C also prevents catalytic activity.

In order to study the functions of RNASE H2 in an in vivo model, I made *Rnaseh2c* knockout mutants in *Drosophila melanogaster*. Unlike their murine counterparts, homozygous *Rnaseh2c* mutant flies were viable providing an opportunity to study loss of RNASEH2C in an in vivo model. Maternal transcripts are used in the first two hours of rapid replication during Drosophila embryogenesis raising the question if maternal loading from heterozygous mothers enabled homozygous *Rnaseh2c* null fly embryos to survive.

When homozygous *Rnaseh2c* females were crossed to wild-type males the hatching rate was significantly reduced compared to wild-type females mated to wild-type males (59% relative to 91%). Observationally very few heterozygous larvae from homozygous mothers survived to adult hood. On the other hand, heterozygous *Rnaseh2c* embryos from wild-type mothers had a normal hatching rate and most larvae survived to adulthood. This implies that loss of RNASEH2C during the first few hours of embryogenesis impairs development in heterozygous progeny. In a startling contrast, homozygous embryos derived from homozygous mothers and fathers had a normal hatching rate and no observed increased larval death.

One untested hypothesis to explain this unexpected result is that loss of RNASEH2C during the first two hours of embryogenesis results in accumulation of RNA-DNA hybrids and rNMPs that Drosophila embryos can tolerate, but activation of the zygotic genome brings back RNASE H2 activity that acts on accumulated substrates and results in toxic intermediates. Currently, we are measuring levels of RNA-DNA hybrids and rNMPs during embryogenesis, and monitoring markers of DNA damage across embryogenesis to assess how they correlate with activation of the zygotic genome.

1711S ***Y*-chromosomes create a survival disadvantage in male *Drosophila melanogaster* that lack Blm protein during early development** Jayden Youngren, Abigail Brown, Brayden Graves, Ava Hasenoehrl, Sara Hathaway, Tesla Presnell, Eric Stoffregen Lewis-Clark State College

The absence of maternally provided Blm DNA helicase during early embryonic development leads to severe DNA damage in *Drosophila melanogaster*. This Blm-deficiency is lethal to most embryos. An extreme sex bias is seen in the small percent that do survive, where ~70-90% of the population is female. This female sex-bias amongst the surviving progeny correlates with repetitive DNA content. The female karyotype (*XX*) contains less repetitive DNA compared to the male karyotype (*XY*), due to the highly repetitive nature of the *Y* chromosome in *Drosophila*. Additionally, embryos from Blm^{-} mothers have a higher probability of aneuploid sex chromosome karyotypes caused by increased meiotic nondisjunction. These karyotypes

include *XO*, where no second sex chromosome exists and results in a male phenotype, and *XXY*, where an extra *X* chromosome results in a female phenotype. We hypothesized that, due to differences in repetitive DNA content, *XO* males would be more common than *XXY* females amongst the survivors of Blm-deficient early development. Additionally, we hypothesized that *XO* males would exhibit longer lifespans than *XY* males because of the reduced repetitive DNA content present during Blm-deficient development. To test these hypotheses, we assayed for the presence or absence of a *Y* chromosome in male and female survivors of Blm-deficient development (from Blm^{-} mothers) and also compared the karyotypes of adult male flies (*XO* vs. *XY*) that exhibited shorter vs. longer lifespans. As expected, we saw significantly more *XO* than *XXY* adult progeny survive Blm-deficient development and *XO* males from Blm^{-} mothers outlive *XY* males.

1712S **Metabolic dysfunction in survivors of Blm-deficient development in *Drosophila melanogaster*** Sara Hathaway, Abigail Brown, Ava Hasenoehrl, Brayden Graves, Tesla Presnell, Jayden Youngren, Eric Stoffregen Lewis-Clark State College

Blm DNA helicase is essential for proper DNA replication during early development in *Drosophila melanogaster*. Blm^{-} mothers, who do not provision their eggs with functional Blm protein, exhibit a maternal-effect lethality. Nearly all progeny from Blm^{-} mothers die prior to larval hatching; however, a few progeny do survive to adulthood (<10% of embryos). These survivors provide a model in which to study the effects of DNA damage during early development on healthspan. We hypothesized that survivors of Blm-deficient development would display alterations in metabolic function. We tested whether development without Blm protein affected triglyceride, free glucose, or total glucose levels in adult flies. Our data suggests that Blm-deficient development results in lower triglyceride levels in adult flies (male and female) and in reduced glycogen levels in adult males. We saw no significant differences in free glucose levels (males and females) or in glycogen levels in females that developed with or without Blm. These data suggest that the DNA damage sustained by embryos lacking Blm during early cell cycles affects metabolic processes, particularly those related to nutrient storage, into adulthood.

1713S **Physiological Response of DGRP lines to hypoxia and cold stress.** Amelia E May[1], Natalia Rivera Rincon[1], Emma Saurette[1], Ulku Huma Altindag[1], Laurie Stevison[1,2] [1]Biological Sciences, Auburn University, [2]Auburn University

A major consequence of global climate change is the exposure to extreme fluctuations in temperature, forcing populations to shift in their ranges. One expected result would be the shift in the geographic range of species to occupy novel niches such as high-altitude environments. Since these environments are typically also quite cold, we examined the interaction between low oxygen and temperatures on fruit fly physiology. Based on previous work on the DGRP related to chill coma and response to oxidative stress, we selected five stocks, three mutually sensitive and two mutually tolerant to these two stressors. We crossed these stocks to a common tester stock with quadruple X-linked recessive visible mutant markers to assay changes in recombination. We then placed crosses in four possible treatment conditions throughout development – (1) control at 25°C and 21% Oxygen, (2) Low Temperature at 18°C and 21% Oxygen, (3) Low Oxygen at 25°C and 8% Oxygen, and (4) Combined at 18°C and 8% Oxygen. Oxygen concentration was controlled with the use of custom hypoxia chambers from Biospherix and certified pre-mixed tanks from AirGas. Here, I focus on the physiological results from these four treatment groups. Specifically, we measured individual changes for females and males in weight (N=377), oxygen consumption (N=284), carbon dioxide emission (N=284), and critical thermal maximum (N=283) across the five strains and four treatment groups. Our weight results showed a significant difference due to the interaction of sex, strain, and treatments. Using both oxygen and carbon dioxide exchange, we were able to measure respiratory quotient (RQ). Finally, our CTmax results showed a decrease in thermal tolerance in sensitive strains when exposed to low temperatures and hypoxia, while tolerant strains exhibited the highest values of CTmax across treatments and strains. Phenotypic attributes across four genetic loci were collected in D. melanogaster for the recombination data. While our analysis of this work is ongoing, it will inform our understanding of how various genetic backgrounds can influence response to climate change.

1714S **Delayed lagging strand synthesis drives asymmetric histone incorporation and promotes progenitor cell reprogramming in the *Drosophila* male germline** Brendon E M Davis[1], Jonathan Snedeker[1], Rajesh Ranjan[1,2], Matthew Wooten[1,3], Vikrant Mahajan[1], Xin Chen[1,2] [1]Biology, Johns Hopkins University, [2]Biology, Howard Hughes Medical Institute, [3]Fred Hutchinson Cancer Research Center

In the *Drosophila* male germline lineage, stem cells display asymmetric histone inheritance while progenitor germ cells exhibit an overall symmetric pattern. We report that an essential molecular mechanism underlying this cellular specificity is delayed lagging strand synthesis, which drives old histone incorporation into the leading strand and is found to be sufficient to generate asymmetric histone incorporation in non-stem cells. A candidate screen identified that proteins involved in lagging-strand synthesis, such as DNA Polymerase α (Polα) and DNA Polymerase δ (Polδ), are expressed at reduced levels in stem cells compared to non-stem cells in the same germline lineage. Genetically compromising Polα induces the replication-coupled histone incorporation pattern in non-stem cells to be indistinguishable from that in stem cells, and this is recapitulated using a Polα inhibitor in a concentration-dependent manner. Furthermore, stem cell-derived chromatin fibers display a temporal difference in the replication of both DNA strands and show a significantly higher degree of old histone recycling to the

leading strand than in progenitor cell-derived fibers. However, upon reducing Polα levels in non-stem cells, the progenitor cell chromatin fibers display asymmetric old histone recycling just like stem cell-derived fibers. Importantly, these altered chromatin features in progenitor cells allow them to act like *bona fide* stem cells under both pathological and physiological conditions. Together, these results indicate that developmentally programmed expression of key DNA replication components could be manipulated to promote progenitor cell dedifferentiation and redifferentiation, suggesting a new pathway for cell reprogramming in stem cell lineages.

1715S **Initiation Mechanism of Drosophila Interchromosome Effect** Bowen Man[1], Bowen Man[2] [1]Case Western Reserve University, [2]Biology, Case Western Reserve University

In Drosophila crossover formation during meiosis, a heterozygous inversion on a homologous chromosome pair will lead to decrease of crossover formation on the local chromosome pair, but the number of crossovers would increase on other chromosomes. This phenotype is caused by a check point that induce prolonged prophase that allows more crossover formation. In this presentation, I would test two different models, axial integrity and lacking crossovers on local homologous chromosomes, that could explain the initiation mechanism of this check point.

1716S **Cell competition and the fate of segmental aneuploidies of varying size** Nicholas Baker, Jacky Chuen Genetics, Albert Einstein College of Medicine

Aneuploidy, the gain or loss of chromosomes, causes of birth defects and miscarriage. Almost all tumors are aneuploid, as are senescent cells, and aneuploidy promotes both tumorigenesis and premature aging. Sporadic aneuploid cells are often lost from otherwise normal tissues. There are many unresolved questions about the mechanisms of these effects.

The distribution of genes encoding 80 ribosomal protein genes across the chromosomes means that in ribosome biogenesis is usually affected in aneuploid cells. Genetic screens in fruitflies identified a transcriptional stress response to ribosomal protein gene haploinsufficiency, mediated by the bZip protein Xrp1. Overall reductions in cellular and organismal growth rates, and in global translation rate, are among the transcriptional effects of Xrp1 expression. An Impaired Ribosome Biogenesis Checkpoint (IRBC) is seen in vertebrates, where it is mediated by p53.

Individual cells carrying Rp gene mutations experience Xrp1-dependent cell competition, ie they are actively eliminated in the presence of wild type cells. FLP/FRT-mediated excision of chromosome previously showed that cell competition based on Rp gene dose is responsible for removing sporadic aneuploid cells (PMID33847264).

Monosomies lacking *Rp* genes typically extend over only ≤2% of the genome. Now we have investigated the effects of more extensive chromosome loss. Heterozygous deletion of larger and larger chromosome regions increasingly reduced cell viability, leading to less and less growth, until eventually cells with heterozygous deletion of sufficient material no longer survive, even without cell competition. Beyond even this point, FLP recombination of FRT sites separated by much of a chromosome arm can produce hyperplasia and tumors. These data suggest that segmental monosomy can create three kinds of stress according to the extent of sequence lost: the first and most sensitive eliminates aneuploid cells through cell competition due to Rp gene haploinsufficiency, mediated by a specific transcriptional stress response; the second is a less sensitive, cell-autonomous toxicity, that becomes significant when larger portions of the genome are affected; finally, still more extensive aneuploidy seems to promote hyperplasia. Taken together, this data suggests that, whereas most aneuploidies, or segmental monosomies at least, inhibit cellular growth through cell-autonomous and non-autonomous pathways, particular, highly aneuploid genotypes exist that promote hyperplasia and tumorigenesis.

1717S **Pumilio-dependent stabilization of Nipped-B mRNA during meiotic prophase is required for cohesion rejuvenation in *Drosophila* oocytes** Muhammad Abdul Haseeb[1], Erin Dickert[2], Sharon Bickel[2] [1]Biological Sciences, Dartmouth College, [2]Dartmouth College

Accurate chromosome segregation of homologs during the first meiotic division requires that cohesion along the arms of sister chromatids be maintained from S phase until anaphase I, when release of arm cohesion allows recombinant homologs to segregate to opposite poles. In Drosophila oocytes, a cohesion rejuvenation program operates during meiotic prophase to promote *de novo* loading of cohesin and formation of new cohesive linkages after cohesion is originally established during premeiotic DNA replication. Disruption of rejuvenation causes premature loss of arm cohesion and missegregation of recombinant homologs. To identify proteins required for cohesion rejuvenation but not S phase establishment, we performed an RNAi screen and found that knockdown of the RNA-binding protein Pumilio during meiotic prophase causes a significant increase in meiotic chromosome segregation errors. Interestingly, Gerber *et al.* (2006) have reported that immunoprecipitation of Pumilio protein from Drosophila ovary extracts pulls down transcripts encoding the cohesin loader, Nipped-B. Using FISH to

detect premature loss of meiotic cohesion in mature Drosophila oocytes, we discovered that Pumilio, like Nipped-B, is essential for maintaining arm cohesion during prophase. We have developed an Smc1 “tag-switch” reporter that expresses GFP-tagged Smc1 exclusively during meiotic prophase and allows us to directly visualize association of newly synthesized cohesin with oocyte chromosomes after premeiotic S phase. Using this tool, we have found that when Nipped-B is knocked down during meiotic prophase, cohesin loading on the arms of meiotic chromosomes is severely disrupted. We observe a similar phenotype in Pumilio knockdown oocytes. Moreover, RNA-seq analysis using ovary extracts from control and Pumilio knockdown extracts revealed a significant reduction in the abundance of Nipped-B transcripts when Pumilio is knocked down during meiotic prophase. Collectively, our findings suggest that cohesion defects in Pumilio knockdown oocytes arise from the destabilization of Nipped-B transcripts and subsequent disruption of Nipped-B dependent cohesin loading and rejuvenation during meiotic prophase. Experiments are currently underway to visualize and quantify Nipped-B protein on meiotic chromosomes in order to test the hypothesis that Pumilio knockdown during meiotic prophase causes a reduction of chromosome associated Nipped-B protein in Drosophila oocytes.

1718S **Topoisomerase 3b Facilitates piRNA Biogenesis to Promote Transposon Silencing and Germ Cell Development** weiping shen[1], Seung kyu Lee[1], William wen[1], yuyoung Joo[2,3], yutong xue[1], shuaikun su[1], tiangyi zhang[4], megan zhang[5], Jinshui Fan[1], yongqing zhang[1], supriyo de[1], alexei sharov[1], Manolis Maragkakis[1], weidong Wang[1] [1]NIA, [2]NIH, [3]niaaa, [4]tianyi.zhang@nih.gov, [5]Yale university

Topoisomerases typically function in the nucleus to relieve topological stress in DNA. Here we show that a DNA-RNA dual-activity topoisomerase complex, Top3b-TDRD3, primarily localized in the cytoplasm of Drosophila germ cells, biochemically and/or genetically interacts with piRNA processing enzymes to promote piRNA biogenesis, post-transcriptional and cotranscriptional silencing of transposons, and germ cell development. A Top3b point mutant that lacks topoisomerase activity is defective in silencing of a transposon reporter, suggesting that Top3b may relieve topological stress in RNA. Top3b-TDRD3 null mutants in flies exhibit phenotypes similar to those of piRNA pathway mutants; including reduced fertility. Notably, mutations in Top3b or TDRD3 are associated with fertility disorders in both humans and mice. Our data reveal a novel role of topoisomerase in RNA-based processes—piRNA biogenesis and transposon silencing; and suggest a possible mechanism of how Top3b-TDRD3 mutations can lead to germ cell dysfunction across vertebrates and invertebrates.

1719S **Regulation of mammalian meiosis by the SUMO-conjugating enzyme UBC9** Sunkyung Lee[1], Dhananjaya Kulkarni[1,2], Yungdae Ryu[1], Tianhong Lu[1], Neil Hunter[1,2] [1]Microbiology and Molecular Genetics, University of California Davis, [2]Howard Hughes Medical Institute, University of California Davis

During meiotic prophase I, the homolog axis organizes chromosome structure and is required for several aspects of homologous recombination including the formation of DNA double-strand breaks (DSB), template selection (homolog versus sister chromatid), and crossing over. Our recent studies have identified the small ubiquitin-like modifier (SUMO) as a key regulator of meiotic prophase I[1)] and in budding yeast, all known components of the homolog axes were identified as targets[2)]. However, targets in mammals and how SUMO regulates axis function remain unknown.

We identified human SYCP3 as a direct (E3-ligase independent) target of the E2-conjugase UBC9 *in vitro*. Although SYCP3 is SUMOylated at multiple sites, modification is largely dependent on a single consensus binding motif for UBC9. Typically, direct targets of UBC9 require additional binding interfaces to stabilize interaction and enable efficient modification. We found that auto-SUMOylation of UBC9 at K14 is important for SYCP3 modification suggesting a bipartite interaction comprising: (i) binding of the SUMO consensus motif on SYCP3 by the UBC9 catalytic cleft; (ii) binding of SUMO conjugated to UBC9-K14 by SYCP3.

To understand the *in vivo* significance of UBC9-K14 SUMOylation for meiosis, we generated a knock-in mouse line Ubc9K14R/K14R. While Ubc9K14R/K14R spermatocytes have ostensibly normal chromosome synapsis, preliminary analysis indicates that chromosome axes are shorter and crossing over is reduced. Ongoing experiments are exploring the fertility of Ubc9K14R/K14R mice, the composition of chromosome axes, and how meiotic recombination is altered. This analysis will provide important insights into how SUMO modification regulates meiosis in mammals.

1720S **Relationships Between Germline Mutation Rates and Reproductive Success** Alexis Garretson[1,2], Beth L Dumont[1,2] [1]Genetics, The Jackson Laboratory, [2]Tufts University

The mutation rate is a critical genomic parameter, as germline mutations are the cause of heritable genetic disorders and the ultimate source of evolutionary novelty. The germline mutation rate is a complex trait, but we know little about how it is modified by heritable genetic features. In humans, elevated mutational burdens have been tentatively linked to reproductive capacity. Higher mutation rates are associated with lower reproductive success and earlier age at last birth. However, the fertility-associated consequences of natural variation in mutation rates are incompletely understood, mainly due to the absence of mutation rate and reproductive phenotype estimates across large population cohorts. Here we harness the breeding funnel design of the Collaborative Cross (CC) mouse population alongside dense breeding records from each CC strain to profile the accumulation of mutations over ~30 inbreeding generations and to evaluate associations between mutation rate and multiple metrics of reproductive fitness. Using a pan-genome, graph-based variant caller applied to publicly available whole-genome sequences for 69 CC strains, we identify ~11,000 *de novo* mutations (DNMs) specific to each CC line and absent from the eight founder strains, including many DNMs with projected functional effects. The per generation rate of mutation accumulation varies 11-fold among strains, exceeding null expectations and pointing to the presence of mutation rate modifiers segregating among the 8 CC founder strains. Mutation rates are negatively correlated with several metrics of reproductive capacity, including average litter size, interbirth interval, and age at the first litter. Further, strains with higher mutation rates exhibit a more rapid increase in the interbirth interval and concomitant decreases in litter size with age. Our findings suggest that germline mutation rates in mice are associated with multiple metrics of fertility and reproductive aging, revealing shared genetic mechanisms underpinning variation in these complex traits.

1721S **Mechanisms and fitness consequences of human embryonic aneuploidy inferred from 129,479 blastocyst-stage embryos** Sara A Carioscia[1], Arjun Biddanda[2], Ivan Vogel[3], Eva Hoffman[3], Rajiv C McCoy[2] [1]Johns Hopkins University, [2]Biology, Johns Hopkins University, [3]University of Copenhagen

Less than half of all human conceptions survive to live birth. Extra or missing chromosomes (aneuploidies) are the primary cause of pregnancy losses, many of which occur during the preimplantation stages. Data from preimplantation genetic testing for aneuploidy (PGT-A) from trophectoderm biopsies of blastocyst-stage in vitro fertilized (IVF) embryos offers a unique view into the origins of aneuploidy and the landscape of dosage sensitivity during the first five days after fertilization. Here we report detailed patterns of chromosome abnormalities detected in biopsies of 129,479 blastocyst-stage IVF embryos from 20,900 sets of patients. Using genome-wide array-based genotyping of embryo biopsies, alongside parental genotypes, we infer transmission of individual parental homologs and assign parental origins of aneuploidies. The scale of the data offers unique insight into the origins of rare abnormalities in genome-wide ploidy. We then leverage this data to investigate biases in transmission of different parental haplotypes among the IVF embryos.

We find that both single-chromosome gains and losses as well as whole-genome gains and losses primarily involve maternal chromosomes. Maternal meiotic-origin trisomies were strongly enriched on chromosomes 15, 16, 21, and 22, consistent with previous findings. Because the predominant mechanisms of maternal meiotic error produce equal ratios of monosomies and trisomies (via reciprocal gain and loss in the egg and polar body, or vice versa), imbalance in this ratio offers insight into impact of selection of gains versus losses during cleavage-stage embryonic development. Moreover, we are able to understand the proportions of different error types (meiosis I, meiosis II, mitosis) across age tranches. This temporal information allows us to characterize the landscape of aneuploidy-generating mechanisms and their relative contributions in early human development, building a foundation to investigate the genetic basis of aneuploidy phenotypes.

1722S **Investigating the Role of DNA Secondary Structures in Centromere Specification** Pei Shyuen Ooi, Jitendra Thakur Biology, Emory University

Centromeres are chromosomal locations that are essential for proper chromosome segregation to avoid aneuploidy and genomic instability, both of which are hallmarks of many cancers and genetic disorders. Centromeres are specified by the strong enrichment of a specialized epigenetic chromatin, where histone H3 is replaced by its variant called centromere protein-A (CENP-A). How CENP-A is targeted to centromere locations remains a longstanding question. Recent studies have shown that centromeres are enriched for DNA secondary structures that differ from the Watson-Crick double helix model of DNA. These studies suggest that these DNA secondary structures may contribute to centromere specification by targeting CENP-A to centromeric DNA. I aim to investigate the function of DNA secondary structures in specifying centromere locations by identifying types of DNA structures and their protein partners that may be involved in CENP-A targeting. To do so, I am using the latest high-throughput secondary structure mapping techniques to identify the sites and types of DNA structures at centromeres. Additionally, I am also using CRISPR/Cas9-based perturbations of potential centromeric protein partners of DNA secondary structures. Interestingly, I have found that a specific type of DNA secondary structure has pockets of

depletion within centromeric regions but is abundant at centromere flanking regions. The findings indicate that this class of DNA secondary structures is processed rapidly by their protein partners at these pockets of depletion, suggesting a potential mechanism for CENP-A targeting. This research will reveal high-resolution footprints of DNA secondary structures at centromeres. Additionally, this research will identify DNA secondary structure protein partners, uncovering the importance of potential interactions of DNA secondary structures with centromeric proteins in centromere specification.

1723S **Characterizing Mutagenesis Across Developmental Time with sciATAC-seq** Yu-Chen Pan, David Mas Ponte, Diego Calderon, Annabel Beichman, Kelley Harris University of Washington

Although somatic mutations are most often studied in the context of cancer and tumor development, they occur spontaneously throughout an individual's lifetime. Recently, there has been a growing interest in studying somatic mutations in healthy tissues to better understand mutational processes in normal cells and to trace cell lineages during development. However, somatic mutations tend to be found in small clusters of cells, and extra-sensitive technologies are needed to detect them. Existing methods for identifying somatic mutations include single clone cell culture expansion, organoid culture and laser capture dissection, but they are relatively low throughput and expensive. Given these limitations, we developed a novel approach to detect somatic mutations with single-cell indexing (sci) ATAC-seq data, which is more scalable and already abundantly available for reanalysis. By calling mutations found in reads derived from chromatin-accessible regions, we detected putative somatic and germline mutations and explored the mutagenesis landscape across tissues during development using previously published sci-ATAC-seq data from fruit fly embryos and human fetal samples. In the fruit fly embryonic development analysis, each 1-mer mutation type showed a slight increase in mutational load over developmental time, affecting both the soma and the germline. The 3-mer mutation spectrum appeared consistent with previous mutation accumulation experiments. We also performed mutational signature analysis across multiple human fetal tissues, which was able to distinguish between somatic and germline mutations and reveal differentiation across tissue types. In our work, we demonstrated that we can successfully detect and differentiate somatic and germline mutations with our pipeline. This new approach will allow us to reuse available datasets to study somatic mutagenesis at a single cell resolution for a relatively affordable cost, enhancing scalability and opening up the possibility for using spontaneous somatic mutations to trace cell lineages.

1724S **Genetic interactions between fission yeast Cdc24 and PCNA** Sally G Pasion[1], Ntsaum S Vang[2] [1]Biology, San Francisco State University, [2]Ross University School of Medicine

In the fission yeast, *Schizosaccharomyces pombe*, Cdc24 has been implicated in lagging strand synthesis and DNA repair (Gould et al., 1998; Tanaka et al., 1999, Zhang et al., 2016). Although Cdc24 is a novel replication/repair protein, it has physical and genetic interactions with the DNA replication and repair protein, Proliferating Cell Nuclear Antigen, PCNA. PCNA has been shown to interact with Cdc24 when the proteins are ectopically expressed in yeast cells (Tanaka *et al*., 1999), and has been shown to be a multicopy suppressor of Cdc24 ts lethality (Reynolds et al., 1998). It is not clear which PCNA components are required for these interactions. In this study, we constructed *cdc24-ts pcn1.K164A* double mutants and report that they exhibited a synthetic growth defect. We also determined that *pcn1.K164A* is epistatic to *cdc24-M81*, in response to UV irradiation, suggesting that Cdc24 and PCNA both function in the same DNA repair pathway. Further, we identified that the PCNA K164A mutation and mutations along the PCNA interdomain-connecting loop (IDCL) affect the ability of PCNA to suppress *cdc24* temperature sensitivity.

1725S **Structural and biochemical basis of retrotransposition by human LINE-1** Akanksha Thawani[1], Eva Nogales[2], Kathy Collins[3] [1]Molecular and Cell Biology, UC Berkeley, [2]UC Berkeley, HHMI, [3]UC Berkeley

The Long Interspersed Element-1 (L1) retrotransposon has generated nearly one-third of the human genome and serves as an active source of genetic diversity and human disease. L1 spreads via a mechanism termed target-primed reverse transcription, in which the encoded enzyme (ORF2 protein, or ORF2p) nicks the target DNA to prime reverse transcription of its own or non-self RNAs. Here, we purified the full-length LINE-1 ORF2p and biochemically reconstituted robust target-primed reverse transcription with template RNA and target site DNA. We report cryo-electron microscopy structures of the human L1ORF2p bound to structured template RNAs and initiating cDNA synthesis. The template polyadenosine tract is recognized in a sequence-specific manner by five distinct domains. Among them, a novel RNA-binding domain bends the template backbone to allow engagement of an RNA stem with the LINE-1 ORF2p C-terminal segment. In addition, our structure and biochemical reconstitutions demonstrate a surprising requirement for the target DNA architecture for nicking and target-primed reverse transcription. By synthesizing biochemical and structural data, our work provides key insights into the mechanism of ongoing transposition in the human genome and informs the engineering of retrotransposon proteins for gene therapy.

1726S **Rethinking Mutation Accumulation: Measuring Mutation Bursts in *Saccharomyces cerevisiae*** Joseph A Stewart[1], Mackenzie Wienke[2], Camryn Schmelzer[1], Lucas Argueso[1] [1]Environmental and Radiological Health Sciences, Colorado State

University, [2]Biology, Colorado State University

In the field of evolution, gradualism is the process of incremental adaptation supported by a slow and random accumulation of mutations that, over time, lead to genetic diversification and fitness gains. Although this Darwinian model is well supported and widely accepted, it cannot always explain the rapid changes seen in some instances such as tumors with extremely high and complex mutation loads. Recent reports in various organisms, including from our group using *Saccharomyces cerevisiae*, provide evidence for an additional mode of rapid and non-independent accumulation of chromosomal rearrangements. We have used a yeast model to follow the accumulation of structural genomic rearrangements such as loss of heterozygosity (LOH). We found that while chances of a single LOH event happening are very low, two or more LOH tracts co-occurred at rates 14- to 200-fold higher than expected if these events were independent of each other; therefore, the conventional process of slow and independent accumulation of mutations are not sufficient to account for every change in the genome. In the present study, we focused on temporal kinetics of bursts of LOH accumulation in yeast. We developed a hybrid diploid yeast experimental strain that enables identification of LOH event both through counter-selection and visual screening for colony color. This hybrid strain, made from the S288c and SK1 genetic backgrounds, possesses ~55,000 heterozygous SNPs distributed throughout the genome and allows for ease of tracking LOH events through sequencing. The screening approach was used in combination with microcultures (one cell grown for 5 or 6 divisions) in phylogenetic analyses that unambiguously revealed cases where multiple LOH events co-occurred in the same cell division cycle. Collectively, these studies offer support for punctuated bursts of mutation accumulation caused by systemic genomic instability (SGI). Additionally, we have investigated a potential mechanism that influences SGI, namely global noise in gene expression.

1727S **Lack of Ung1 increases *S. cerevisiae* sensitivity to anticancer ruthenium complex KP1019** Rishi Narayan, Andrew Chinn, Pamela Hanson Furman University

Although platinum-based drugs are often used to treat cancer, they have limitations that include severe side effects, as well as development of drug resistance. Some ruthenium-based complexes overcome these limitations as they cause fewer side effects while remaining effective against multidrug resistant cancer and yeast cells. One such ruthenium-based drug is indazolium trans-[tetrachlorobis(1H-indazole)ruthenate(III)] (KP1019). In a phase I clinical trial, KP1019 had low toxicity yet stabilized disease progression in 5 of 6 evaluable patients. In addition to poorly characterized cytoplasmic targets, DNA appears to be an important target of KP1019 in both yeast and cancer cells, as previous studies show the drug can cause double-strand breaks, DNA adducts, and interstrand crosslinks. An unpublished barcode sequencing screen suggests that yeast lacking the evolutionarily conserved uracil DNA glycosylase Ung1 are hypersensitive to KP1019. Using a growth inhibition assay, we verified this result, determining that the average IC50 value for ung1 deletion strains was significantly lower than wild-type controls (13±5 vs 22±5 ug/mL, respectively; $p<0.05$). This finding suggests that cytosine deamination is an additional type of DNA damage caused by KP1019. Interestingly, acute exposure to 80 ug/mL KP1019 reduced survival rates of wild-type and ung1 mutants to a similar extent with roughly 30% of cells surviving relative to untreated controls. Given the difference in growth inhibition and survival assays, lack of Ung1 appears to have a greater impact on yeast resistance to the cytostatic rather than cytotoxic effects of KP1019. To determine whether loss of Ung1 alters the frequency of KP1019-induced DNA damage, loss of function of the nuclear gene CAN1 was used to measure mutation frequencies. In the absence of drug, ung1 mutants had a 50% higher mutation frequency than wild-type ($p<0.05$). KP1019 increased mutation frequency approximately ten-fold in both strains, but there was not a significant difference between strains. Since Ung1 is localized to both the nucleus and mitochondria in yeast, yet we observed no difference in drug-induced mutation frequency of a nuclear gene, we propose that KP1019 may deaminate mitochondrial DNA, resulting in cytostatic effects. Moreover, since KP1019 has been shown to accumulate in the mitochondria of ovarian cancer cells and Ung1 is involved in mitochondrial DNA repair, the mitochondria is a potential target of KP1019.

1728S **Ccq1 restrains Mre11-mediated degradation to distinguish short telomeres from double-strand breaks** Julien W. Audry[1], Haitao Zhang[1], Carly Kerr[1], Kathleen L Berkner[2], Kurt W Runge[1] [1]Inflammation and Immunity, Cleveland Clinic Lerner Research Institute, [2]Cardiovascular and Metabolic Sciences, Cleveland Clinic Lerner Research Institute

Telomeres cap chromosome ends and are distinguished from DNA double-strand breaks (DSBs) by means of a specialized chromatin composed of DNA repeats bound by a multiprotein complex called shelterin. We investigated the role of shelterin components in distinguishing telomeres from DSBs by studying viable mutants lacking these proteins. Mutants were studied using a *Schizosaccharomyces pombe* model system that induces cutting of a proto-telomere bearing telomere repeats to rapidly form a new stable chromosomal end, in contrast to the rapid degradation seen at a control DSB. Cells lacking the shelterin components Taz1, Rap1, or Poz1 or the telomere-associated protein Rif1 formed a chromosome end that was stable for multiple cell divisions. Surprisingly, cells lacking Ccq1, or impaired for recruiting Ccq1 to the telomere, converted the cleaved proto-telomere to a rapidly degraded DSB. Ccq1 recruits telomerase, establishes heterochromatin and affects DNA damage checkpoint activation; however, these functions were separable from protection of the new telomere by Ccq1.

Telomere degradation in cells lacking Ccq1 was greatly reduced by eliminating nuclease activity of Mre11, a component of the Mre11-Rad50-Nbs1/Xrs2 complex that processes DSBs. Cells lacking Ccq1 and Mre11 that did not degrade the new telomere still activated the cell cycle checkpoint, showing that DNA degradation and checkpoint activation were separable in this mutant. These results demonstrate a novel function for *S. pombe* Ccq1 to effect end-protection by restraining Mre11-dependent degradation of the DNA end.

1729S **Chromosomal Crossing Over During Meiosis: crossover-specific resolution of double Holliday Junctions** John E mccarthy, Neil Hunter UC Davis

Crossing over between homologous chromosomes is required for their accurate segregation during meiosis to produce haploid euploid gametes. A critical step in this process is the formation of double-Holliday Junction (dHJ) recombination intermediates, which are specifically resolved into crossovers products with exchange of chromosome arms, as opposed to a random mixture of crossover and non-crossover products as predicted by canonical models. While the steps leading to dHJ formation are well understood, how dHJs are specifically resolved into crossovers is unclear. We are elucidating the mechanism of dHJ resolution in budding yeast *Saccharomyces cerevisiae*. Recent experiments from our lab evoke a model in which crossover-specific dHJ resolution occurs through a mechanism similar to the initiation steps of DNA mismatch repair. Specifically, sliding clamp PCNA directs the MutLγ endonuclease to create strand-specific nicks on either side of the two Holliday Junctions (HJs). The conserved Bloom helicase/decatenase complex (Sgs1-Top3-Rmi1 in budding yeast) then unwinds the DNA between the nicks to resolve the dHJ. The immediate resolution products are predicted to contain both single-stranded flaps and gaps that require trimming and gap-filling activities to produce mature crossover products. These predictions are being tested *in vivo* using unique molecular-genetics tools developed in budding yeast that enable the synchronization of cells at the dHJ-resolution step, inactivation of pertinent factors in real time, and direct monitoring of dHJ resolution. Our insights will be broadly relevant for understanding meiotic crossing over in higher eukaryotes, including mammals.

1730S **Histone Variant H2A.Z and Linker Histone H1 Influence Chromosome Condensation in *Saccharomyces cerevisiae*** Anna M Rogers, Nola R Neri, Lorencia Chigweshe, Scott Holmes Molecular Biology and Biochemistry, Wesleyan University

Chromosome condensation is essential for the fidelity of chromosome segregation during mitosis and meiosis. Condensation is associated both with local changes in nucleosome structure and larger scale alterations in chromosome topology mediated by the condensin complex. We examined the influence of linker histone H1 and variant histone H2A.Z on chromosome condensation in budding yeast cells. Linker histone H1 has been implicated in local and global compaction of chromatin in multiple eukaryotes, but we observe normal condensation of the rDNA locus in yeast strains lacking H1. However, deletion of the yeast *HTZ1* gene, coding for variant histone H2A.Z, causes a significant defect in rDNA condensation. Loss of H2A.Z does not change condensin association with the rDNA locus, or significantly affect condensin mRNA levels. Prior studies reported that several phenotypes caused by loss of H2A.Z are suppressed by eliminating Swr1, a key component of the SWR complex that deposits H2A.Z in chromatin. We observe that an *htz1Δ swr1Δ* strain has near normal rDNA condensation. Unexpectedly, we find that elimination of the linker histone H1 can also suppress the rDNA condensation defect of *htz1Δ* strains. Our experiments demonstrate that histone H2A.Z promotes chromosome condensation, in part by counteracting activities of histone H1 and the SWR complex.

1731S **Role of telomeric proteins in the repair of a single double-strand break in an expanded CTG trinucleotide repeat** Cécile Palao[1,2], Wilhelm Vaysse-Zinkhöfer[1], Maria Teresa Teixeira[3], Guy-Franck Richard[1] [1]Pasteur Institute, [2]Sorbonne University, [3]Institute of Physico-Chimical Biology

Microsatellites are DNA tandem repeats of 1 to 6 nucleotides. Discovered in the 1960s and considered a long time as “Junk DNA”, microsatellites are known to play many roles in gene regulation and chromosome organization. But they are also involved in some cancers and neurological disorders such as fragile X syndrome, Huntington disease or myotonic dystrophy type 1 (DM1). DM1 is a neurodegenerative disease induced by a pathological expansion of the microsatellite (CTG)n localized in the 3’UTR of the *DMPK* gene. The resulting pathogenic mRNA transcribed from this expanded repeat is responsible for the disease. One possible therapeutic approach would be to reduce the number of CTG trinucleotide repeats below the pathological length in humans, by the use of highly specific DNA endonucleases.

Preliminary results of the feasibility of this approach have been obtained in the model yeast *Saccharomyces cerevisiae*. A double-strand break (DSB) was induced by a TALE nuclease (TALEN) in an expanded CTG trinucleotide repeat integrated in a yeast chromosome. Contraction of the repeat occurs by single-strand annealing (SSA) and leads to reduction of the triplet repeat length. After DSB induction, DNA is resected on both sides of the break, resulting in single-stranded recombinogenic 3’-OH ends, complementary to each other. They can anneal to each other, eventually leading to CTG repeat contraction.

To better understand this mechanism, we studied resection proteins and found that the endonuclease activity of Mre11p as well as its partner Sae2p are necessary to process the DSB within CTG repeats, but not in a non-repeated region. It is known that CTG repeats can form secondary structures *in vitro*, suggesting that Mre11 activity is required to remove these structures that would hinder the loading and processing of DSB ends by other proteins. The deletion of *EXO1*, a gene responsible for late resection steps, showed a minor effect on resection and repair of the same DSB. However, Dna2p, another protein involved in late resection is essential for the processing of the DSB on both ends of the DSB, even in presence of Mre11p and Sae2p.

We also discovered that the deletion of certain telomeric proteins increased resection at a CTG DSB, but not at the same locus that does not contain the repeat tract. The sequence similarity of CTG repeats with telomere sequences in S. cerevisiae (G1-3 T) led us to investigate the potential role of the telomeric machinery in the resection and repair of a DSB induced in a long expanded CTG microsatellite. ChIP experiments were performed to determine whether the telomeric proteins that decrease resection at CTG DSB are enriched at this trinucleotide repeat tract and/or if they are enriched after a DSB within the CTG. RNA-seq experiments were conducted to identify differential gene expression in the presence of CTG repeats in the genome of Saccharomyces cerevisiae. The results obtained will be discussed.

1732V **Investigating the function and regulation of the Haspin homolog, HASP-1, in the *C. elegans* germline** David Wynne University of Portland

The protein kinase Haspin is critical for proper chromosome segregation during cell division. Haspin-dependent phosphorylation of histone H3 recruits the Chromosomal Passenger Complex (CPC) to chromosomes, along with a parallel pathway that depends on the kinase Bub1. Despite long interest in the function of the CPC, Haspin has been studied in relatively few cell types and mostly during mitosis. How the pools of CPC recruited by Haspin and Bub1 are distinct and whether CPC recruitment mechanisms are altered in different cell types and during meiosis remain poorly understood. Recent work in *S. cerevisiae* and mouse oocytes has validated the hypothesis that CPC pools function differently in mitosis and meiosis. We are using *C. elegans* to better understand the mechanisms of Haspin regulation and the function of Haspin-dependent CPC recruitment in the germline. The *C. elegans* gonad contains mitotically dividing nuclei as well as meiotic divisions that produce sperm and oocytes. We previously confirmed that the *C. elegans* Haspin homolog *hasp-1* promotes the mitotic divisions in the germline and spermatogenesis in addition to its demonstrated role in oocyte meiosis. We are generating a series of N-terminal deletion mutations to investigate the mechanisms by which the HASP-1 protein is recruited to chromosomes and activated. These tools will allow us to assess the function of the HASP-1-dependent pool of CPC in the diverse cell types of the *C. elegans* germline.

1733V **RING Finger Proteins in Crossover Designation and Interference** Emerson Frantz, Susan McMahan, Jeff Sekelsky UNC Chapel Hill

The RING Finger proteins Vilya, Narya, and Nenya (VNN) are believed to facilitate crossover designation in meiosis. If crossing over occurs incorrectly, it can result in nondisjunction which can cause genetic conditions like Down Syndrome. VNN are found concentrated in the synaptonemal complex, a structure that forms between chromosomes during meiosis, in locations where crossovers occur. Because of this, we believe that increases in expression of these genes will lead to an increase in crossovers and a decrease in crossover interference. In order to test the role of VNN, a transgene containing the three genes was assembled using a UAS::GAL4 promoter system via Goldenbraid cloning. The completed transgene was injected into Drosophila and paired with a nanos driver to amplify expression. When compared to a negative control, it was found that there are higher rates of crossovers due to higher expression of VNN, indicating that crossover interference also lessens as predicted. Further research to increase our understanding of the genes includes analyzing the VNN transgene with different drivers and creating marked deletions for each individual gene to look at their effects. In order to quantify the dosage of VNN, we also plan on performing qRT-PCR.

1734V **Synaptonemal & CO Analyzer: a novel tool for the analysis of immunofluorescence images in meiotic recombination studies** Elena de la Casa-Esperon[1], Angela Belmonte-Tebar[2], Joaquim Soriano[2] [1]Biochemistry and Molecular Biology, University of Castilla-La Mancha, [2]University of Castilla-La Mancha

Meiotic recombination is fundamental process that not only generates genetic diversity, but is also required for proper chromosome segregation. Chromosomes that do not recombine or have anomalous crossover distributions often separate poorly during the subsequent cell division and end up in abnormal numbers in ova or sperm, causing miscarriage or birth defects. Hence the importance of studying recombination, which in vertebrates is usually performed by immunostaining of chromosome spreads of pachytene-stage spermatocytes or oocytes. This allows to visualize the synaptonemal complex formed between the homologous chromosomes as well as the number and position of the crossovers. But recombination studies often require the analysis of large numbers of cell images, which is very time-consuming and a major bottleneck to achieving

conclusions.

To overcome this limitation, we present a new image analysis tool. Yielding reliable results in half the time of manual analysis, this Fiji/ImageJ macro can analyze microscopy images of many vertebrate species (e.g., mouse, chicken, zebrafish) with diverse antibody labels for crossover and synaptonemal complex studies. Its development under Fiji/ImageJ is specially designed for researchers with different requirements, so they can implement and adapt it to their needs. It is easy-to-use, compatible with different operating systems (Windows and MacOS) and freely accessible through public repositories. In summary, Synaptonemal & CO Analyzer is a free, easy to use, flexible and versatile tool that speeds microscopy image analyses and, hence, facilitates recombination studies.

1735V **Chromatin remodeling complexes function in chromosome segregation and ploidy maintenance** Md Riajul Hossain, Jesus Moreno, Adelle Warford, Ines Pinto Biological Sciences, University of Arkansas

The integrity of genomes requires the faithful segregation of the newly replicated chromosomes during cell division. The main goal of this work is to gain an understanding of the role that chromatin and chromatin remodeling complexes have during mitotic chromosome segregation. To identify proteins that are involved in ploidy maintenance, we carried out a screen of the *S. cerevisiae* non-essential deletion library for genes that when mutated caused ploidy increase. Among the mutants that increased ploidy, we encountered members of the INO80 and SWR1 complex (INO80C and SWR1C). Both ATP-dependent chromatin-remodeling complexes participate in a variety of biological processes including transcription, DNA repair and DNA replication. INO80C catalyzes the eviction of the H2A.Z histone variant replacing it with H2A in nucleosomes. This complex is comprised of 15 subunits, and their specific contribution to chromosome segregations remains largely unknown. The INO80C has been implicated in the maintenance of ploidy through the characterization of mutations of the genes encoding the Ies6 and Ino80 subunits (Chambers et al. doi:10.1101/gad.199976.112), which result in ploidy increase. The SWR1C catalyzes the exchange of H2A for H2A.Z. The yeast SWR1C is comprised of 14 subunits. The Swr1 subunit creates the scaffold of the complex and is essential for its enzymatic activity. To evaluate the contribution of each subunit to chromosome segregation, we tested deletion mutants of all the non-essential subunits of both complexes, and Ts alleles of *ARP4* and *SWC4,* for benomyl sensitivity, ploidy maintenance and chromosome segregation. Furthermore, we analyzed genetic interactions among *ino80Δ* and *swr1Δ,* the catalytic subunits of both complexes. Although both individual mutants increase ploidy, *ino80Δ swr1Δ* double mutant maintains the ploidy increase behavior of *ino80Δ* mutants. This finding suggests that INO80C may have additional functions to ensure proper chromosome segregation, or that there are parallel ways to deposit H2A.Z. Our data indicate that both complexes are required for the maintenance of normal ploidy and genomic stability, but only the catalytic subunits and a few other subunits are required for this function, including the essential ones. Moreover, the Ino80 and Swr1 subunits associate with pericentric chromatin and their presence correlates with the expected H2A.Z turnover.

1736V **Visualization and Immunoprecipitation of distinctively tagged PCH-2 strains in C.elegans** Micaela C Colmenarez, Natalie Gallagher, Valery Ortiz, Dr. Anna Russo, Dr. Needhi Bhalla Molecular, Cell and Developmental Biology, UC Santa Cruz

Mitosis and Meiosis are both essential for proper segregation of chromosomes. Defects in mitosis/meiosis produce aneuploid cells and are associated with cancer progression, birth defects and infertility, underscoring their importance to human health. In this experiment, we used C.elegans to better understand the meiotic and mitotic checkpoint protein, pachytene checkpoint protein (PCH-2). PCH-2's role in preventing aneuploidy is complex in both meiosis and mitosis. Therefore, in order to determine PCH-2's role, we conducted immunoprecipitations on distinctively tagged PCH-2 strains to identify protein interactors and post-translational modifications that may regulate its function.

We will use strains that have PCH-2 tagged at the N or C terminus with Green Fluorescent Protein (GFP) and 3X Flag (3XF) in order to visualize the protein in vivo and immunoprecipitate it. We will also use mutations in PCH-2 that are predicted to bind substrates better (EQ mutants). We have shown that C-terminally tagged PCH-2 is functional during mitosis but not meiosis. I tested whether the N-terminally tagged PCH-2 (3XF::GFP:: PCH2) was functional during meiosis and found that 3XF::GFP::PCH2 exhibited no defects in recombination, similar to control worms and different than pch-2 mutants. We also verified that N-terminally tagged PCH-2 (3XF::GFP::PCH2) was also functional in mitosis. Thus, we have two tagged versions of PCH-2, one functional in both mitosis and meiosis and the other, functional in mitosis. By completing these experiments, we will be able to see if PCH-2 has post-translational modifications or interacts with proteins that specifically affect its function throughout mitosis and meiosis.

1737T **Analyzing the expression of *C. elegans* IGEG-1, a novel EGFR ligand that promotes sleep** Marine Barsegyan, Cheryl Van Buskirk Biology, California State University, Northridge (CSUN)

Sleep is observed across the animal kingdom, both in vertebrates and invertebrates, but its cellular function remains a mystery.

In *C. elegans,* sleep is independent of circadian regulation, providing an ideal model for the study of sleep need independent of day-night timing. Interestingly, these nematodes sleep following exposure to damaging conditions, pointing to cell damage as the molecular basis of sleep need. Evidence of this phenomenon, stress-induced sleep (SIS), has been found in other species, including vertebrates.

In *C. elegans*, SIS is mediated by the activation of Epidermal Growth Factor (EGF) receptors within sleep-promoting neurons. However, the sole previously identified *C. elegans* EGFR ligand, LIN-3, is dispensable for this process. In a genetic screen for SIS-defective mutants, we have identified IGEG-1, a previously uncharacterized EGF family ligand. We have also identified a stress-responsive EGF sheddase, ADM-4, that is required for IGEG-1 processing. Our ADM-4 site of action data suggests that IGEG-1/EGF can be shed from a range of damaged tissues to trigger sleep. To further test this model, we wish to examine the expression pattern of IGEG-1.

As sleep can be induced rapidly following damage, we reason that regulated shedding, rather than *igeg-1* transcription, is the limiting step in this signaling pathway, and we hypothesize that IGEG-1 will be constitutively expressed in a range of tissues. Here, we present insights into the spatial, temporal, and potentially stress-responsive patterns of *igeg-1* gene expression *in vivo* using a Green Fluorescence Protein (GFP) transcriptional reporter, which will inform our understanding of this novel sleep signal.

1738T **Understanding the Activity of Polycystin-2 in Relation to Its Localization in Cilia and Extracellular Vesicles Using C. elegans Model** Carlos Nava Cruz, Juan Wang, Inna A Nikonorova, Elizabeth Desranleau, Jonathan D Walsh, Maureen M Barr Department of Genetics and Human Genetic Institute of New Jersey, Rutgers- The State University of New Jersey

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a form of ciliopathy resulting from mutations in either PKD1 or PKD2. ADPKD is dominantly inherited but thought to be caused by a somatic second hit and loss of heterozygosity. PKD1 and PKD2 encode polycystin-1(PC1) and the TRP channel polycystin-2(PC2). The localization of these polycystins to cilia and extracellular vesicles (EVs) is conserved across species, ranging from the nematode C. elegans to humans. The relationship between the function of polycystins and their localization to cilia and EVs, as well as the dynamic interplay between ciliary and EV localization in contributing to ADPKD, remains unclear. In this study, we will utilize C. elegans model to investigate the cellular localization of PKD-2 in both gain-of-function and pathogenic loss-of-function contexts, with the aim of elucidating how PKD-2 activity is related to its ciliary and EV localization.
Constitutively active PC2(F604P) more effectively rescues cyst formation in the pronephric kidney when endogenous PC2 expression is down-regulated (Pavel et al 2016). The F604 residue in PC2 is highly conserved and corresponds to F445 in C. elegans PKD-2. We have generated an endogenous PKD-2::GFP CRISPR reporter and will engineer this F445P gain-of-function mutation into the PKD-2::GFP locus. This approach will enable us to directly observe the ciliary and extracellular vesicle (EV) localization of PKD-2(F445P) and assess its effects on male mating behavior, which is a read-out of polycystin ciliary function. Employing the same methodology, we will introduce other pathogenic mutations into PC2 that inhibit its channel activity, and monitor their impacts on PKD-2 expression, trafficking, localization, and function. Investigating these PC2 mutations in C. elegans will provide insights into the partitioning of PC2 between cilia and EVs. These studies may elucidate how modulating the interplay between ciliary and EV localization of polycystins could attenuate or prevent aberrant cilia and EV signaling, ultimately reducing cyst development in ADPKD patients.

PMID: 27071085 Wang *et al*,2021, Sensory cilia act as a specialized venue for regulated extracellular vesicle biogenesis and signaling. Curr Biol. ;31:3943-3951. PMID: 34270950

1739T **EFN-4 and VAB-8 act downstream of MAB-5/Hox to promote QL.a and QL.ap posterior migration.** Vedant Jain, Erik Lundquist Molecular Biosciences, University of Kansas

Q neuroblasts are a pair of bilateral neuroblasts that are born in the posterior-lateral region of the animal, with QL on the left and QR on the right. Q cells are the anterior sisters of the V5 seam cells. Initially, QR protrudes and migrates anteriorly over V4 seam cell, whereas QL migrates posteriorly over V5 seam cell. The second phase of migration is Wnt-dependent and begins after the first phase and the first Q cell division. QL descendants QL.a/p encounter EGL-20/Wnt which is a posteriorly expressed Wnt ligand. This ligand leads to the initiation of canonical Wnt pathway and expression of the MAB-5/Hox transcription factor in QL. *mab-5*expression in QL.a enables migration posteriorly over QL.p, after which QL.a undergoes cell division to generate two daughter cells QL.aa and QL.ap. QL.aa undergoes apoptosis, and QL.ap continues migration posteriorly and differentiates into the PQR neuron. *mab-5/Hox* is both necessary and sufficient for posterior migration, as ectopic expression in QR results in posterior migration of QR.ap (AQR neuron). The genes regulated by MAB-5 to drive posterior migration have remained

unknown. Early L1 larval Q cells from *wild-type*, *mab-5* loss-of-function (lof), and *mab-5* gain-of function (gof) strains were FACS sorted and subject to RNA-seq. Differential expression analysis identified genes with increased or decreased expression in these mutants. Expression of the unconventional kinesin gene *vab-8* was reduced in *mab-5* lof and increased in *mab-5* gof. In *vab-8* mutants, QL.a failed to migrate posteriorly from its birthplace, resulting in PQR at the place of QL division. This suggests that *vab-8* is required for posterior QL.a migration. *efn-4/Ephrin* expression was also reduced in *mab-5* lof. In *efn-4* mutants, QL.a undergoes its initial posterior migration, but after division, QL.ap (PQR) fails to complete the final phase of migration, resulting in PQR residing just anterior to the anus. Live imaging suggests that QL.ap differentiates prematurely into the PQR neuron in *efn-4* mutants. These results suggest that *efn-4* affects a later step of QL.ap migration, and that distinct genes might be regulated by *mab-5* to control each step. Transgenic expression of *vab-8* and *efn-4* in the Q cells rescued PQR migration, suggesting that *vab-8* and *efn-4* act autonomously in the Q cells downstream of MAB-5. Through our unique live imaging approach, we have been able to decipher the functional roles of these genes in the posterior migration process. In sum, we have identified two genes, *vab-8* and *efn-4*, that act downstream of *mab-5/Hox*in a transcriptional program to control posterior migration.

1740T **EGL-1 and CED-4, components of the core programmed cell death pathway, inhibit anterior QL.a and QL.p migration, possibly downstream of MAB-5/Hox** Celeste Gormly, Erik Lundquist Molecular Biosciences, University of Kansas

Neuroblasts QL and QR are born bilaterally in the posterior lateral region of the worm between the V4 and V5 hypodermal seam cells. QR migrates anteriorly over V4 and QR migrates posteriorly over V5, and both cells then divide. EGL-20/Wnt is secreted in the posterior region of the worm where QL daughter cells QL.a/p encounter it. EGL-20 drives the expression of MAB-5 in QL via canonical Wnt signaling. MAB-5 is both necessary and sufficient to drive posterior migration. Before, MAB-5 re-programs QL.a to migrate posteriorly, it must prevent anterior migration of QL./p, which is a default state. To identify genes regulated by *mab-5,* we performed FACS sorting and RNA-seq in early L1 Q cells from *mab-5* gain-of-function (gof) and loss-of-function (lof) mutants as well as wild-type worms. Differential expression analysis was used to identify genes that were upregulated and downregulated in each of the mutants compared to the wildtype. Notably, *egl-1* was significantly upregulated in *mab-5* gof. Canonically, EGL-1 activates the programmed cell death pathway (PCD) by inhibiting CED-9/Bcl2, although the PCD pathway is involved in other developmental events such as synapse elimination (Meng et al., 2015). *egl-1* mutations had no effect on posterior QL migration alone, but significantly enhanced anterior QL.ap (PQR) migration defects of a hypomorphic *egl-20* mutants. *ced-4/APAF* also strongly enhanced anterior PQR migration in *egl-20* and *bar-1* hypomorphic mutants. These results suggest that EGL-1 and CED-4 are required to inhibit the anterior migration of QL.a and QL.p, and that EGL-1 might be upregulated by MAB-5 in QL.a/p to inhibit anterior migration. *ced-4* did not suppress *mab-5* gof, consistent with it acting redundantly with other pathways. Future studies are aimed at characterizing other PCD pathway members in this process, as well as determining the mechanisms by which this pathway might inhibit anterior migration, possibly by destabilizing the actin cytoskeleton.

1741T **CED-1 negatively regulates extracellular vesicle release from ciliated sensory neurons into the environment** Tao Ke, Jessica Tanis Department of Biological Sciences, University Of Delware

Extracellular vesicles (EVs) are membrane-wrapped structures containing proteins, RNAs, lipids, and metabolites that are released from most if not all cell types to mediate intercellular communication. The primary cilia of the RnB sensory neurons of male *C. elegans*, which produce different subpopulations of EVs, are surrounded by the ray structural cells (Rnst), RnA dendrites and hypodermal cells. Thus, the number of EVs released into the environment could be determined by both EV shedding from the RnB neurons and the uptake and clearance by Rnst or hypodermal cells. Our previous studies showed that EVs containing the *C. elegans* calcium homeostasis modulator (CALHM) ion channel CLHM-1::tdTomato cargo are shed from the ciliary base, while the EVs with transient receptor potential (TRP) channel PKD-2::GFP cargo primarily bud from the ciliary tip. In the current study, we are investigating whether release of the different EV subpopulations is regulated by *ced-1*, which encodes a transmembrane receptor in engulfing cells that mediates engulfment of apoptotic cell corpses and debris. We hypothesized that CED-1 is important for the uptake and clearance of EVs that are produced at the ciliary base and can be phagocytosed by adjacent cells. Young adult male worms with single-copy insertion of PKD-2::GFP and CLHM-1::tdTomato were imaged with total internal reflection fluorescence (TIRF) microscopy and the number of EVs released into the environment was quantitated with Imaris software. Our imaging data showed that *ced-1(e1735)* worms released 2.0-fold more PKD-2::GFP containing EVs and 2.4-fold more CLHM-1::tdTomato EVs compared to the control. Notably, the relative increase in the number of the EVs with CLHM-1::tdTomato cargo was greater than the EVs with PKD-2::GFP cargo. These data suggest that the CED-1 receptor negatively regulates the number of EVs released into the environment, particularly the EV subpopulation with the CLHM-1::tdTomato cargo that are released from the ciliary base. Further studies to determine the potential roles of CED-1 in the cells surrounding the RnB cilia will delineate whether this receptor is required for EV uptake and has a non-cell-autonomous mechanism to regulate EV release into the environment.

Keywords: *C. elegans*, extracellular vesicles, primary cilia, *ced-1*, CLHM-1, PKD-2

1742T **CASY-1 Orchestrates Foraging Dance: Unveiling the Genetic Symphony of Food-Evoked Locomotion in *C. elegans*** Navneet Shahi, Nisha Kumari, Kavita Babu Centre for Neuroscience, Indian Institute of Science

Food availability in an organism's environment is a critical determinant of its food-seeking and exploration behaviors. The integration of multisensory cues associated with food perception leads to the optimization of locomotion and the development of foraging strategies for survival. Numerous studies emphasize the ecological significance of foraging behavior and the potential physiological factors that influence it. However, a comprehensive understanding of the genetic underpinnings of the foraging behavior regulation remains elusive.

To investigate the intricate neuro-molecular mechanisms responsible for governing the food-responsive behaviors, we have employed the nematode *Caenorhabditis elegans* as a model system. *C. elegans* acts as an ideal model system for this study due to its genetic tractability and the conservation of gene functions with mammalian systems. Several cell-adhesion molecules (CAMs) have been reported to dynamically regulate locomotory circuit function. CASY-1, a mammalian calsyntenin orthologue, is one such CAM predominantly expressed in the sensory neurons and functions to maintain the Cholinergic motor neuron output. Interestingly, our study has found that the *casy-1* mutants display aberrant foraging behavior, characterized by swarming and reduced dispersal to food encounters. Based on these observations, we plan to investigate if *casy-1* present in the sensory neurons can regulate this food-seeking phenotype by modulating the function of the motor neurons.

Notably, Neuromodulatory circuits comprising Neuropeptide receptors (NPR) and their neuropeptide ligands have been reported to regulate the food search and response behaviors in *C. elegans*. Our preliminary experiments have shown that the neuropeptide processing *egl-3* and *egl-21* mutants suppress the foraging defects of *casy-1* mutants. These findings are corroborated by the genetic interactions of *casy-1* with the neuropeptide *flp-21*, and its receptor *npr-1*, in the locomotion assays. This led us to hypothesize that CASY-1 acts through neuropeptidergic signaling to regulate sensory-evoked motor output. This study aims to shed light on the molecular mechanisms through which CASY-1 orchestrates foraging behavior in *C. elegans*, providing valuable insights into the genetic basis of food-related locomotory responses.

1743T **Influence of RasGAP on PXF-1 mediated synaptic development** Reagan Lamb[1], Salvatore Cherra[2] [1]Neuroscience, University of Kentucky, [2]University of Kentucky

Small G proteins coordinate the development of synapses in the nervous system. Pairs of guanine exchange factors (GEFs) and GTPase activating proteins (GAPs) act in a reciprocal nature to modulate the activity of small G proteins. Previously, we found that *pxf-1,* a *Caenorhabditis elegans* RapGEF homolog, promotes synaptic development in cholinergic neurons. Using the cholinergic neuromuscular junction, we sought to identify which GAPs may interact with the PXF-1 pathway to coordinate the development of neuromuscular junctions. We found that a loss of function mutation in *gap-1* restored neuromuscular function to *pxf-1* mutants*.* Using endogenous and transgenic markers of cholinergic synaptic vesicles, we found that *gap-1* mutants also reduced the synaptic vesicle deficits seen in *pxf-1* mutants. To determine whether the canonical target of GAP-1, LET-60/Ras, may be involved in this pathway, we looked at synaptic vesicle phenotypes with a constitutively active mutant, LET-60(G12V). We found that neuronal expression of LET-60(G12V) rescued *pxf-1* mutant synaptic vesicle phenotypes. Since PXF-1 typically activates Rap G protein signaling, we sought to determine whether a Ras GEF may modulate LET-60 signaling and synapse development. We examined whether a putative Ras GEF, *R05G6.10,* displayed any deficits in the development of cholinergic neuromuscular junctions. We found that a deletion in *R05G6.10* decreased synaptic vesicle intensity to similar levels as *pxf-1* mutants. Moreover, double mutants between *R05G6.10* and *pxf-1* did not cause any additional defects in synapse development*.* Overall, these data indicate that LET-60 signaling interacts with PXF-1 to promote the development of neuromuscular junctions. These findings highlight an understudied interaction between G proteins that will contribute to a greater understanding of neuronal developmental.

1744T **Toward understanding the inherent left-right asymmetric differences in *C. elegans* Q neuroblasts** Felipe L. Teixeira, Erik A. Lundquist Molecular Biosciences, University of Kansas

Cell migration is a crucial mechanism for proper development of the nervous system, and the asymmetrical migration of *Caenorhabditis elegans* Q neuroblasts serves as a useful model to study the importance of such mechanism for neuronal development. *C. elegans* Q cells are bilateral neuroblasts born approximately one hour before hatching at similar positions on the left (QL) and right (QR) lateral side of the animal. Despite the position similarity, QL and QR will follow an asymmetrical pattern of migration. During the first four hours after hatching, QL will migrate posteriorly to a position dorsal to the seam cell V5 and QR will migrate anteriorly to a position above V4. After reaching these positions, the Q cells will divide and their descendants migrate further along the anterior-posterior axis. This asymmetry is determined by intrinsic differences between QL and QR during their early migration. To better understand these differences, we are studying the early life of *C. elegans* Q

cells, particularly the period between their birth and first cell division. By using two markers that are co-expressed exclusively on Q cells (*Pegl-17::gfp; Pscm::mCherry*), we were previously able to FACS sort these neuroblasts from arrested L1s to use in bulk RNA-sequencing analysis. To sort younger Q cells, we used microscopy to confirm that these markers are also expressed in embryonic Q cells and we adjusted *C. elegans* growth conditions to stimulate egg holding by gravid adults. This allowed recovery of eggs spanning all stages of embryo development, including eggs in which Q cells were already born. In order to get cells that covered the entirety of QL and QR lifespan, we allowed further embryo development and egg hatching by incubating isolated eggs for three to four hours, which also helped increase the proportion of Q neuroblasts in the cell population. Cells were successfully extracted from the mixed population of eggs and L1s by using a novel combination of chitinase, SDS-DTT and pronase treatment protocols. FACS of dissociated cells allowed for identification and sorting of a cluster of cells that matched *C. elegans* Q neuroblasts. We now plan to use single-cell RNA-sequencing of the sorted Q cell population to identify two expression clusters representing the two Q cells, QL and QR, followed by differential gene expression analysis to identify genes associated with each population.

1745T **The role of peroxisome mediated glial-neuronal communication during Drosophila aging.** Anurag Das, Hua Bai Genetics, Development & cell Biology, Iowa State University

Peroxisomes are responsible for metabolic activities through the regulation of antioxidant enzymes and oxidases. An important process highlighted during cellular aging is when increased oxidative stress leads to a reduced import efficiency of peroxisomal matrix proteins containing a C-terminal peroxisomal targeting signal type 1 (PTS1). One of the key import factors that is predicted to enable cargo proteins holding PTS1 and its delivery to the peroxisomal matrix is the PEX5 (peroxin-5) protein *(Huang et al., 2020)*. Even though there is emerging evidence of peroxisomal distribution in and its dependency on glia cells *(Chung et al., 2020)* but an overarching question remains – "which adult glial subtype among *Drosophila* CNS contains peroxisomes?" We have made a novel identification that the cortex glia has a predominance of peroxisomes in the adult *Drosophila* brain. Further, we aim to establish a closely intertwined connection between peroxisome biology and glial of the adult *Drosophila* during the process of cellular aging. We have seen the dynamic changes in transport of the peroxisomal import machinery from the cytosol to the peroxisome marked with eYFP carrying the peroxisomal targeting signal - PTS1. We demonstrate that eYFP.PTS1 reporter driven by Repo-GAL4, a pan-glial marker, can be used to understand the decline of peroxisomal transport in the glial cells of the adult female *Drosophila* brain. Our preliminary data suggest that peroxisome import declines in aged glial cells. Among future directions, we are investigating how PEX5 impairment in different CNS glial cells, and peroxisome dysfunction affects glial and neuronal function during aging. Thus far, we have seen greater lipid droplet accumulation for cortex glia-PEX5 mutants compared with control as well as other glia drivers combined PEX5 mutants which is supported by literature as previously seen in (*Kis et al., 2015*) where they had shown lipid droplet accumulation being specific to the superficial cortex glial cells in the larval *Drosophila* brain. Our lab generated data also supports a PEX5 dependent decline in the climbing behavior of the flies which supports the idea of peroxisome mediated glia-neuronal cross talk.

1746T **Investigating the roles of *doublesex* and *dissatisfaction* in neurons contributing to female courtship behavior** Kara E Miller, Troy R Shirangi Biology, Villanova University

In *Drosophila*, transcriptional regulators encoded by the *doublesex* (*dsx*) and *dissatisfaction* (*dsf*) genes play important roles in the development of female courtship behaviors, but how they contribute to neuronal sexual development is unclear. Here, we investigated the phenotypic effects from the developmental knockdown of *dsx* and *dsf* transcripts in two female-specific *dsf* and *dsx* coexpressing neurons in the abdominal ganglion, the DDAG_C/D neurons. These neurons contribute to ovipositor extrusion, a courtship rejection behavior performed by mated females, and develop during metamorphosis as remodeled larval neurons. Knockdown of *dsx* in females had no obvious effect upon the DDAG_C/D development, whereas reduction of *dsx* function in males caused the gain of DDAG_C/D neurons. Conversely, knockdown of *dsf* resulted in the loss of the DDAG_C/D neurons in females, while the males were unaffected. Interestingly, optogenetic activation of the DDAG_C/D neurons in males with reduced *dsx* activity induced an extrusion of the terminalia, a behavior resembling ovipositor extrusion of mated females. Taken together, our results suggest that the male isoform of DSX promotes cell death of the DDAG_C/D neurons during metamorphosis, whereas DSF acts as an anti-apoptotic factor for the DDAG_C/D neurons in females. We hypothesize that DSX-M may promote DDAG_C/D cell death by antagonizing DSF's function as a pro-survival factor in the DDAG_C/D neurons.

1747T **Mapping synaptic partners of female-specific neurons that regulate female receptivity in *Drosophila melanogaster*** Micaela Murphy, Troy Shirangi Biology, Villanova University

In *Drosophila*, genes such as *doublesex* (*dsx*), *fruitless* (*fru*), and *dissatisfaction* (*dsf*) identify neurons that regulate sexually dimorphic behaviors in adults. *Dsx*- and *dsf*-expressing interneurons in the abdominal ganglion, named the DDAG neurons, are a small sexually dimorphic population that mediates abdominal behaviors in unmated and mated females that signal

their willingness or unwillingness to mate with courting males. Here, we utilize retro- and *trans*-Tango, two genetic tools for retro- and anterograde transsynaptic tracing, respectively, to identify pre- and postsynaptic partners of the DDAG neurons. Our work in progress has identified a population of interneurons with localized processes in the abdominal ganglion as putative postsynaptic partners of the DDAG neurons in females, mapping the DDAGs and their postsynaptic partners as upstream of abdominal motor neurons for female behavior. Future experiments will test the activity of these putative DDAG postsynaptic neurons for their contribution to courtship behaviors of unmated and mated females. Results from these experiments will provide insight into *dsf* and *dsx* function in the assembly of a sex-specific neuronal circuit that regulates female courtship behavior in *Drosophila*.

1748T **Notch signaling regulates temporal patterning for timely neuroblast elimination in a lineage specific manner** Kendall R Branham, Chhavi Sood, Sarah E Siegrist Biology, University of Virginia

The neurogenic period, where neural stem cells proliferate to produce molecularly distinct progeny in the developing brain, is a critical time of growth in many organisms. Proper brain development is crucial for survival and requires strict regulation of neural stem cell (NSC) divisions along the developmental timeline. In NSCs cell intrinsic programs integrate with extrinsic cues to control periods of rapid growth through temporal patterning genes. Without regulation, NSCs can under proliferate leading to diseases like microcephaly, or over proliferate leading to macrocephaly and tumors. We know programs that control timing of proliferation and elimination of NSCs exist, but many elements of temporal cassettes are still unclear. We currently lack a comprehensive understanding of temporal cassette regulation and how this impacts NSC progeny. To address these questions, we carried out a large-scale RNAi in Drosophila NSCs, known as neuroblasts (NBs), and identified Notch and its ligand, Delta as upstream regulators of temporal cassettes through the early factor Imp. We went on to show that reduced Notch signaling led to persistence of most central brain neuroblasts beyond their normal termination point (Sood et al., 2023). However, in mushroom body neuroblasts (MBNBs) we found loss of Notch resulted in premature elimination. The opposing phenotypes we saw in different NB lineages led us to investigate what factors could confer these differences. We studied the MBNB specific factor Eyeless (Ey) as a candidate for regulating Notch signaling and found that without Ey, Notch signaling is reduced. In this work, we discover that cell signaling pathways that involve the receptor Notch and its ligand Delta function to regulate NB proliferation in *Drosophila* by regulating early temporal factor expression, and Ey may contribute to Notch's differential roles in NB lineages.

1749T **Glial-specific knockdown of a subunit of the ER membrane complex (EMC) impacts development and adult survival of *D. melanogaster*** Maria Jose Orozco Fuentes[1], Ines Riojas[2], Otoha Tatami[2] [1]Neuroscience and Biology, Lake Forest College, [2]Biology, Lake Forest College

The ER membrane protein complex (EMC) is believed to participate in crucial functions of the endoplasmic reticulum such as protein folding, insertion, and packaging. This complex consists of 8-10 subunits and it is evolutionarily conserved from yeast to humans. A previous study showed decreased expression of EMC4 in glia after a traumatic brain injury (TBI) in Drosophila. Consequently, we decided to study the effect of an RNAi knockdown of EMC4 in glia, which resulted in notable phenotypes, such as delayed development, strongly impaired locomotion, a substantially shorter lifespan of 5-6 days, and increase in protein aggregation. We conducted a temporally-restricted knockdown and observed that fruit flies with normal levels of EMC4 during development but an adult-specific knockdown do not exhibit the same severity of adult phenotypes. This suggests that EMC4 has an important role in glia during development that impacts organismal health during adulthood. Additionally, preliminary studies suggest changes in expression of markers of ER stress response. The dramatic effect of this development-specific glial knockdown together with the known role of EMC in protein biogenesis suggest that EMC4 plays a critical role in some developmental function of glia involving transmembrane proteins.

1750T **Disruption of the arylalkylamine Nacetyltransferase-like-7 gene*, AANATL-7*, identifies an additional metabolic pathway for histamine inactivation in *Drosophila melanogaster*** Lydia Cruce[1], Margaret Cubitt[1], Katie Westfall[2], Martin G Burg[2] [1]Cell & Molecular Biology, Grand Valley State Univ, [2]Biomedical Sciences, Grand Valley State Univ

In *Drosophila melanogaster*, 8 genes encoding arylalkylamine Nacetyltransferase-like enzymes have been identified that likely acetylate molecules involved in several biological processes, from aminergic neurotransmitter inactivation, melanin synthesis, to sclerotization of the cuticle. The arylalkylamine Nacetyltransferase-like-7 protein (encoded by the *AANATL-7* gene) has been shown to acetylate histamine *in vitro*, producing N-acetylhistamine (NAH) **(1)**. In *D. melanogaster*, histamine is a photoreceptor neurotransmitter and is also present in the CNS, likely functioning as a neuromodulator. Genes that contribute to histamine metabolism in photoreceptors include histidine decarboxylase (*Histidine decarboxylase*; histamine synthesis), β-alanyl synthase, (*ebony*; histamine conversion to carcinine), and β-alanyl hydrolase (*tan*; carcinine conversion to histamine) **(2).** We have detected *Hdc*-dependent histamine-like immunoreactivity in the secondary cells of male accessory glands where NAH has also been shown to be present **(3)**. Pre-absorption of a "histamine" antibody indicated it can be blocked

by histamine, carcinine, or NAH. In *ebony* mutants, the immunoreactivity is still present in secondary cells, suggesting that this immunoreactivity could be identifying NAH. Since AANATL-7 acetylates histamine *in vitro* **(1)** and is expressed in the accessory gland **(4)**, we generated *AANATL-7* mutants using a co-CRISPR/cas9 mutagenesis approach, using *ebony* as a visual marker. From 96 G_0 parents, 25 G_0 flies generated *ebony* progeny (ranging from 1-53% mutant progeny within each *ebony*-producing G_0 brood), from which single *ebony* flies were used to establish isogenic lines. Male flies from these isogenic lines were subjected to sequence analysis, which indicated that progeny from at least 7 isogenic lines contained frameshift mutations at the sgRNA-targeted site in the *AANATL-7* gene. Immunostaining *AANATL-7* mutant accessory glands with the "histamine" antibody indicated that the histamine-like immunosignal was mostly eliminated. This result suggests that the AANATL-7 protein acts as a histamine acetylase in male flies, as the *AANATL-7* mutations eliminate most of the immunoreactivity in the accessory gland and is therefore presumed to be detecting NAH. These results suggest that histamine acetylation is a novel step in histamine metabolism in *D. melanogaster*.

1751T **Exploring the Connection Between Circadian Rhythms and Sex-Specific Behavior in *Drosophila*** Brooke E Bascom[1], Anthony S DeLuca[1], Matthew A. Kocher[1], Daniela A. Key Planas[1], Marielise Torres[1], Michelle Arbeitman[2] [1]Florida State University, [2]Biomedical Sciences, Florida State Univ

Circadian rhythms govern daily activities in *Drosophila.* Here we investigate the relationship between sex-specific behavior and the circadian system by examining a set of neurons that express the transcriptional regulatory genes *clock (clk)* and *fruitless (fru)*. *Clk* encodes a transcription factor of the core molecular circadian pacemaker, governing the diurnal activity pattern. *fru P1* encodes male-specific transcription factors that are necessary and sufficient for male courtship behavior. *fru P1* expressing neurons are found in both males and females and underlie reproductive behaviors. Our previous single-cell RNA sequencing data revealed intersecting *fru P1* and *clk* (*fru* Ω *clk)* expressing neurons, present in both male and females. Here we examine individual *fru* Ω *clk* – expressing neurons in males and females over six circadian time points through confocal microscopy, using a multi-cassette FLP-out approach. In addition, we examine how the sex hierarchy regulates sex differences in *fru* Ω *clk* - expressing neuron number and morphology. We examine the role of *fru* Ω *clk* - expressing neurons in establishing circadian period length, sleep and activity, and reproductive behavior by activating and silencing these neurons. Using the Trans-Tango system that labels neuronal targets, we find *fru P1*+ targets of *clk*, Per+ targets of *fru P1*, and Per+ targets of the other sex hierarchy transcription factor encoded by *doublesex* (*dsx*). In addition, using a transcriptional reporter of neuronal activity called CRTC, we determine if mating changes male fru Ω clk neuron activity. Finally, we ask if conditions that result in a shortened period, through activation of fru Ω clk neurons, impact the molecular clock in a non-autonomous fashion.

1752T **The Role of F-box Protein FBXL20/CG9003 in Drosophila Synapse Development** Tianlu Wei, Lily Liu, Junghwan Kim University of Nevada,Reno

The ubiquitin proteasome system (UPS) is crucial for protein homeostasis in the nervous system. The F-box proteins are one of the fundamental components in the UPS by playing a role in substrate selectivity. Dysregulation of the F-box proteins can lead to detrimental effects on synaptic connectivity and plasticity in neurodegenerative conditions. In this work we characterized the synaptic function of *CG9003*, the *Drosophila* ortholog of human F-box proteins--FBXL20 and FBXL2, in the larva neuromuscular junction (NMJ) and the larval sensory circuit. We found that *CG9003* mutants exhibited a reduction in both bouton number and total length in NMJ. Furthermore, *CG9003* mutations caused decrease in synaptic connectivity of the larval sensory circuit, which was revealed by a reduction in the synaptic GFP reconstitution across synaptic partners between the sensory neuron and its postsynaptic projection neurons. These findings suggest a role of *CG9003* in synapse development. Interestingly, FBXL20 and FBXL2 physically interacts with YPEL proteins in human cells. *YPEL3* belongs to the Yippee-like gene family, which is conserved across eukaryotic species from yeast to humans. We found that CG9003 physically interacts with dYPEL3 in *Drosophila*. Previous research from our laboratory has demonstrated a similar reduction in the sensory synaptic connectivity by *dYPEL3* mutations. We further found that *dYPEL3* mutations caused similar NMJ defects as in *CG9003* mutants. In summary, our findings suggest that *CG9003* and *YPEL3* operate within the same pathway to regulate synapse development.

1753T **Life, Death, & Cannibalism** Emily Siff, John Carlson Molecular, Cellular, & Developmental Biology (MCDB), Yale

Where there is life, there is death. Death can occur due to a variety of factors, such as lack of resources, disease, predation, and old age. Although death may be a common occurrence, how animals sense and respond to the dead of their own kind (conspecifics) remains curiously unexplored. Utilizing behavioral, genetic, neural, and computational approaches in the fruit fly (*Drosophila*), this work seeks to elucidate fundamental questions about how animals sense and respond to the dead. While death is often viewed as an aversive state, this research uniquely studies contexts in which death has a positive valence, thus generating entirely new findings, as well as re-contextualizing previous work Zooming out, this research contributes to a larger,

interspecies body of work that has begun to suggest that life, death, and cannibalism are closely intertwined.

1754T **Connecting temporal patterning in neural progenitors to neuronal identity in Drosophila Visual System** Asif Ahmad A Bakshi[1], Claude Desplan[1,2] [1]Center for Genomics and Systems Biology, New York University Abu Dhabi, [2]Department of Biology, New York University

Neural progenitors in the Drosophila visual system are temporally patterned to produce a variety of neuronal types. Apart from temporal patterning, the neuronal diversity is driven mainly by spatial patterning, and binary cell fate decisions mediated by Notch signaling. The integration of all three mechanisms specifies around 200 neuronal types in developing Drosophila visual system. Temporal patterning is primarily driven by the sequential and overlapping expression of a series of transcription factors called temporal TFs (tTFs). Most of these tTFs express in NBs and pass on to newly born neurons, however they are not maintained throughout development. tTFs activate the expression of a set of transcription factors called Selectors, whose sustained expression is maintained in the neurons and they specify the molecular and functional identity of neurons downstream of temporal factors. However, how do tTFs pass on the early specification program in NBs to regulate and maintain neuronal identity via cell type-specific selectors genes is not clear. I am using DamID based genomics followed by its integration with the single cell multiome data to answer this question. Identifying potential target genes of tTFs, particularly Selectors, in cell-type specific manner will be the first step towards getting a deeper understanding of the underlying mechanisms driving neuronal diversity in Drosophila visual system.

1755T **Non-ionic GluR signaling remodels DLG to induce rapid retrograde homeostatic plasticity** Chengjie Qiu[1,2], Yifu Han[3], Christine Chen[3], Pragya Goel[3], Sarah Perry[3], Dion Dickman[4] [1]Neuroscience Graduate Program, University of Southern California, [2]Department of Neurobiology, University of Southern California, [3]University of Southern California, [4]Department of Neurobiology, Unviersity of Southern California

Synapses must be resilient to the challenges they confront during development, growth, disease, and aging. At the glutamatergic *Drosophila* neuromuscular junction (NMJ), acute pharmacological perturbations of glutamate receptors (GluRs) by philanthotoxin-433 (PhTx) can be counteracted by enhanced presynaptic neurotransmitter release to maintain synaptic strength, a process called presynaptic homeostatic potentiation (PHP). Much is now known about the genes and mechanisms in the presynaptic neuron that enable the expression of PHP. However, how retrograde PHP signaling is rapidly induced in the postsynaptic compartment remains enigmatic. Importantly, recent evidence suggests that perturbation of ionic flow through GluRs or reductions in postsynaptic Ca^{2+} influx are insufficient to induce rapid PHP expression. Here, we combine molecular genetics, electrophysiology, and confocal and super-resolution microscopy to suggest that conformational signaling through GluRs is necessary for the induction of rapid, retrograde PHP. First, we find that pharmacological antagonism of GluRIIA-containing receptors provokes changes in GluR organization, which is propagated throughout the postsynaptic apparatus. Indeed, preliminary data suggests these structural changes to the postsynaptic compartment are necessary for the presynaptic adaptations that characterize PHP, including active zone remodeling and enhanced neurotransmitter release. Second, we identify Discs large (Dlg), from a CRISPR/Cas9-based genetic screen, as a key postsynaptic scaffold that is targeted for conformational signaling and that is selectively required for rapid PHP expression. Finally, we interrogated whether synaptic activity itself was necessary for PHP inductive signaling. Surprisingly, we find that homeostatic remodeling of both the pre- and post-synaptic compartments persists following pharmacological antagonism of GluRs in the absence of neurotransmission. Altogether, our findings support a model in which acute perturbation of GluRs initiates conformational signaling, which is propagated throughout the postsynaptic apparatus, transmitting retrograde information that is necessary to induce homeostatic plasticity to presynaptic release sites.

1756T **Neural origin of a female-specific sexual behavior in *Drosophila santomea*** Minhao Li[1], Dawn Chen[1], Ian Junker[1], Aaron Comeault[2,3], Daniel Matute[2], Yun Ding[1] [1]Biology, University of Pennsylvania, [2]University of North Carolina at Chapel Hill, [3]Bangor University

Courtship interactions are remarkably diverse in form and complexity among species and intrinsically dynamic. How neural circuits evolve to encode new adaptive social behaviors that function in the appropriate sensory and motivational contexts is not known. Here we leverage *Drosophila* species as an emerging neural comparative model and a recently evolved female sexual behavior to explore the circuit basis underlying the origin of new social behaviors. Females in *D. santomea* exhibit wing spreading as a functional receptive response to male courtship songs – an ancestral behavior that has been lost in the lineage of *melanogaster* subgroup but re-emerged after the divergence from the sibling species *D. yakuba* within the recent 0.4 million year. We hypothesized that wing spreading originated through modification of pre-existing female sexual circuits that express the sex determination gene *doublesex*. Therefore, we developed genetic tools that specifically label and manipulate *doublesex* neurons for functional comparison in *D. santomea*, *D. yakuba*, and the model species *D. melanogaster*. Optogenetic activation of *doublesex* neurons across species and the co-occurence of wing spreading with the conserved female

behavior vaginal plate opening together suggests that vpoDN, a pair of descending neurons that integrates male courtship song stimuli and female internal state to drive vaginal plate opening, drives robust wing spreading in *D. santomea* but not in *D. yakuba* or *D. melanogaster*. Interestingly, *D. santomea* vpoDN neurons exhibit a species-specific arbor that innervates wing neuropil. Surprisingly, vpoDN activation elicited wing spreading in a very small number of females in *D. melanogaster*, and its efficacy to elicit wing spreading drastically increased at a higher developmental temperature, supporting the existence of latent circuits that plastically potentiate wing spreading. Overall, we identified the neural mechanism of a newly originated female behavior in *D. santomea* and revealed the existence of a latent and plastic ancestral circuit in *D. melanogaster*. Our study shows that new social behaviors may arise from the assembly of key circuit nodes that interpret social contexts with latent motor programs, highlighting how ancestral circuits potentiate and shape behavioral evolution.

1757T **Clearance of cell corpses in the phagocytosis-deficient *Drosophila* brain** Cheng Yang (Jason) Shi[1], Guangmei Liu[2], Iqra Amin[2], Kim McCall[2] [1]Biology, Boston University, [2]Boston University

Billions of cells die per day to maintain homeostasis during development, growth and aging. Physiologically, dead cells are rapidly engulfed and degraded by phagocytes through phagocytosis. In the central nervous system, glial cells play a pivotal role in eliminating dead cells. Deficits in phagocytosis can result in different pathologies, including autoimmune and neurodegenerative diseases. In *Drosophila*, Draper (Drpr) is a crucial phagocytic receptor on the surface of glia to recognize dead cells. Our lab previously found that knocking down *drpr* in glia lead to persistence of neuronal corpses, actively dying glia, and age-dependent neurodegeneration. Notably, these neuronal corpses are neurons that died during larval and early pupal development, and the number of neuronal corpses remains constant as fly aged. However, whether neurons that die after developmental stages are engulfed and cleared is not known. Unlike persisting neuronal corpses in the *drpr*-deficient flies, glia are actively dying and the number of glial corpses decreases over time suggesting they are cleared independently of *drpr*. However, the mechanism by which these glial corpses are cleared is still unknown. Using markers to detect engulfment, we are investigating whether neurons and glia that die during adulthood are cleared by fellow healthy glia in the absence of *drpr*.

1758T **A microRNA screening reveals miR-33 as a modifier of TDP-43 toxicity in flies** Swapnil Pandey, Alfonso Martin-Pena, Deepak Chhangani, Shivam Kaushik, Diego Rincon-Limas Neurology, University of Florida

Abnormal distribution and phosphorylation of TAR DNA-binding protein 43 (TDP-43) are hallmarks of frontotemporal lobar degeneration (FTLD) and amyotrophic lateral sclerosis (ALS). Although the mechanisms underlying TDP-43 proteinopathies are largely unknown, recent evidence suggest that aberrant microRNA (miRNA) biogenesis or function might be linked to TDP-43 neurotoxicity. Indeed, FTLD/ALS patients display abnormal expression of at least 23 miRNAs. Since the mechanisms controling these miRNAs and the identification of their bona fide targets remain to be elucidated, the overall impact of miRNAs on TDP-43 proteinopathies is largely unknown.

To shed light on this issue, we recently screened a library of 107 *Drosophila* miRNAs in a fly model expressing human TDP-43^{M337V}. This library contains miRNAs that are highly conserved throughout evolution and was recently created with an attP-based UAS vector to ensure identical miRNA expression levels from all constructs. We found that most miRNAs do not modify the TDP-43^{M337V}-induced eye phenotype or lead to severe developmental eye phenotypes when misexpressed on their own. However, we found that over-expression of mir-33 dramatically suppressed mutant TDP-43 toxicity in the *Drosophila* eye. This is relevant because human mir-33 is downregulated in FTDL patients with TDP-43 pathology. Importantly, mir-33 does not rescue eye phenotypes in fly models of other proteinopathies, suggesting that the robust ability of mir-33 to block TDP-43 toxicity is highly specific. Interestingly, we have tested several mir-33 targets for their potential to mimick the rescue of TDP-43 phenotype when knocked down by expression of their especific RNAi contruct. These results led us investigate the role of extracellular matrix (ECM) glycoproteins involved in cell adhesion, signaling, and neurite outgrowth. Thus, we hypothesize that TDP-43 pathology triggers mir-33 dysfunction, which results in ECM alterations. To test this, we are currently assessing the role of mir-33 in the fly CNS to obtain a better understanding of the TDP-43 pathology and its association with ECM abnormalities. This work is supported by the NIH grant R01AG059871 to DERL.

1759T **Identifying the genetic basis of olfactory learning and memory skills in *Drosophila melanogaster*** Reiley Heffern, Jamie Baumann, Victoria Hamlin, Elizabeth King Biological Sciences, University of Missouri - Columbia

Learning and memory skills are necessary for organisms to adapt to their changing environment. For example, if a population migrates, those organisms may use olfactory stimuli to learn and remember where food or threats are in their new environment. Studies have shown that these skills are influenced in part by one's genetic makeup. Learning and memory abilities are complex traits, meaning that multiple genes and the environment contribute to these skills. In our investigation using nine recombinant inbred lines (RILs) of *Drosophila melanogaster*, we are aiming to identify which genetic variants are associated with higher performance on learning and memory tasks.

Operant conditioning is the process by which organisms learn to predict an outcome from a certain stimulus. We utilize operant conditioning to train flies of each RIL to associate a certain odor with a sugar reward. We then use Y-mazes to present them with a choice between the odor we conditioned them to (the positive stimulus) and an odor that is not associated with a reward (the negative stimulus). We conduct this testing on one group of flies immediately after conditioning to test their learning skills, and again four hours after conditioning on the other group to test their short-term memory skills. At the conclusion of each test, we collect and count the number of flies that chose correctly, chose incorrectly, and did not choose. We then quantify these results for each RIL by calculating a performance score. After completing three replicates of testing, we will computationally analyze our phenotyping data to identify quantitative trait loci (QTLs) that are linked to learning and memory skills. Then, we plan to look at those QTLs and analyze the significance of any differences in haplotype frequency at these QTLs in each RIL. If RILs that have high performance scores have a high frequency of a certain haplotype at a QTL, and RILs that have low performance scores have a low frequency of that haplotype at the same QTL, that haplotype at that QTL may contribute to higher learning and memory abilities.

1760T **Identification and Characterization of Sleep-Regulating Neuronal Subsets within the Central Complex of *Drosophila melanogaster*** Preeti Sundaramurthi[1], Tanya Wolff[2], Nan Chen[2], Divya Sitaraman[1], Gerald M Rubin[2] [1]Psychology, California State University, East Bay, [2]Janelia Research Campus, Howard Hughes Medical Institution, Ashburn VA

Sleep is a fundamental, highly conserved behavioral state that is important for the survival of most animal species ranging from those with few neurons, like jellyfish, to those with brains and complex nervous systems, like humans. The ability of an animal to switch between sleep and wakefulness states, and to persist in the wakefulness state to carry out activities such as mating and feeding is a hallmark of the sleep-wake behavior. Discrete populations of neurons have been identified in multiple organisms such as fish, worms, and flies that either increase (sleep-promoting) or decrease (wake-promoting) the animals' propensity to sleep. Interactions between these neurons is critical for the sleep-wake behavior, but the precise mechanisms of communication between these identified sleep-regulating neurons is poorly understood.

The fruit fly, *Drosophila melanogaster*, has proven to be an excellent model to study the circuit basis of sleep. A specific brain region called the Central Complex has been implicated in sleep regulation. Using a library of split-GAL4 lines targeting specific neuronal cell types within the central complex we have identified several neurons that are critical to sleep onset and maintenance. We will present the results of the screen and discuss the role of a specific class of sleep promoting neurons known as PFGs that innervate multiple regions within the central complex. PFGs regulate sleep in a sexually dimorphic way using a combination of neurotransmitters and neuropeptides. We will explore the function of these neurochemicals and present hypotheses related to how PFGs integrate within existing sleep regulatory circuits within the central complex.

1761T **Are the functions of Netrin and Frazzled conserved among insects?** Piyasi Ghosh, Ben Wadsworth, Tim Evans BISC, University of Arkansas

Axon guidance in bilaterians is often controlled by signaling pathways in the nervous system that determine the fate of the axons, for example, if they would cross the midline or not. One such pathway involved is a ligand-receptor pair Netrin (Net) and Frazzled (Fra), which is also known as the "attractive pathway". Net and Fra together promote midline crossing of axons in insects and other bilaterians. Orthologs of the pathway receptor Fra in insects, is Deleted in Colorectal cancer (DCC) in vertebrates, and UNC-40 in *Caenorhabditis elegans.* How well are the regulatory roles of these proteins conserved is not well understood. Hence, this project aims to compare the direct evidences of midline attractive roles of the Frazzled receptor in the flour beetle (*Tribolium castaneum*) and fruit fly (*Drosophila melanogaster*) using CRISPR/Cas9 gene editing tools. In this project we rescued the role of Frazzled from Drosophila (DmFra) in promoting midline crossing of axons in Drosophila using an HA-tagged Frazzled from Tribolium (TcFra).

1762T **Insights into the aging brain through unraveling the development and transcriptional signature of polyploid cells** Deena Damschroder, Jenny Sun, Laura Buttitta University of Michigan

Polyploid cells contain multiple copies of chromosomes and are derived various ways, including a non-canonical cell cycle known as an endocycle, which involves DNA synthesis without cytokinesis. Numerous tissues are known to contain polyploid cells, including the brain. In fact, in mammals there is a well-established correlation between polyploid neurons in the aging brain and neurodegeneration. Despite this correlation, the genes responsible for the formation of polyploid cells in the aging brain and the functional role of these cells is unknown.

In our previous work, we observed the accumulation of polyploid cells in the adult brains of multiple genotypes and species of aging Drosophila. Here, we expand on that work examining how known lifespan modifiers influence the accumulation of polyploid cells in the aging brain. We find that the accumulation of polyploidy with age can be impacted by diet and temperature-dependent lifespan extensions, but that it does not proportionately scale with lifespan extensions. This suggests

that the genetic networks involved in neuronal and glial polyploidy in the adult brain are complex, and may be impacted by both developmental and adult physiological processes.

To understand the consequences of polyploidy in the brain, we are examining the transcriptional signature of polyploid neuronal and glial cells in the adult brain. From this work we aim to identify molecular markers of polyploidy in these broad cell types and identify genetic regulatory networks that may be activated or repressed in these cells to impact their cellular functions. Collectively, we aim to shed light on the causes and consequences of polyploidy in the brain under normal physiological conditions

1763T **Effects of peripheral vs local immune activation on larval neuroblast proliferation** Omina Nazarzoda[1], Michelle Bland[2], Sarah Siegrist[3] [1]University of Virginia, [2]Pharmacology, University of Virginia, [3]Biology, University of Virginia

Healthy brain development depends on optimal environmental conditions such as food, temperature, and protection of fetus and mother from pathogens. In resource-poor environments, where children and mothers are constantly exposed to pathogens and lack accessible health care, chronic immune activation is associated with disrupted growth and cognitive development in children. One way to predict neurodevelopmental disruption is to look at the earliest stages of neural stem cell proliferation that makes the brain. We investigate if neural development is affected by genetic immune activation in different tissues/cells. We use *Drosophila* neuroblast proliferation as a proxy for neural development, and expression of a mutated Toll^{10b} receptor for a constitutive activation of immune signaling in fat body or glial cells. We observe reduced neuroblast proliferation in larvae expressing Toll^{10b} in larval fat body (r4-Gal4 > UAS-Toll^{10b}). We also measured the mRNA levels of antimicrobial peptide Drosomycin (Drs), which is induced in response to Toll pathway activation. We find a significant increase in Drs mRNA levels in whole larval brain when Toll^{10b} is expressed in glia (repo-Gal4), but inconsistent in fat body (r4-Gal4 and cg-Gal4 driver). Taken together, these results suggest that brain development is impacted by the activation of immune signaling in fat body likely via secreted factors or via activation of hemocytes. Activation of immune signaling in glial cells, on the other hand, shows that glia are competent to respond to Toll^{10b} expression by inducing Drs, suggesting local effects of immune signaling on larval brain development.

1764T **Investigating the Role of the ER Integral Membrane Protein Jagunal in Neural Development in *Drosophila*** Nina Nicole Marcelo[1], Maria L Mendoza Aragon[1], Judy Abuel[2], Blake Riggs[2] [1]Biology, San Francisco State University, [2]San Francisco State University

Cell division is an important occurrence in life and is essential for the creation of all multicellular organisms. Although we understand how cells divide during mitosis, it is still unknown how cells adopt their cell fate and become specialized cells. Recent studies have shown that the highly conserved endoplasmic reticulum (ER) transmembrane protein, Jagunal (Jagn), is necessary for the asymmetric cell division (ACD) of the ER during mitosis in early *Drosophila* embryos. Preliminary data shows that Jagn-deficient larval brains display a shift towards stemness with an over proliferation of neuroblasts. This leads us to examine the role that Jagn plays in neural development. We hypothesize that Jagn is involved in the regulation of cell differentiation allowing cell fate determinants to orient properly which is vital in the development of *Drosophila* brain. Jagn mutants display lethality in 1st instar, thereby making it difficult to properly examine the role of Jagn in larval brain development. In order to test our hypothesis, we dissected 3rd instar larval brains of a Jagn-RNAi line driven with a Delta-Gal4 driver to investigate whether Jagn is necessary in the development of the *Drosophila* larval brain. Our results reveal that Jagn-RNAi 3rd instar larva display a significantly smaller brain size compared to the controls. Specifically, inhibition of Jagn, showed a reduction of the ventral nerve cord (VNC) in the larval brain. Based on this result, we sought to examine any defects in larval feeding behavior by performing a feeding assay. However, our results show that Jagn-RNAi larvae consumed around the same amount of food as our control. In order to understand the *Jagn*-induced lethality, we immunostained larval brains with an apoptotic marker, DCP1, to examine if Jagn-RNAi brain cells experience higher levels of cell death. We found that indeed, Jagn-RNAi larval brains displayed higher levels of DCP1, suggesting that Jagn is necessary in developing the brain and in maintaining homeostasis and cell populations in tissues. Future direction will focus on staining cell fate determinants that play a role in neurodevelopment during larval brain development, as well as perform behavioral assays to assess the locomotor, learning, and memory deficits. Furthermore, our findings will contribute to the understanding of neurogenesis and cell fate differentiation during early development of *Drosophila* brains.

1765T **Investigating cell type-specific requirements for the RNA exosome within the brain through study of Pontocerebellar Hypoplasia Type 1b disease mutations in *Drosophila*** Lauryn A Higginson[1], Derrick J Morton[2] [1]University of Southern California, [2]Biological Sciences, University of Southern California

Accurate post-transcriptional regulation of gene expression is critical for proper neuronal development and function. Many of these highly coordinated post-transcriptional regulatory events are mediated by an evolutionarily conserved and ubiquitously

expressed RNA processing complex, the RNA exosome. Despite the broad, essential roles of the RNA exosome, missense mutations in genes that encode subunits of this complex cause neurological disorders characterized by distinct cell type defects. Recessive mutations in RNA exosome subunit gene *EXOSC3* cause a devastating human neurodevelopmental disorder, Pontocerebellar Hypoplasia Type 1B (PCH1b). PCH1b is characterized by defective development and atrophy of the brainstem and cerebellar structures. Why mutations in genes encoding structural subunits of the RNA exosome preferentially affect cells within specific brain regions and result in distinct pathology is unclear, but this suggests that specific tissues depend on the RNA exosome more than others. To understand whether regulatory programs in specific cell types within the brain require unique functions of the RNA exosome complex, we have generated an allelic series of pathogenic variants in the RNA exosome cap subunit, *EXOSC3* (fly *Rrp40*) in *Drosophila* modeling severe (Rrp40-G11A) or moderate (Rrp40-G146C) disease. My preliminary studies show that PCH1b disease-causing Rrp40 variants cause a spectrum of organismal phenotypes, including reduced viability, behavioral defects, and defects in brain morphology. In addition, single-nuclei RNA-sequencing analysis of each *Rrp40* mutant fly reveals distinct gene expression profiles for cell subpopulations. Furthermore, differential expression analysis on these distinct cell subpopulations shows aberrant accumulation of functionally important neuronal transcripts, including *Arc1*, a key regulator of synaptic plasticity. To validate our single-nuclei datasets, we employed quantitative mRNA imaging technology throughout the entire *Drosophila* brain via Hybridization Chain Reaction (HCR) RNA-FISH to visualize defects in mRNA expression and localization, including *Arc1*. In sum, this work represents the first cell-specific analysis of pathogenic RNA exosome mutations in an intact nervous system *in vivo* and, thus, provides insight into whether the RNA exosome is vital for the proper function of all cell types within the brain or whether it has specialized roles in neuronal cell subtypes.

1766T **Investigating the Cross-regulation of DATILÓGRAFO and NOCFLY in Decision Making** Amina Jahan Shammo[1], Ornella Meko[2], Kexin Zhang[3], Aravindan Krishnan[1], Rui Sousa-Neves[2], Claudia Mizutani[1] [1]Biology, Case Western Reserve University, [2]Genetics and Genome Sciences, Case Western Reserve University, [3]Case Western Reserve University

The transcription factor DATILÓGRAFO (DATI) is required in a neural circuit in the brain that decides whether a female accepts or rejects male courtship. Recently, we identified computationally the targets of DATI that are conserved from *Drosophila* to humans. Interestingly, 20% of these genes are candidates for Alzheimer's Disease (AD) and/or interact with the central gene of familial AD, the Amyloid Precursor Protein (APP). AD is a disease mostly known for its devastating effects on memory, and it also impairs decision making. Among the DATI targets identified that interact physically and/or appear as candidates for AD, we find *nocfly* (*CG44422*). Here we provide evidence that, like DATI, NOCFLY is required for female acceptance. NOCFLY (CG44422), is the homolog of the Potassium voltage-gated channel interacting proteins 1/4 (KCNIP1/4) that acts as Calcium-dependent transcriptional repressor and a regulator of Calcium and Potassium channels. These data argue that DATI is required for the expression of *nocfly*, which is turn represses a set of DATI targets. To further investigate this possibility, we searched computationally for candidate genes to be regulated by NOCFLY. Surprisingly, 89% of the DATI targets are NOCFLY candidate targets, suggesting an extensive cross-regulation between DATI and NOCFLY. This result suggests that NOCFLY may dampen the expression of a large group of DATI targets. To test this possibility, here we analyze the effects that the loss of DATI or NOCFLY have on the transcriptome of the cholinergic neurons that make these decisions. We generated flies expressing RFP in the cells of interest in a normal background, and in cells with loss of expression of either DATI or NOCFLY and used FACS to sort these cells for RNAseq analyses. We expect this approach will enable us to gain insights into the gene network and co-regulation of target genes by these two transcriptions factors.

1767T ***Pax3* expression within neural crest is essential for differentiation of sacral progenitors that form pelvic autonomic neurons** Michelle Southard-Smith[1], Edom Seyoum[1], Ysabel Gomez[1], Karen Deal[1], Zunyi Wang[2], Dale Bjorling[2] [1]Genetic Medicine, Vanderbilt University Medical Center, [2]Surgical Sciences, University of Wisconsin Madison

Innervation of the lower urinary tract (LUT) is required for normal micturition patterns. Motor neurons that mediate contraction of the urinary bladder are part of the autonomic nervous system that originates from the neural crest. In rodents, these neurons are aggregated into major pelvic ganglia (PG) just dorsolateral to the bladder neck. PG are formed from sacral level neural crest whose migration paths into the fetal urogenital sinus have been recently described. However, knowledge of the genes that regulate PG neurogenesis has been lacking. To identify candidate factors during development of PG, we assessed transcription factor expression patterns in lower urinary tracts of fetal mice. This analysis identified a prominent pulse of *Pax3* expression during PG neurogenesis and subsequent hybridization chain reaction in situ identified *Pax3* mRNA in differentiating PG neurons. Global loss of *Pax3* causes perinatal lethality that prevents postnatal analysis of LUT function. We devised crosses using a conditional allele *Pax3*$^{tm1.1Sjc}$ (*Pax3*^{flox}*, after cre Pax3*^{cKO}) to delete *Pax3* from neural crest progenitors that give rise to pelvic autonomic neurons. Using a cre line that is prominently expressed in neural crest progenitors (Tg(Sox10-cre)1Sout) we examined whether neural crest expression of *Pax3* is required for normal development of PG, bladder innervation, and bladder function. Offspring from *Pax3*^{flox} x Tg(Sox10-cre) crosses (*Pax*$^{NC\text{-}cKO}$) lack *Pax3* in multiple neural crest lineages including melanocytes, peripheral nervous system, and autonomic neurons. In fetal stages, *Pax*$^{NC\text{-}cKO}$ mice

have normal-sized aggregates of sacral NC progenitors that colonize the fetal urogenital sinus. However, differentiation of PG neurons is delayed in fetal *Pax3* $^{NC\text{-}cKO}$ mice and postnatally the PG of these mutants are smaller, with abnormal morphology. *Pax3* $^{NC\text{-}cKO}$ mutants survive to adulthood, exhibit altered voiding patterns, and functional studies of bladder contractility using electrical field stimulation on bladder muscle strips found reduced bladder contractility in these mutants. These studies demonstrate that *Pax3* plays an essential role in differentiation of sacral neural crest that form the PG and establishes a novel, viable mouse model for further study to define essential gene regulatory networks in PG neurogenesis.

Funding: NIH R01DK136891.

1768T **Epistatic mutations in *Ssc4d* and *Kpna3* regulate age dependent hyperactivity in mice.** Yehya Barakat[1,2], Sean Deats[3], Tom Sproule[3], Marina Santos[3], Jacob Beierle[3], Vivek Kumar[3] [1]Kumar Lab, The Jackson Laboratory, [2]Tufts University, [3]The Jackson Laboratory

The NCHS estimates that 8.56% of children in the United States are diagnosed with developmental disorders. It is therefore critical to understand the neurobiological mediators of developmental disorders to improve patient outcomes. Through ENU mutagenesis our lab has generated a mutant mouse line (Crichton ENU) that exhibits age dependent hyperactivity starting at 6 and plateauing at 20 weeks of age. Quantitative trait loci analysis (QTL) identified 2 genome wide significant QTLs and identified missense mutations within *Ssc4d* and *Kpna3* as causal. Both mutations are needed to express the hyperkinetic phenotype, demonstrating a novel epistatic relationship between the understudied scavenger receptor *Ssc4d* and nuclear import factor *Kpna3*. This was confirmed by generating a *Ssc4d*$^{mut/mut}$ and *Kpna3*$^{mut/mut}$ CRISPR mouse line (Crichton CRISPR) which had a similar pattern of hyperactivity to the original ENU line. To interrogate the mechanism of this epistasis, we examined protein stability, protein binding, and RNA expression in the brain. We observe no destabilization in the mutant proteins but analysis of differential KPNA3 binding partners revealed a general loss of canonical binding partners important for its nuclear import capabilities.

We also investigated transcriptomic differences between young (4-week-old) and adult (20-week-old) Crichton and wildtype mice in the prefrontal cortex (PFC), hippocampus, and choroid plexus using bulk RNAseq. *Ssc4d* is highly expressed in the ChP, where differentially expressed gene (DEG) analysis and gene ontology enrichment analysis revealed decreases in cell organization genes in old mutants. DEG analysis revealed cilia and developmental synaptic pathways being impacted in Crichton CRISPR. Finally, PFC DEG analysis highlighted myelination and oligodendrocyte differentiation downregulation in the young mutants. These results reveal a slew of developmental changes that will enable us to interrogate this epistatic relationship on a mechanistic level. Additional future directions will involve examining choroid plexus structurally and functionally and using viral tools to examine the role of SSC4D in the brain. By pursuing these gene expression changes it will lead us to closer to understanding how *Kpna3* and *Ssc4d* interact to promote motor control development.

1769T **Role Of CRISPR-Cas9 Screens in Elucidating the Gene Functionality in Patients Derived Induced Pluripotent Stem Cells (iPSCs) For Neurodegenerative Disorders** Ammara Talib Biomedical Engineering, Near East university north Cyprus

Neurodegenerative illnesses are wreaking havoc on sufferers and the global economy. The number of patients is continually increasing as life expectancy rises. These disorders are caused by nerve cell degeneration or loss of function. There are currently certain medicines that may alleviate some physical and mental distress, but we cannot slow or eliminate the disease. One major impediment to developing medicines is our lack of understanding of the underlying mechanisms. iPSCs have emerged as key participants in disease modeling and drug development, providing a sustainable source of human neurons for research. In this abstract, we discuss the critical function of CRISPR Cas screens within the iPSCs paradigm for elucidating the processes underlying neurodegenerative disorders that are required to comprehend the molecular mechanism at the functional level and to therapeutically target relevant genes. A revolutionary development has been the implementation of CRISPR-Cas9 technology for functional genomic screening. This is a flexible tool to investigate gene interactions, functions, and their effects on diverse biological processes, illnesses, and prospective therapeutic approaches. With the amazing success of the CRISPR Cas gene editing system in driving clinical research, there is a great deal of promise for the use of CRISPR screens in neurodegenerative illnesses. CRISPR screens are especially effective when combined with induced pluripotent stem cell technology, which allows for the generation of multiple cell types, including neurons and glia, as well as brain organoids, from cells taken from patients. CRISPR RNA interface, oligonucleotides and cDNA overexpression libraries were previously utilized to research loss and gain of function. CRISPR screens can aid in the identification of possible therapeutic targets. By carrying out loss of function or gain of function experiments Researchers can identify the genes that cause the disease by screening iPSCs-derived neurons. CRISPR-based genetic screening in human neurons produced from iPSCs could identify crucial variables driving neurodegeneration and the selective vulnerability of certain neurons.

1770T **Investigating the Role of Huwe1 and Fbxo16 in Neurogenesis** Haeli J Lomheim, Banu Saritas, Elena Silva Biology, Georgetown University

Our current knowledge of the regulation of neurogenesis primarily centers around the transcription factor cascade, with limited understanding of the role of protein degradation. Understanding neurogenesis at all levels is essential for the development of treatments for neurodegenerative diseases, neurodevelopmental disorders, and traumatic central nervous system (CNS) injuries. In an effort to better understand the role of protein degradation in neurogenesis, we are analyzing the function of two E3 ligases in Xenopus laevis: the F-Box protein Fbxo16 and the HECT, UBA, and WWE domain protein Huwe1. E3 ligases are ubiquitin proteins that are best known for targeting other proteins for degradation through poly ubiquitination and the 26S proteasome pathway. Fbxo16 is expressed in the neural plate and with gain and loss of function studies, we found that it is required for neuron formation and the formation of anterior neural structures. We sought to identify Fbxo16 target proteins via Mass Spectrometry of co-immunoprecipitated proteins and identified Huwe1. With morphant and half-life analysis, we are examining the role of Huwe1 and the mechanism of action of Fbxo16. Together our research indicates that surprisingly, these two E3 ligases play a role in stabilizing Neurogenin 2 thereby increasing neurogenesis.

1771T **Retinal neuron regeneration in zebrafish (Danio rerio) when TGFβ signaling is manipulated** Julinette Gines-Garcia[1], Daniela Sedano[2], Randi Marshall[2] [1]Biological Sciences, Goucher College, [2]Goucher College

Zebrafish have a greater ability to regenerate neurons in the central nervous system than many vertebrates, including mammals. We are using zebrafish (*Danio rerio*) to study the cell cycle dynamics of Müller glial cells (MGs) in retinal neuron regeneration. In zebrafish, MGs are responsible for initiating the regenerative process once they detect damage. MGs activate, dedifferentiate, generate neural progenitors, and then re-differentiate into MGs. Previous studies showed that fish with mutations in TGFβ signaling co-repressors (Tgif1 and Six3b) exhibit less regeneration but express higher ascl1a, a target of TGF β signaling and a pro-neural transcription factor required for some retinal neuron regeneration. Thus, we are particularly interested in the balance between TGFβ corepressors and ascl1a expression during neuron regeneration. We induced acute light lesions that target photoreceptors neurons and examined regenerative cellular processes in fish with increased TGFβ (*tgif1*^{fh258}*;six3b*^{vu87}), and a rescue condition with reduced functional Ascl1a (*tgif1*^{fh258}*;ascl1a*$^{t25215/+}$). We quantified MG activation, progenitor proliferation, and neuron regeneration to determine which phase of regeneration was disrupted in previous studies. Preliminary results suggest that at 1 day post lesion (dpl) MG activation is reduced in *tgif1*^{fh258}*;six3b*^{vu87} fish, and at 3dpl *tgif1*$^{fh258/fh258}$ fish have fewer proliferating cells than wild type and *tgif1*^{fh258}*;six3b*^{vu87} fish. At 3dpl, fish with the ascl1^{t25215} allele exhibited increased proliferation suggesting this can rescue the proliferation defect in *tgif1*$^{fh258/fh258}$ fish. By understanding the basic biology of retinal neuron regeneration in zebrafish we can uncover pathways and genes that can be targeted in biomedical research.

1772T **Functional analysis of two alternate Lef1 isoforms that may have distinct roles in regulating hypothalamic neurogenesis and innate stress-response behavior** Guangning Wang[1], Priscilla Figueroa[2], Richard Dorsky[1] [1]Neurobiology, University of Utah, [2]University of Utah

The Wnt/β-catenin signaling pathway transcription factor Lymphoid enhancer factor 1 (Lef1) has been demonstrated to regulate hypothalamic neurogenesis and stress-related behaviors in mice and zebrafish. Specifically, lef1 null mutant zebrafish fail to generate Crhbp+ neurons in the caudal hypothalamus and show decreased exploratory behavior. Different Lef1 protein isoforms have been described in animal brain regions, but their roles have not yet been explored. Alternative splicing creates Lef1 isoforms with a highly-conserved C-terminal N- or B-tail, and we are investigating whether these tail sequences function differentially in regulating neurogenesis and behavior.

Overexpression of human LEF1 N-tail isoform-encoding mRNA in zebrafish embryos induces abnormal dorsal axis formation, while B-tail encoding mRNA induces brain patterning defects, suggesting a potential difference in Wnt-dependent activity. Previous research in mice showed higher expression of B-tail-encoding mRNA in the embryonic brain, with a switch to higher expression of N-tail-encoding mRNA in adults, indicating stage-dependent regulation during development. In addition, a nonsynonymous human SNP in the final LEF1 exon affects a potential phosphorylation site (Thr369Met) unique to the B-tail. The frequency of this SNP varies significantly in different ethnic groups, with the highest levels found in Latin American and East Asian populations, and it has previously been linked to autoimmune disease in Koreans.

To determine if the B- or N-tail Lef1 isoforms are uniquely required for hypothalamic neurogenesis and behavior, we used CRISPR/Cas9 mutagenesis to generate isoform-specific zebrafish mutant lines. Our preliminary analysis indicates that the expression of known Lef1-dependent gene targets in the caudal hypothalamus is differentially affected in the two lines. We will first confirm these results, and then evaluate the stress response through physiological measurements and behavioral assays. Lastly, we will test whether the human SNP affects Lef1 activity in response to stress or Wnt signaling, using a CRISPR/Cas9-mediated knock-in approach.

1773F **Conserved autism genes regulate GABAergic neuron plasticity in adult male *C. elegans*** Kristi Zoga, Michael Hart University of Pennsylvania

Structural changes to neuronal circuits have the potential to alter behavior and increase memory storage in the brain. Remodeling of GABAergic neurons and resulting changes to excitatory/inhibitory balance has been implicated in neurodevelopmental and neuropsychiatric conditions characterized by behavioral changes, including autism. We previously discovered that the GABAergic neuron, DVB, undergoes experience- and activity-dependent structural plasticity in adult male *C. elegans*. DVB neuron remodeling is characterized by progressive neurite outgrowth and branching that modifies specific synaptic connections, alters a step of male mating behavior (spicule protraction), and is regulated by conserved autism genes *NRXN1*/*nrx-1* and *NLGN3*/*nlg-1*. Here we screened 20 conserved autism-associated genes for roles in DVB remodeling and plasticity. Using confocal imaging and manual tracing of the DVB neuron at day 3 of adulthood, we analyzed the morphologic parameters of neurite length and branching. We also applied a novel multi-modal computational framework, CAJAL, for analysis and integration of DVB single-cell morphologic data. Together these approaches identified novel genes with roles in DVB remodeling, including *chd-1/CHD1*, *daf-18/PTEN*, *gap-2/SYNGAP1*, *unc-44/ANK2,* and others. Additionally, we screened the same list of conserved autism genes for roles in DVB behavioral plasticity, which identified genes with roles in both spicule protraction behavior and DVB morphologic remodeling, and genes with specific roles in only behavior or morphologic remodeling. We are currently characterizing each candidate gene for expression, localization, and function within DVB and the spicule protraction circuit. Mutations in *unc-44/ANK2*, an ankyrin important for cytoskeleton organization and axon maintenance, increase DVB morphologic plasticity and number of synaptic puncta and decrease inhibition of spicule protraction. Characterization of *unc-44/ANK2* isoforms and expression suggests a potential cell non-autonomous role in suppression of morphologic plasticity in DVB. Mutations in *set*-4/*KMT5B*, a histone H4K20 methyltransferase, increase DVB morphologic plasticity without altering spicule protraction or synaptic architecture. Our candidate screening approach has provided mechanistic insight into genes that contribute to GABAergic morphologic and behavioral plasticity, including novel roles for conserved autism genes.

1774F **Novel insights from Humanization in *C. elegans*: Functional Rescue of G-alpha(o)-Dependent Behavior** Jacqueline S Cho, Adam Friedberg Neuroscience, Brown University

Sleep is an essential behavior observed across species. A key characteristic of sleep is behavioral quiescence which includes cessation of movement and feeding. *C. elegans* experience two states that can be classified as sleep: developmentally time sleep (DTS), which occurs just before molting during periods known as lethargus, and stress-induced sleep (SIS), which occurs following exposure to environmental stressors (Trojanowski & Raizen, 2015). A classical genetic screen identified genes capable of disrupting sleep in *C. elegans*, and *goa-1*, a gene that encodes a G-alpha(o), was identified (Huang 2017). Notably, variation in the chromosomal-region containing the human ortholog GNAO1 is associated with insomnia, suggesting GNAO1 may have a potential regulatory role in sleep across species (Lane 2019). To investigate functional conservation of G-alpha(o), we humanize *goa-1* in *C. elegans* using a two-phase approach: (1) replacing the 3' coding sequences of *goa-1* with the corresponding sequence of *GNAO1*, and then (2) replacing the 5' coding sequences of *goa-1* after confirming viability of step 1. The final construct retains the endogenous intron 2, the largest intronic region. We will assess conservation of G-alpha(o) function by assaying four *goa-1* dependent behaviors: reversal rate, egg-laying, DTS, and SIS. Through direct comparison of wild-type and humanized C. elegans, we aim to measure the rescue of G-alpha(o) function in sleep and non-sleep behaviors. Leveraging population-genetics and CRISPR-Cas9 technologies, we investigate novel contributions of G-protein signaling in conserved sleep mechanisms.

1775F **The glutamate receptor *glr-5* regulates stress-induced sleep in *C. elegans*** Caroline Kominick, Matthew Nelson St. Joseph›s University

The stress response of *C. elegans* consists of two distinct behavioral states: 1) Threat avoidance characterized by heightened activity; 2) stress-induced sleep which promotes recovery. These opposite and essential behaviors are controlled by a small number of neurons. Avoidance and arousal require sensory neurons like ADL and ASH, and the hub interneuron RMG. Stress-induced sleep requires the ALA and RIS interneurons. We showed that the *npr-38* neuropeptide receptor is required in the ADL neurons for both avoidance and sleep, suggesting that the ADL neurons also function during sleep. The ADL neurons express many neuropeptide genes and are also glutamatergic. To determine if glutamate signaling from the ADL neurons regulates sleep, we examined the glutamate receptor *glr-5*, which is expressed in cells postsynaptic to the ADL neurons, including RMG, ALA, RIM, AIB, RIS, and PVC. We used CRISPR to construct a loss-of-function strain (*glr-5(stj554)*) and obtained a deletion mutant (*glr-5(tm3506)*). Surprisingly, *glr-5(stj554)* animals displayed reduced stress-induced sleep while *glr-5(tm3506)* animals showed a significant increase in sleep. We are testing the hypothesis that *tm3506* is a gain-of-function allele. To determine where *glr-5* functions during sleep we are conducting cell-specific rescue experiments. So far, expression of *glr-5* in the RMG neuron does not restore sleep. The site-of-action is still unknown.

1776F **The neuropeptide receptor *npr-4* and the neuropeptide *nlp-61* regulate stress-induced sleep in *C. elegans*** Quinn M Howe, Matthew Nelson Biology, Saint Joseph›s University

Sleep is evolutionarily ancient and regulated by conserved signaling mechanisms. Recent work in our lab has identified the neuropeptide receptor *npr-38* as a key regulator of stress-induced sleep. We found that *npr-38* is required in the ADL neurons for the full induction of sleep. *npr-38* is also expressed in the ASH, RMG, AIB, ALA, and RIS neurons, which form a 6-celled circuit. We sought to better understand how the ADL neurons, as well as the other cells in this circuit, regulate sleep. My project focuses on characterizing the function of *nlp-61*, a neuropeptide expressed in the ADL neurons, and *npr-4* a receptor expressed in all 6 cells of this simple circuit. I have found that *nlp-61* is required for stress-induced sleep, while *npr-4* mutants display heightened sleep. Currently, I am using cell-specific rescue to determine the precise site of action for both genes.

1777F **Identification of transcription factors that bind to novel promoter motif in *C. elegans*** Nadia G Gaytan[1], Mailyn Nishiguchi[2], Sarah Hall[2] [1]Department of Biology, Program in Neuroscience, Syracuse University, [2]Syracuse University

Environmental stress in early life can alter gene expression through epigenetic mechanisms, resulting in phenotypic changes in adulthood. Using *C. elegans*, we have previously shown how developmental programming of neuronal genes can lead to behavioral plasticity. When larvae experience stressful conditions such as starvation and crowding, they develop into an alternate life stage known as dauer, which is stress resistant and non-aging. When the stressful conditions alleviate, the animals will exit dauer and develop into postdauer (PD) adults. In contrast, favorable conditions in early life promote continuous development of larvae until they grow into a control (CON) adult. We have shown previously that the *osm-9* TRPV channel gene, required for chemosensory and olfactory behaviors, is downregulated in ADL neurons of PD adults while remains expressed in CON adults. OSM-9 and the ADL neuron is required for the detection of the ascr#3 pheromone, which signals unfavorable crowding conditions at high concentrations and promotes avoidance behaviors in CON hermaphrodites. In contrast, PD hermaphrodites show a lack of ascr#3 avoidance. We showed previously that a conserved sequence in the upstream regulatory region of the *osm-9* gene is required for its downregulation in PD ADL neurons and is bound by DAF-3/SMAD in TGF-β signaling pathway. Interestingly, this sequence is found upstream of 1009 genes with expression patterns that are enriched for germline and neuronal-expressed genes.To identify additional pathways that may regulate gene expression through this conserved sequence, we performed a yeast one-hybrid screen of transcription factors with known expression in neurons. With an *osm-9*p::*gfp* reporter transgene, we have validated whether a subset of candidates identified in our screen plays a role in the developmental programming of *osm-9* in PD ADL neurons. Here, I present *osm-9* expression and ascr#3 avoidance results for three candidate transcription factors: NHR-64, SOMI-1, and EGL-43. Additionally, we have shown previously that TGF-β signaling in neurons can modulate germ cell proliferation by regulating the *lag-2* Notch ligand gene that contains a conserved motif in its upstream regulatory regions. We are currently utilizing auxin-induced degradation to investigate the tissue-specific role of DAF-3/SMAD in this process. Together, these experiments dissect the gene regulatory mechanisms by which early life stress affects phenotypic plasticity in *C. elegans*.

1778F **Drugging Worms to Study Substance Use Disorder** Shelby N Lauzon, Prince Mosely, HaoSheng Sun CDIB, The University of Alabama at Birmingham

Substance use disorder (SUD) or drug addiction is a ubiquitous problem affecting over thirty million people in America. Presently, few treatment options are available for SUD, despite our advances in SUD neurobiology. Most studies have primarily used rodents and humans as models, which do not allow for high-throughput screening of genetic contributors or potential therapeutic compounds. The benefits of using Caenorhabditis elegans (C.elegan) as a model are its short embryo to adult development, compact and well-delineated nervous system, and conserved neurobiological systems that underlie drug responses. We acutely and chronically expose worms to varying doses of stimulants and opioids to identify the behaviors associated with stimulants and opioids in C. elegans. Compared to control animals, the acute and chronic cocaine-exposed groups displayed a decrease in speed, amongst other locomotion parameters. We are currently investigating the neurotransmitter system(s) and molecular modulators that control cocaine-induced behavioral changes. Concurrently, we are currently generating molecular atlases of drug response nervous-system-wide in single neuron resolution using a combination of cell-type specific bulk analysis and single nuclei (sc) analysis of transcriptome and chromatin landscape. A major goal for future research is to establish a platform for high-throughput identification and characterization of novel regulators of drug-induced plasticity in distinct neuronal cell types, which can be used for clinical translation of improved therapeutics for SUD.

1779F **Investigating the cis-regulatory locus of the *ceh-43* homeobox gene in *Caenorhabditis elegans* neuronal specification** James Lao[1,2], Berta Vidal[1,2], Oliver Hobert[1,2] [1]Biological Sciences, Columbia University, [2]Howard Hughes Medical Institute

Terminal differentiation of neuron classes is regulated by homeodomain transcription factors, encoded by highly conserved homeobox genes across animal nervous systems. In *Caenorhabditis elegans*, each neuron class is defined by the expression of a unique combination of homeodomain proteins. Currently, 113 out of the 118 neuron classes of *C. elegans* are known to require a homeobox gene for proper terminal differentiation. Yet, there remain five neuron classes, including the ASJ sensory neuron pair, which do not have a known homeobox regulator. The Distalless/DLX ortholog *ceh-43* is expressed in ASJ

and several other neuron classes in the head, midbody, and tail (ADE, AIN, AIZ, ASJ, BDU, CAN, CEP, IL1, PDE, PVQ, SDQ). We previously showed that *ceh-43* is required for the differentiation of dopaminergic neurons and the ring interneuron AIZ, and we are now investigating potential additional roles of *ceh-43* in ASJ and other neurons. To circumvent the embryonic lethality of *ceh-43* null mutants, we generate novel cis-regulatory alleles of the *ceh-43* locus, seeking to selectively eliminate *ceh-43* expression in ASJ and/or other neuron classes in otherwise viable animals. We present here a cis-regulatory mutant analysis of *ceh-43* as a means of finding a homeobox regulator for ASJ, as well as a tool to better study *ceh-43* gene function in other *ceh-43*-positive neurons that have not yet been studied for an involvement of *ceh-43* (e.g. SDQ). Comprehensive analysis of homeobox function may point to an evolutionary and central role of this gene family in delineating neuronal identity specification during development.

1780F **Investigating aggregate feeding behavior across Caenorhabditis superfamily** Reina Eugene[1], Dustin Haskell[2], Michael Hart[3] [1]Liberal Arts, Pennsylvania State University, [2]Genetics, University Of Pennsylvania, [3]University Of Pennsylvania

Caenorhabditis elegans display two distinct foraging behaviors; solitary foraging or group foraging. These behavioral states depend on the integration of environmental cues including pheromones, food, touch, and oxygen/carbon dioxide levels. Aggregation of animals into groups during foraging is in part driven by Caenorhabditis elegans tendency to avoid higher oxygen levels in a lab setting. This also drives a related behavior termed bordering, where the animals feed on the border of the food lawn where bacteria is the thickest. Aggregation and bordering behavior is controlled by the conserved neuropeptide receptor npr-1/NPY gene, with mutations in the gene resulting in changes to aggregation behavior. While it is unclear if all nematode species aggregate, we hypothesize that this behavior and neuronal circuit may be conserved amongst members of the Caenorhabditis superfamily. To assay aggregation behavior, we pick 50 L4 (4th larval stage) animals of each species onto a 6-well plate filled with agar and seeded with a standard bacterial lawn (E. coli - OP50). Images of the plates are taken every 30 minutes on an automated WormWatcher platform and the number of aggregating worms (out of 50) are quantified at the 15-hour time point - day 1 adult animals. Loss of function npr-1 C. elegans display high levels of aggregation behavior and served as the controls. We find that Caenorhabditis aggregation behavior is not entirely conserved across species. In contrast, bordering behavior appears prevalent in all members of the clade tested thus far.

1781F **The SCRM-1 Phospholipid Scramblase Regulates Shedding of Extracellular Vesicles from the Ciliary Base** Alexis Semmel, Jessica Tanis University of Delaware

Small secreted extracellular vesicles (EVs) that contain bioactive molecules are shed by most, if not all, cell types. It is important to identify mechanisms of EV biogenesis in order to understand how this type of intercellular communication is regulated to impact physiological and pathological processes. EVs can be released from cilia, microtubule-based organelles that protrude from the cell surface. In our model organism Caenorhabditis elegans, EVs bud from the non-motile cilia of sensory neurons and are released into the environment through pores in the cuticle. We discovered that the CLHM-1 ion channel is a cargo in EVs released from the ciliary base, while the polycystin TRP channel is present in EVs shed from the cilium distal tip. Using C. elegans that express CLHM-1 tagged with tdTomato and PKD-2 tagged with GFP at single copy we are able to quantify shedding of the different EV subpopulations from the male tail RnB neurons. Phospholipid scramblases, including SCRM-1, are plasma membrane transporters of lipids, which randomly flip phospholipids between leaflets of the plasma membrane. Notably, activation of SCRM-1 has been shown to activate externalization of the phospholipid phosphatidylserine (PtdSer). Asymmetrical distribution of PtdSer is observed in platelet-derived microvesicles and apoptotic bodies. We sought to determine if loss of scrm-1, impacts EV biogenesis and sorting of the CLHM-1 and PKD-2 cargoes. Total internal reflection fluorescence (TIRF) microscopy was used to image EVs released from scrm-1 mutant and control animals expressing CLHM-1::tdTomato and PKD-2::GFP followed by Imaris spot detection to quantitate the number of EVs released into the environment. Deletion of scrm-1 caused a significant decrease in shedding of CLHM-1 EVs while the number of PKD-2 EVs was unaffected. Analysis of CLHM-1::tdTomato localization in the RnB neurons showed that the amount of CLHM-1 was reduced in the ciliary base, but no change was observed in the cilium proper. This suggests that regulation of PtdSer asymmetry in one ciliary subcompartments can be used to specifically regulate biogenesis of the EVs that are shed from that location.

1782F **Astrocyte Regulation of Excitatory Synapse Formation** Hallie A Youker[1], Nelson A Perez-Catalán[2], Katie Schneider[1], Jimmy A Kelly[2], Claire A Bui[2], Keiko A Hirono[2], Laurina A Manning[2], Chris Q Doe[2], Sarah D Ackerman[1] [1]Washington University in St. Louis, [2]University of Oregon

Vertebrate nervous system development is a complex process requiring tight regulation of the cellular processes required to form balanced neuronal circuitry. Astrocytes, the most abundant glial cell found in the central nervous system, is a key regulator of neural circuit formation. Astrocytes modify neural circuits by regulating synaptogenesis, synapse maintenance, and through direct synaptic pruning, modifying the number of synaptic connections in an activity-dependent manner. Astrocytes remain closely associated with synaptic terminals and mediate neuron-neuron communication via various extracellular signals,

both secreted and membrane-bound, monitoring the activity of these neurons and adjusting circuitry accordingly. Imbalanced neural circuits manifests various neurological disorders, from epilepsy to schizophrenia. The clinical relevance of astrocytes in development has led to closer examination of the ways in which astrocytes maintain healthy neural circuits. In fact, recent *in vitro* work has demonstrated a direct link by which astrocytes instruct the formation of glutamatergic synapses, a type of excitatory synapse. However, very little work has been done to explore the astrocytic mechanisms regulating other synapse types, especially *in vivo*. To address this, we used the power of *Drosophila* genetics to study the role of various astrocytic extracellular matrix (ECM) proteins in cholinergic synapse formation. Using *alrm-Gal4*, an astrocyte-specific promoter, we drove selected RNAi lines for the knockdown of various ECM components in astrocytes, and measured changes in cholinergic synapse density using Synaptic Tagging with Recombination. Excitingly, we identified a subunit of laminin in astrocytes that causes a significant reduction in cholinergic synapse density. This finding was only present in late-stage *Drosophila* larvae (L3), suggesting a potential role of this astrocyte-associated molecule in a pruning pathway, rather than in synaptogenesis. Importantly, we observe significant changes in synapse number without underlying differences in astrocyte development. Thus, we have identified an astrocyte-specific cue that drives formation of the most abundant excitatory synapse type in *Drosophila*. As laminin is a common extracellular ligand, future efforts will focus on identifying the neuron-bound receptor that responds to this astrocytic cue, and how astrocyte-neuron signaling triggers synapse instability.

1783F **Abnormal spindle employs non-cell autonomous mechanisms to promote proper brain growth and development** Shalini Chakraborty, Todd Schoborg University of Wyoming

Autosomal recessive primary microcephaly (MCPH) is a congenital neurodevelopmental disorder (NDD) characterized by a reduction in brain volume, intellectual disabilities, and lifespan. The most common cause of human MCPH is homozygous mutations in the *abnormal spindle like microcephaly associated* (*aspm*) gene, which has a *Drosophila* ortholog called *abnormal spindle (asp).* Although the MCPH phenotype is clinically well-characterized, the cellular and molecular mechanisms responsible for the small brain phenotype remain poorly understood. This is because we lack fundamental knowledge of Asp's neurodevelopmental behavior, the cell types in which it is expressed, and the molecular functions of Asp that dictate proper neurogenesis in time and space. To address this gap in knowledge, we first assessed the endogenous localization of Asp in various cell types of the fly CNS across development. Asp is highly expressed in all neurogenic cell types from embryonic to late larval stages, with low levels of protein persisting into pupal and adult neurons. Cell-type specific genetic rescue assays expressing either full length (Asp^{FL}) or a truncated rescue fragment (Asp^{MF}) in asymmetrically dividing central brain and optic lobe medulla neuroblasts (*Insc-Gal4*) was sufficient to restore central brain, but not optic lobe size and morphology in adults. We then further dissected the remaining lateral-most neural stem cell populations in the optic lobe and found that expression in the lamina precursor cells alone (*GCM-Gal4*) was sufficient to restore optic lobe size and neuropil organization along with the lamina in adult *asp* mutants. It also restored neuroepithelial cell and tissue morphology of the larval outer proliferation center (OPC) despite the fact that these cells did not express the rescue fragments, pointing towards a non-cell autonomous role for Asp in the developing optic lobe. Transcriptional profiling and protein interaction experiments highlighted Notch signaling and temporal transcription factors (tTFs) as potential downstream effectors of Asp's non-cell autonomous function, providing new insights into how Asp promotes proper brain growth and development that may be relevant in the etiology of human MCPH.

1784F **Natural variation in behavioral and transcriptional responses to social isolation in *Drosophila melanogaster*** Jesús E Sotelo-Fonseca[1], Chengcheng Du[1], Corbin Jones[2], Pelin Volkan[3] [1]Biology, Duke University, [2]Genetics, University of North Carolina at Chapel Hill, [3]Duke University

Social experience has long-lasting effects on animal behaviors. In humans, social isolation contributes to neuropsychiatric conditions like depression, anxiety, aggression, and sleep disruptions. Responses to social isolation have been observed in other animals ranging from mice to flies. Nevertheless, effects of isolation vary among individuals, and how these are shaped by environmental and genetic constraints remains unclear. *Drosophila melanogaster* is an ideal system to address these questions. In addition to being an excellent genetic model, *D. melanogaster* is a human commensal species, and its demographic history mirrors that of humans. For this reason, geographically diverse populations of *D. melanogaster* serve as a natural experiment to investigate the impact of genetic variation on behavioral responses to isolation. We specifically focus on the social experience-dependent changes in male courtship behaviors as 1) previous research has shown that social isolation increases courtship behavior in *D. melanogaster* laboratory strains, 2) genes and neuronal circuits that control male courtship have been delineated, and 3) previous studies in our lab have found courtship regulatory genes that are differentially expressed between grouped and isolated laboratory strain flies.

We have identified variation in courtship responses to social isolation in six *D. melanogaster* Global Diversity Lines collected from five different continents. Some of these lines exhibited contrasting courtship responses between grouped and isolated flies. We hypothesize that differential gene expression in the male brains across populations underlies differences in courtship

behavioral responses to the social environment. To test this hypothesis, we performed bulk RNA-seq from the brains of isolated or grouped male flies in specific GDLs. Comparison of line-specific gene expression responses to social isolation identified a small number of candidate genes. We anticipate future experiments to causally link the gene expression to behavioral changes will inform how natural genetic variation influences specific pathways to modulate susceptibility to social isolation.

1785F **Efficient methods for expanding cell-type-specific genetic tools for studying neuronal development in the Drosophila visual system** Elizabeth Abraham[1], Yu-Chieh David Chen[2], Claude Desplan[2] [1]New York University, [2]Developmental Biology, New York University

Drosophila has emerged as a powerful model for unveiling fundamental principles underlying neuronal development. Currently, we have a comprehensive understanding of the patterning mechanisms driving cell differentiation in the *Drosophila* visual system. However, there is still a significant knowledge gap concerning how each cell type acquires its unique neuronal structure and establishes precise connections during development. To address these developmental questions, the first crucial task is the precise identification and labeling of every neuronal cell type. The Desplan Lab has recently established a pipeline to identify two genes that are specifically expressed in one cell type based on the single-cell transcriptomic atlas in the developing *Drosophila* optic lobe. We can selectively label and distinguish specific cell types through the generation of split-GAL4 of the selected gene pairs. Despite the successful identification of distinct cells through this method, efficient gene-specific split-GAL4 generation is limited to certain marker genes that contain transposable elements in the coding intronic regions. Additionally, there are some cell types that lack optimal gene pairs for gene-specific split-GAL4 genetic intersection. Thus, there is a necessity for exploring alternative methods to allow for the efficient generation of highly cell-type-specific genetic tools for optic lobe neurons, including utilization of the attP/attB integrase system and analysis of multi-omic data. In my research, I aim to extend the genetic tool kits for studying all cell types in the developing optic lobes by 1) establishing a robust pipeline to use existing single attP knock-in fly line in Drosophila to make gene-specific split-GAL4 lines via recombinase-mediated cassette exchange (RMCE); 2) selecting enhancers from our recent multi-omic dataset (scRNAseq + scATACseq) for generating split-GAL4 lines for the cell types without ideal gene pairs. Our primary aim is to expand our genetic toolkit for pinpointing uncharacterized cell types, thus overcoming current genetic constraints. These advanced tools will facilitate a comprehensive exploration of neuronal development within distinct cell types in *Drosophila* optic lobes, with potential applications extending to other neural and non-neural tissues of the fly.

1786F **Effect of social experience on gene expression, circuit function and behaviors** Chengcheng C. Du[1], Jesus E.S. Fonseca[1], Shania C. Appadoo[1], Luis C. Garcia[1], Yuta Mabuchi[2], Nilay Yapici[3], Corbin Jones[4], Pelin C. Volkan[5] [1]Department of Biology, Duke University, [2]Columbia University, [3]Cornell University, [4]UNC-CH, [5]Biology, Department of Biology, Duke University

Social experiences influence various animal behaviors, but the molecular and circuit-based mechanisms underlying experience-dependent behavioral changes are not known. Recent evidence suggests a link between experience-induced alterations in gene regulation and behavioral adjustments. The Drosophila courtship behavior serves as an excellent model for investigating this relationship, where connections between courtship behaviors, genes, and circuits have been elucidated. In Drosophila melanogaster, Fruitless^{M} (Fru^{M}) and Doublesex^{M} (Dsx^{M}) are master transcription factors controlling sex-specific innate and learned courtship behaviors. *fru^{M}* is expressed in around 2000 interconnected neurons throughout the nervous system, marking courtship circuits, while *dsx^{M}* is predominantly expressed in approximately 700 neurons and mainly found in non-neuronal cells. Social isolation boosts courtship vigor in wild-type males, while monosexual grouping suppresses it. We previously showed that *dsx* and *fru* levels are modified with social experience and pheromone receptor signaling in the antennae where pheromone-sensing olfactory neurons reside. These lead to the misregulation of *fru* and *dsx* target genes and pheromone responses. In the central courtship circuits, social isolation also increases the baseline and evoked neuronal activity. Single-cell RNA sequencing from *fru* and *dsx*-positive neurons in grouped and isolated male brains revealed that social isolation affects *fru* expression in only a subset of neurons within the courtship circuit. Whole-brain transcriptome profiles identified an upregulation of *dsx* in isolated male brains. Pheromone-sensing Or47b olfactory circuit contributes to the suppression of courtship by grouped males. Interestingly, blocking the activity of different pheromone circuits results in distinct effects on gene regulation in the brain. This suggests different social signals in the environment trigger different transcriptional responses in the brain. We particularly find neuropeptides and their receptors associated with the modulation of behaviors are differentially regulated by different pheromone circuit activity. Our findings offer insights into the fundamental mechanisms through which sensory experiences drive behavioral adjustments by altering the expression of genes critical for neural circuit structure and function.

1787F **Temporal manipulation of serotonin during development creates persistent behavioral defects in *Drosophila* larvae** Hayden Schneider[1], Ken'Nisha Patton[1], Emma Walker[1], Will Dugan[1], Douglas H Roossien[2] [1]Ball State University, [2]Biology, Ball State University

The neurotransmitter serotonin modulates a variety of behaviors in *Drosophila melanogaster*, such as locomotion, feeding, courtship, and aggression. Prior to assuming this canonical role, however, serotonin acts as an autocrine signaling molecule regulating the development of its own axons. For example, mutations limiting serotonin production cause an increase in axon outgrowth and branching, whereas exogenous serotonin decreases outgrowth and branching in cultured serotonergic neurons. In vertebrates, there is a critical period during development where serotonin signaling can cause these structural changes, but how this impacts circuit function and behavior at later stages of development is unclear. Here we performed pharmacological manipulations of serotonin temporally during embryonic and first instar larval stages, the period in which robust serotonergic axon outgrowth and wiring occurs, after which serotonin levels were allowed to return to normal during second and third instar stages. We then assayed behavior at the late third instar stage, and found both locomotion and feeding to be disrupted. Defects in these behaviors were equivalent regardless of whether serotonin was increased or decreased. This suggests that dysregulation of serotonin levels during this critical period of serotonergic axon development caused defects in the circuits underlying these behaviors, which persisted into later stages of development.

1788F **Ecdysis Triggering Hormone Both Activates and Suppresses Ecdysis Motor Programs** Niall Dermady[1], Richard Farrel III[2], Haojiang Luan[3], Benjamin White[3] [1]NIM, National Institutes of Health, [2]National Institutes of Health, [3]NIMH, National Institutes of Health

Insects must shed their exoskeletons during development in order to grow. This process is called ecdysis and is initiated by the release of Ecdysis Triggering Hormone (ETH). In *Drosophila*, ETH is known to coordinate the motor programs governing ecdysis by positively regulating neurons that express the A isoform of the ETH receptor, ETHRA. A second isoform of the ETH receptor, ETHRB, is also expressed in a large number of *Drosophila* neurons, but the role of these neurons in ecdysis has been less well characterized. Here, we use an ETHRB-Gal4 driver to selectively activate or inhibit ETHRB-expressing neurons at the time of adult ecdysis using optogenetic and thermogenetic techniques.

Adult ecdysis involves the serial execution of two principal motor programs, the first is used to exit the pupal case at eclosion and the second is used to subsequently expand the wings. We find that selectively activating ETHRB neurons using UAS-dTrpA1 robustly suppresses eclosion. Preliminary data also indicates that suppressing ETHRB neurons using UAS-GtACR1 accelerates eclosion. Similarly, suppressing ETHRB-expressing neurons using UAS-GtACR1 significantly accelerates wing expansion, while activating them using UAS-dTrpA1 suppresses this motor program. Surprisingly, our results thus indicate that ETHRB-expressing neurons—in contrast to neurons expressing ETHRA—inhibit the adult ecdysis motor programs in *Drosophila*. This supports a proposed model in which ETHRB neurons act as “first responders” to ETH and provide blanket inhibition to the ecdysis neural network by targeting the ETHRA neurons responsible for driving the ecdysis motor programs. In this model, the sequential suppression of subsets of ETHRB neurons relieves inhibition first of the ETHRA neurons that drive eclosion and then of the ETHRA neurons that drive wing expansion. A major goal of future work is to test this model by identifying the population(s) of ETHRB neurons that inhibit wing expansion and eclosion and to determine whether the ETHRA neurons regulating these motor programs are among their direct targets.

1789F **A multi-input optic glomerulus mediates diverse behavioral responses to visual objects.** Ines M.A. Ribeiro[1,2], Maria Leonte[2], Michael Sauter[2], Stephan Prech[2], Alexander Borst[2] [1]LMU-Munich, [2]Max Planck Institute for Biological Intelligence

Drosophila melanogaster males and females perform distinct visually guided behaviors during courtship. Upon exposure to female non-volatile pheromones, the male orients towards and chases the female to remain in close proximity to her and beat competition. In contrast, the female turns away from the male, seemingly exploring the courtship arena. Both females and non-courting males turn away from another fruit fly with undefined chemosensory profile. Vision starts as an abstract 2-dimensional array of light intensities fluctuating over time, from which visual features, such as discrete objects or color, are extracted. Visual projection neurons then relay varied combinations of visual features to the central brain. During courtship, Drosophila males rely on LC10a visual projection neurons to track the female. LC10a are part of the LC10-group neurons, that co-project to the anterior optic tubercle (AOTU). The projection of different visual neuron types to the same retinorecipient brain region could underlie convergence of sets of features to create a rich representation of a visual object. Alternatively, the different LC10-group neuron types could form parallel output neural circuits that use the spatial organization present in the AOTU for downstream operations. To discern between these possibilities, we used single-pair and fly-on-ball behavioral assays, functional imaging and optogenetics. We found that LC10d neurons mediate avoidance of a fly without a defined chemosensory signature in non-courting males and females, and of a small visual object in the fly-on-ball assay. Functional imaging of neuronal responses to a barrage of visual features revealed that both LC10a and LC10d neurons detect discrete objects, with LC10d neurons exhibiting overall broader tuning properties than LC10a. Activation of unilateral subsets of LC10d neurons, using the light-gated LOV-LexA genetic tool, elicits a small contralateral turn, whereas activation of similar numbers of LC10a cells leads to ipsilateral turns. LC10d and LC10a neurons similarly sense discrete objects but mediate opposing behaviors, implying that opposite valences of visual objects are encoded by LC10a (orienting towards) and LC10d (turning

away). The AOTU thus appears to function as a hub for processing visual cues in parallel, likely reliant on spatial organization, that subserve different, even opposing behaviors.

1790F ***Drosophila* neuronal Glucose-6-Phosphatase regulates glycogen storages via FMRFa signaling in the jump muscle** Tetsuya Miyamoto, Sheida Hedjazi, Chika Miyamoto, Hubert Amrein Cell Biology and Genetics, Texas A&M University

Neuropeptides and their cognate receptors are critical molecular effectors of diverse physiological processes, many of which modulate a variety of behaviors. We recently reported of a non-canonical function of the *Drosophila Glucose-6-Phosphatase* (*G6P*) gene in a small subset of neurosecretory cells in the CNS and showed that *G6P* mutant flies failed to maintain whole body glucose homeostasis, a phenotype that could be rescued by constitutive activation of *G6P* neurons. We proposed that *G6P* is required for adequate signaling in a subset of peptidergic neurons.

Here, we show that the *G6P* expressing neurons define 7 different groups of peptidergic neurons, 5 in the brain and 2 in the thoracic ganglia, expressing five different neuropeptides. One such group, located in the thoracic ganglia and expressing FMRFa neuropeptides, is necessary and sufficient to maintain whole body glucose homeostasis in starved flies. Moreover, we find that FMRFa neurons lacking *G6P* exhibit a smaller Golgi apparatus and have a reduced neuropeptide release capacity. Using *FMRFa Receptor$^{2A\text{-}GAL4}$* knock-in fly strain, we show that the *FMRFaR* gene is highly expressed in the jump muscle, with some weaker expression in the CNS. Muscle, and to a lower extent the fat body, is known to maintain large amounts of glycogen as a source for the mobilization of energy. We found that *G6P*/*FMRFa*/*FMRFaR* mutant flies exhibited significantly reduced glycogen content not only in the jump muscle but also in the flight muscle and fat body when compared to wild-type flies. Taken together, our data suggest that *Drosophila* G6P is required to build up glycogen stores via FMRFa signaling, primarily in the jump muscle and secondarily in other organs known to store glycogen.

1791F **Neuropeptide mediated changes in synaptic output at individual active zones** Stephen Clifford, Kiel G Ormerod Biology, Middle Tennessee State University

Drosophila melanogaster has become a popular model organism for the study of human neurological disorders due to its unparalleled versatility regarding genetic manipulation, and its extensive genomic conservation between flies and humans. Most human neurodegenerative disorders are attributable to mutations and alterations at the molecular level. Thus, establishing models to investigate the function of the cells that make up the nervous system, in neurons, is invaluable. Our laboratory uses a model glutamatergic synapse in *Drosophila* to investigate the roles of neuromodulators and dense core vesicular trafficking on nervous system health and function. To further investigate these roles, we aimed to establish a functioning GCaMP assay using GCaMP8 ultra-fast high-resolution fluorescence microscopy, allowing us a higher resolution of optical neurotransmitter fusion dynamics than other current imaging techniques readily available to us. Many neuropeptides are known to modify the output of synapses by altering pre and postsynaptic machinery. Here we exploit GGaMP imaging to investigate if different unique neuropeptides alter release of SVs at active zone resolution. We additionally use genetic approaches to alter putative proteins involved in this neuropeptide-mediated change in synaptic output to further elucidate these molecular and cellular processes. Abnormalities in the packaging or release of these molecules results in some of society's most severe and debilitating diseases and conditions including neurological disorders, cancers, obesity, diabetes, and many other conditions. However, before we can begin to understand and treat devastating diseases and conditions that affect our society, we must understand the basic components of cellular communication and what happens when they malfunction or breakdown.

1792F **5-HT1A regulates axon outgrowth in a subpopulation of *Drosophila* serotonergic neurons** Ava Kinser[1], Delaney Long[1], Abby Olalde-Welling[1], Luke Brewer[1], Juri Lim[1], Dayle Matheny[1], Breanna Long[1], Douglas H Roossien[2] [1]Ball State University, [2]Biology, Ball State University

Serotonergic neurons produce extensively branched axons that fill most of the central nervous system, where they modulate a wide variety of behaviors. Proper behavioral output therefore depends on the precise outgrowth and targeting of serotonergic axons during development. To direct outgrowth, serotonergic neurons utilize serotonin as a signaling molecule prior to it assuming its neurotransmitter role. This process, termed serotonin autoregulation, regulates axon outgrowth, branching, and varicosity development of serotonergic neurons. However, the receptor that mediates serotonin autoregulation is unknown. Serotonin receptors are expressed either in non-serotonin producing neurons as heteroreceptors or in serotonergic neurons as autoreceptors. In non-serotonin producing neurons, serotonin receptor activity regulates neurite outgrowth and branching. Yet, there has not yet been a systematic test of the role of autoreceptor activity in the outgrowth of serotonergic axons. Here we asked if serotonin receptor 5-HT1A plays a role in serotonergic axon outgrowth and branching. Using cultured *Drosophila* serotonergic neurons, we found that exogenous serotonin reduced axon length and branching only in those expressing 5-HT1A. Pharmacological activation of 5-HT1A led to reduced axon length and branching, whereas disruption

of 5-HT1A rescued outgrowth in the presence of exogenous serotonin. Altogether this suggests 5-HT1A is a serotonin autoreceptor in a subpopulation of serotonergic neurons and initiates signaling pathways that regulate axon outgrowth and branching during *Drosophila* development.

1793F **Serotonin autoreceptors are differentially and dynamically expressed throughout development in *Drosophila*** Luke Brewer, Juri Lim, Solmari Solano, Douglas H Roossien Biology, Ball State University

Serotonin receptors (5-HTRs) are G-protein couple receptors expressed throughout the nervous system, where they are responsible for modulating a variety of behaviors such as mood, sleep, and appetite. Serotonin receptors are expressed either in non-serotonin producing neurons (heteroreceptors) or in serotonergic neurons (autoreceptors), and can have divergent function depending on which. In addition, the intracellular signaling pathways initiated by the same serotonin receptor can diverge depending on whether they are acting as hetero- or autoreceptors. We recently found that 5-HT1A is expressed in a subpopulation of cultured *Drosophila* serotonergic neurons. This is in agreement with reports by others suggesting 5-HT1A and 5-HT1B are autoreceptors in the adult *Drosophila* brain, while conflicting with a report suggesting there are no autoreceptors in the third instar larval brain. We therefore performed a systematic study profiling the spatial and temporal expression of all five *Drosophila* serotonin receptors during the larval and adult stages. Because there are no viable antibodies toward *Drosophila* serotonin receptors, we used a genetic labeling approach. Flies from either 5-HTR-Gal4 or 5-HTR-LexA drivers were crossed to fluorescent reporter lines, and brains from offspring were stained with anti-5HT. Co-labeled serotonergic neurons were scored and mapped to previously published anatomical maps of larval or adult serotonergic neurons. We found that each serotonin receptor is expressed in subpopulations of serotonergic neurons, with some overlap. In general, the number of serotonergic neurons is highest in first instar stages followed by a decrease over time. This suggests serotonergic neurons consist of subpopulations with diverse and dynamic gene expression programs during early *Drosophila* development.

1794F **Neuropeptide Biology in Drosophila** Hardik Bansal, Veronika g Mousa, Tadros a Hana, Kiel G Ormerod Biology, Middle Tennessee State University

Neuromodulatory substances regulate critical processes spanning from regulated secretion to physiology and behavior. Consequently, most genomes encode hundreds of neuromodulatory substances and their receptors. Within the Drosophila genome over 30 genes encode for one of the major classes of neuromodulators in neuropeptides, and an even greater number encode for neuropeptide receptors. Neuropeptides are packaged within cells in large electron dense structures known as dense core vesicles (DCVs). DCVs are known to transport, store, and release neuropeptides and proteins at multiple cellular locations, which mediate critical biological processes like synaptogenesis, synaptic transmission, synaptic plasticity, and others. However, much of the cellular machinery involved in sorting, processing, trafficking, and releasing DCV content remains largely unknown. Here we have taken advantage of the genetic and molecular toolkits of Drosophila to address these fundamental questions about DCV biology. We have identified several novel roles for motor proteins and their subunits in trafficking and delivering DCVs to synapses. We have also identified several critical resident DCV proteins that are necessary for proper processing of prepropeptides into bioactive peptides ultimately impacting their ability to be trafficked to and undergo regulated secretion from the neuromuscular junction. Additionally, we have created over 20 different fluorescently tagged neuropeptide and resident neuropeptide proteins to characterize the cellular mechanisms of sorting of uniquely labeled cargo. Lastly, using quantal level imaging, we are characterizing the synaptic machinery mediating trafficking and release of DCVs. Our results create novel tools and provide important insights into the proteins and pathways regulating DCV sorting, trafficking, and secretion in vivo.

1795F **The RNA binding protein Nab2 regulates m^{6}A levels and splicing of the RhoGEF *trio* transcript to govern axon development** Carly Lancaster[1], Pranav Yalamanchili[1], Sara W Leung[2], Matthew Tegowski[3], Kate Meyer[3], Anita Corbett[1], Ken Moberg[1] [1]Emory University, [2]Biology, Emory University, [3]Neurobiology, Duke University

The evolutionarily conserved zinc finger polyadenosine RNA binding protein Nab2/ZC3H14 is implicated in several post transcriptional regulatory processes including polyadenylation, 3' end formation, splicing, and nuclear export. Mutations in the human *ZC3H14* gene cause a form of nonsyndromic intellectual disability, indicating that ZC3H14 is essential for proper brain function. To explore the function of Nab2/ZC3H14 in neurons, we performed RNA-Sequencing analysis of neuronally-enriched tissues from *Nab2* mutant flies. This analysis revealed that a small number of neuronally enriched transcripts show aberrant splicing or intron retention upon loss of Nab2. Our subsequent studies of one of these transcripts, the sex-determining factor *Sxl*, using DART (deamination adjacent to RNA modification targets) and meRIP-qPCR have uncovered a novel role for Nab2 in modulating levels of N^6-methyladenosine (m^{6}A) in a *Sxl* exon and intron. Prior work demonstrating that Nab2 is required within neurons is consistent with the observation that patients with loss of function mutations in *ZC3H14* suffer from intellectual disability. These data led us to focus on brain mRNAs that are regulated by Nab2/ZC3H14. One of these is a well-

conserved growth cone guidance factor, the guanine-nucleotide exchange factor (GEF) Trio, whose vertebrate homolog TRIO acts through the F-actin regulatory GTPases Rho and Rac to guide axon projection. We find that Nab2 controls Trio levels in the fly brain by modulating an intron-retention event within the 5' UTR of *trio* mRNA isoforms, and this mechanism appears to be dependent on m^6A levels within the *trio* pre-mRNA. Data will be presented on the role of the m^6A methyltransferase Mettl3 and Nab2 in controlling *trio* splicing and expression, and downstream effects of Nab2 loss on Trio protein and GEF activity in regulating axon development within the *Drosophila* central nervous system. Together, these studies provide possible insight into how the regulation of m^6A methylation by a conserved RNA binding protein is critical for proper neuronal function.

1796F **Neuronal interaction mediated by Dscam1 receptor differentially guides dendrite formation and axon targeting in motoneuron 24** Kathy Bui, Daichi Kamiyama Cell Biology, University of Georgia

Necessary for functional neural connections are subcellular structures that send out and receive neurotransmitter signals (e.g., axon terminals and dendrites, respectively). Previously, our group showed that dendrite formation occurs precisely at the interaction site between *Drosophila* aCC motoneuron and MP1 neuron – mediated by Down syndrome adhesion molecule (Dscam1) on the membrane. However, it is known that dendrites of 36 motoneurons form at unique sites – thus, an ensuing question: does the Dscam1 receptor play a role at other sites where motoneuron dendrites form and if so, how? Using established techniques of genetics, retrograde labeling, and confocal microscopy, we address whether neuronal interaction, mediated by Dscam1 receptor, plays a broad role in dendrite formation among motoneurons. In this study, we show that the Dscam1 receptor also can play a role in motoneuron 24 (MN24) dendrite formation in the *Drosophila* embryonic central nervous system due to its distinct location from the aCC-MP1 contact site, its highly stereotyped dendrite development, and the availability of genetic tools that allow for targeted cell-specific knockdown. Using retrograde dye labeling, we label single MN24 and show a significant reduction in dendrite branches that form in the *dscam1* mutant background. Unexpectedly, we also show a severe defect in axon targeting of MN24, suggesting that Dscam1 plays multiple roles for neurite development in MN24. To determine whether Dscam1 plays a cell-autonomous function, we use MN24-specific expression of short hairpin RNA for *dscam1* knockdown and show a similar reduction in dendrite branches (but a milder axon targeting defect) compared to that in the *dscam1* mutant. To determine whether Dscam1 plays a non-cell-autonomous function, we use *dscam1* knockdown in a subset of neuronal projections overlapping with the site of MN24 dendrite formation and, surprisingly, phenocopies the reduction in dendrite branches and the severe axon targeting defect. Altogether, this study highlights the differential roles of the Dscam1 receptor for dendrite formation and axon targeting within a single motoneuron. The sets of experiments suggest that Dscam1-Dscam1 interaction regulates dendrite formation whereas Dscam1 interaction with another ligand regulates axon targeting in MN24. Overall, we conclude that Dscam1 mediates diverse functions within a single neuron, refining the current understanding of Dscam1 function for neural circuitry formation.

1797F **Neuropile Ensheathing Glia Modulate Seizure Susceptibility of *Drosophila melanogaster*** Lexis Grandel, Samantha Casciani, Dionna DeFazio, Mar Hinestroza, Sarah Iannone, Alexis Hill Biology, College of the Holy Cross

The nervous system must be able to respond quickly and appropriately to changes in environmental conditions, such as exposure to extreme temperatures. Homeostatic control mechanisms that mediate such responses are essential for survival, allowing behavioral and other bodily functions to remain intact under environmental pressure. Here we show that in *Drosophila melanogaster*, a specific type of glial cell, neuropile ensheathing glia (EGN), plays a significant role in regulating the nervous system. Genetic manipulations specifically in EGN affect susceptibility to heat-induced and bang-induced seizure assays in the adult fly. In other contexts, EGN have been shown to have phagocytic functions. Therefore, we hypothesized that the phagocytic function of EGN may underlie its role in mediating seizure susceptibility. Supporting this hypothesis, EGN-specific knockdown of the engulfment receptor *draper* increases seizure susceptibility. We have also determined that EGN-specific knockdown of the voltage-gated potassium channel gene *seizure* (*sei*) and the sodium/potassium/chloride transporter *ncc69* increase seizure susceptibility, though whether these genes affect phagocytic functions of EGN has not yet been tested. Additional ongoing and future experiments will determine whether developmental and/or adult expression of EGN *draper*, *sei*, and *ncc69* modulate adult neural excitability and behavior in seizure susceptibility assays. This project contributes to our understanding of the important roles that glia play in modulating homeostatic nervous system control. Furthermore, we specifically identify EGN as a glial subtype that may allow us to discover key genes and mechanisms by which glia regulate nervous system activity and behavior.

1798F **Alterations in Sequential Motor Patterns of a Model of Neurofibromatosis Type 1** Hannah Brunner[1], Genesis Omana-Suarez[1,2], Seth Tomchik[1,2,3] [1]Neuroscience and Pharmacology, University of Iowa, [2]Scripps University, [3]Pediatrics, University of Iowa

Neurofibromatosis type 1 is a genetic disorder caused by the loss of the neurofibromin protein (Nf1). Neurofibromatosis has a wide range of physical and cognitive manifestations including autism spectrum disorder and attention deficit hyperactivity

disorder. Loss of Nf1 function may alter circuit activity, leading to behavior changes. We have found that loss of Nf1 in *Drosophila* alters spontaneous motor behaviors, including increasing grooming frequency. Whether Nf1 deficiency alters the frequency and pattern of sensory-evoked behaviors is unknown. If flies are covered with dust, they engage in vigorous grooming to remove the dust. Here we test the effects of dusting wild-type and *nf1* mutant flies, and if the typical grooming hierarchy has been affected. The data suggest that dusting increases grooming frequency in both genotypes, and that the grooming pattern in *nf1* mutants is altered: the normal sequence/prioritization is scrambled. This suggests that Nf1 loss both increases spontaneous grooming frequency and changes the pattern of this temporally-sequenced motor behavior.

1799F **Natural Variation in Neural Stem Cell Reactivation Offers Opportunity for Novel Insight into Neurogenesis** Taylor L. Nystrom, Alan O Bergland, Sarah Siegrist Biology, University of Virginia

During early life neurogenesis, neural stem cells (NSCs) give rise to thousands of morphologically and functionally diverse neurons that will build the adult brain. Ultimately, these neurons form functional circuits that allow proper functioning and survival of the adult animal. As neurogenesis progresses, NSCs transition through periods of quiescence and proliferation, with the transition from quiescence to proliferation referred to as reactivation. Reactivation is a temporally-regulated process that is known to be influenced by both intrinsic and extrinsic signaling, yet we still have a limited understanding of the genes and pathways involved in this process. Our work seeks to reveal new insights into the integration of intrinsic and extrinsic signaling by studying how an extrinsic factor, nutrient signaling, and an intrinsic factor, natural genetic variation, interact during NSC reactivation in Drosophila melanogaster. In order to capture genetic variation reflective of wild populations, we used a collection of wild-caught, geographically diverse, inbred lines of flies for all experiments. We then used classic developmental experiments to measure development and reactivation at distinct time points. Our work revealed significant differences in the timing of NSC reactivation from quiescence when genetically distinct larvae are raised in a common, calorically rich environment. We also saw that a delay in reactivation is generally correlated with a delay in overall developmental timing in the lines that we tested. Finally, in vitro experiments revealed a loss of variation in reactivation, suggesting that this variation is the result of a tissue extrinsic factor. These findings reveal that there is natural variation in NSC reactivation, as well as suggest a genetically encoded basis for variation in neurogenesis. Together, this knowledge provides a new opportunity to uncover novel genes or pathways involved in the transition from quiescence to proliferation.

1800F **Seizure and Motor Phenotypes Caused by Overexpression of *dube3a* in Neuronal and Glial Tissues** Megan N Sleep[1], Andrew Lacoste[1], Selene Tan[1], Lawrence T Reiter[2], Atulya Iyengar[1] [1]The University of Alabama, [2]The University of Tennessee Health Science Center

Duplication 15q (Dup15q) syndrome is thought to be caused primarily by increased copy number for the E3 ubiquitin ligase gene, *UBE3A*. Dup15q syndrome is characterized by motor deficits, developmental delays, and pharmacoresistant epilepsy. However, neuronal overexpression of *Ube3a* in vertebrate models of Dup15q syndrome fail to recapitulate seizure phenotypes. Interestingly, *Drosophila* overexpressing *dube3a* (the fly ortholog of *UBE3A*) in glial cells results in mechanical shock-induced seizures ("bang-sensitivity"). Here, we aimed to directly compare the motor phenotypes arising from *dube3a* overexpression in glia versus neurons in *Drosophila*. Specifically, we crossed UAS-*dube3a* with the glial driver, *repo*-GAL4, and the neuronal driver, *nsyb*-GAL4, and monitored open field behavioral phenotypes on a temperature-controlled stage. We used IowaFLI Tracker to quantify locomotion features such as average velocity, distance traveled, and time of activity. Flies overexpressing *dube3a* in glia (*repo* > *dube3a*) were significantly ataxic and experienced a 54% decline in average velocity compared to controls. In contrast, neuronal *dube3a* overexpression (*nsyb* > *dube3a*) had less effect on locomotion with a 24% decrease of average velocity (rank-sum test, *repo>dube3a* vs *nsyb>dube3a*, $p=3.4 \times 10^{-5}$). Interestingly, we observed several bouts of prolonged immobilization in *repo* > *dube3*a flies, indicative of underlying seizure activity. We found high temperature-stress (36-39 °C) also triggered seizure-related activity in *repo* > *dube3a* flies: caroming, spinning, uncontrolled wing buzzing, and immobilization. 48% of *repo* > *dube3a* flies experienced prolonged immobilization compared to 22% of *nsyb* > *dube3a* (χ^2 test, p=0.000054). Our findings confirm that glial overexpression, but not neuronal expression, of *dube3a* primarily contributes to the emergence of seizure-related phenotypes in the context of Dup15q syndrome.

1801F **Restoring histone acetylation homeostasis in Alzheimer's Disease using Tip60 HAT activators** Aprem Zaya[1], Akanksha Bhatnagar[1], Gu Gu Nge[1], Sandhya Kortagere[2], Felice Elefant[1] [1]Biology, Drexel University, [2]Microbiology and Immunology, Drexel University College of Medicine

Reduced histone acetylation in the brain caused by disruption of histone acetylation homeostasis is an early event in Alzheimer's Disease (AD) etiology that causes cognitive impairment prior to amyloid beta plaque formation. While genetics plays a role in the development of AD, over 90% of patients hospitalized for AD are diagnosed with sporadic AD, highlighting the importance of epigenetic dysregulation in disease progression. Numerous small molecules, including epigenetic modulators, are currently in clinical trials for AD. These epigenetics-based treatments aim to restore histone acetylation homeostasis by inhibiting histone deacetylases (HDACs), which remove acetyl marks from histones causing chromatin to

condense, leading to a reduction in gene expression. While promising, many HDAC inhibiting treatments are not specific to one HDAC, causing side effects likely due to global hyperacetylation. Our work focuses on Tip60 histone acetyltransferase (HAT), which generates pattern-specific acetyl marks onto histones to decondense chromatin, leading to enhanced transcription. We have shown that genetically increasing Tip60 HAT levels functionally rescues both cognitive deficits and expression of critical neuroplasticity genes repressed in a well-characterized Drosophila amyloid precursor protein (APP) model of AD by restoring histone acetylation homeostasis. Since our findings support a neuroprotective role for Tip60 HAT in AD, we propose an epigenetics-based therapeutic strategy using small molecules that selectively activate Tip60 HAT to restore histone acetylation homeostasis. We developed small molecule compounds using a structure based approach with a general HAT activator, then further optimized the compounds using a pharmacophore function-based approach. Using an in vitro HAT assay, we identified three of the compounds as robust and specific Tip60 HAT activators. Future work will elucidate the efficacy of these compounds in functional assays to assess locomotion and learning & memory in the Drosophila AD model and assess expression profiles of neuroplasticity genes responsible for cognitive function using real-time quantitative polymerase chain reaction (RT-qPCR). Our therapeutic strategy of designing a specific Tip60 HAT activator that restores histone acetylation homeostasis is a promising AD treatment that could address cognitive impairment that precedes other disease characteristics observed at later stages.

1802F **The genetic basis of neural circuit evolution for *Drosophila* mate preferences** Emily L Behrman, David L Stern HHMI Janelia Research Campus

Behaviors that arbitrate interspecies courtship are at the crux of evolutionary barriers between species. Species- and sex-specific pheromone profiles in *Drosophila* have rapidly diversified that signify species' identity to encourage courtship among conspecifics and discourage interspecies courtship. The dominant pheromone produced by *Drosophila melanogaster* females is an aphrodisiac to their males, but the same chemical cue inhibits courtship in male *D. simulans*, whose females do not produce that pheromone. We identify a gene that has evolved to reshape the neural circuit that processes this pheromone and change the male's response from attraction to repulsion. We assess how differential regulation of this gene in specific neurons changes the anatomical and physiological properties of the circuit between the species to produce divergent behaviors. This provides a unique mechanistic understanding of the genetics underlying neural circuit evolution.

1803F **Metabolic Dysfunction in Frontotemporal Dementia** Angelina Freeman[1], Ana Penagaricano-Abreu[1], Valentina Torres-Cerda[1], Marla Tipping[2] [1]Biology, Providence College, [2]Providence College

Frontotemporal dementia (FTD) is a neurodegenerative disease characterized by changes in behavior, a decline in executive function, and a loss of language abilities. With increased awareness that metabolic changes often present in disease, there has been a shift toward investigating the metabolic etiology of diseases, such as cancer. However, this shift is not as prevalent in the study of neurodegenerative disease. Using a *Drosophila melanogaster* model, we are studying the connection of neurodegeneration with the dysregulation of lipid metabolism associated with FTD. We utilized staining to visualize lipid stores, metabolic assays to quantify triglyceride levels, behavior analysis to monitor activity levels on a light-dark cycle, and quantitative PCR and western blots to measure other metabolic factors. The goal of this project is to evaluate the dysregulation of lipid metabolism in FTD and determine targets for potential treatments.

1804F **Hemocyte dependent regulation of alcohol induced responses as a function of temperature** Madhavi Kuchibhotla[1], Airined Montes[1], Josue A Rodriguez[1], Carolina I Maldonado[1], Raoul A Lebron Rivera[1], Dr.Jose L Agosto[1], Dr. Alfredo Ghezzi[1], Dr. Tugrul Giray[1], Dr. Maria E Perez Hernandez[2] [1]Biology, University of Puerto Rico, Rio Piedras Campus, [2]Mathematics, University of Puerto Rico, Rio Piedras Campus

Alcoholism is the third leading cause of deaths. One of the key components in the development of alcoholism is the gradual increase in resistance to alcohol over repeated exposures. This adaptation is also known as tolerance, which is thought to involve neural adaptations and plasticity within the brain leading to alcohol use disorders (AUD). Recently, the Neuroimmune system has emerged as an important player in the development of AUD. Well Established studies on polymorphisms in macrophages and immune genes were linked to higher risk of alcoholism,supporting the role of immunity and neuroimmune signaling in alcohol addiction. Drosophila studies have identified the RNA binding protein pumilio (pum) as a regulator of ethanol tolerance. Pum has also been linked to innate immunity and alcohol tolerance. The effects of temperature on sensitivity and tolerance have not been previously studied. We are inclined to hypothesize the tolerance might increase with higher interaction of dose just as doses alone to tolerance. Therefore, we were motivated to fill this knowledge.Thus, the overall goal of this study is to evaluate the role of pumilio within hemocytes in alcohol induced behaviors as the function of temperature. One of our focuses is to understand how pumilio can alter alcohol responses with temperature. For which, we employed GAL4/UAS binary system to generate targeted expression of GFP and/or pumRNAi transgenes precisely in hemocyte-specific driver line (hml-GAL4). We performed a 2-day ethanol assay paradigm on F1 age matched female Drosophila

melanogaster flies and sensitivity and tolerances were calculated using recorded sedation scores. All flies were subjected to 50% ethanol at 3 different temperatures (18°C, 22°C and 27°C) at 3 different instances. The focus of the study is to reveal the relation between ethanol responces and temperature. Our results indicate that, within the genotype, sensitivity to ethanol increases with temperature and pumilio knockdown increases sensitivity with temperature. Pumilio knockdown demonstrated an significant increase in tolerance index with temperature ($p<0.0002$) as opposed to its corresponding control flies, which were also statistically significant ($p<0.0001$). Overall, our data suggests that neuronal adaptation mechanisms underlying ethanol tolerance might be different from the perspective of dose only vs interaction of doses and environmental temperature. More specifically, at colder temperatures, one needs high doses of ethanol to be able to develop tolerance, suggesting the nervous system is less excitable and therefore needs more alcohol to be able to trigger plasticity mechanisms.In Contrast, high doses will not develop tolerance as much as at lower, suggesting high temperatures and high ethanol doses too much excitability is observed and plasticity mechanisms are blocked.

1805F **Contribution of Painless and TrpA1 to *Drosophila melanogaster* nociception** Jacob Jaszczak[1], Avi Simon[2], Luke Breuer[3], Nilson Palma[4], Susan Younger[2], Lily Jan[2], Yuh-Nung Jan[2] [1]New Mexico State University, [2]HHMI at the University of California, San Francisco, [3]Better Tools for Scientists, [4]City College of San Francisco

Nociception, the sensory mechanisms which respond to potentially damaging stimuli, depends on the coordination of multiple sensory channels. Understanding how multiple channels contribute to pain perception is critical for the management of chronic pain. *Drosophila melanogaster* larva exhibit a nociceptive escape behavior in response to a range of noxious temperatures (greater than 40°C) through the activation of two channels, Painless and TrpA1. These channels are both expressed in peripheral C4da neurons, which envelop the larval cuticle through their dendritic arbors. While both Painless and TrpA1 are thermally activated *in vitro*, different *painless* alleles have been reported to have distinct effects on larval nociceptive behavior, and we find that mutations of *painless* do not enhance the *TrpA1* phenotype. We compared the larval thermal nociceptive phenotypes of different *painless* alleles over a range of nociceptive temperatures. We find the alleles that have the strongest loss of nociceptive behavior also retain some RNA or protein products, whereas the *painless* alleles that do not retain detectible RNA or protein products do not lose their nociceptive phenotype. Ongoing work aims to create isoform specific and neomorphic *painless* mutants in order to test their contribution to the disruption of thermal nociceptive behavior and coordination with TrpA1 function.

1806F **Spatial transcriptomics reveals region-specific and cell-type-specific gene dysregulation in a *Mecp2* mouse model of Rett syndrome** Young Y Zhou[1], Julie Ruston[1], Bharti Kukreja[2], Nareh Tahmasian[2], Brian Kalish[2,3,4], Monica J Justice[1,3] [1]Genetics and Genome Biology, The Hospital for Sick Children, [2]Neuroscience and Mental Health, The Hospital for Sick Children, [3]Department of Molecular Genetics, University of Toronto, [4]Department of Paediatrics, University of Toronto

Rett syndrome (RTT) is a rare neurometabolic disorder primarily attributed to mutations in the X-linked methyl-CpG-binding protein 2 (*Mecp2*). In female RTT patients, a period of seemingly normal development spans from 6 to 18 months, followed by a gradual regression of speech and motor skills, accompanied by stereotypic hand movements, movement disorders, and sleep disturbances. While heterozygous (*Mecp2/+)* female mice are more clinically relevant, hemizygous male mice (*Mecp2/Y)* are the preferred model due to their penetrant phenotype. Notably, in male mice, the phenotype becomes evident at 4-5 weeks of age, although molecular perturbations manifest earlier. Our previous results from RNAseq and immunofluorescence experiments unveiled a critical developmental ‹switch› within the *Mecp2* brain, occurring between postnatal day 14 and postnatal day 21, leading to the onset of RTT symptoms. To illuminate the precise timing and cellular underpinnings of this ‹switch,› we harnessed MerFISH, a spatial transcriptomic technology with high spatial resolution and sensitivity. Employing this approach, we discerned distinct region-specific and cell-type-specific differentially expressed genes associated with cholesterol synthesis, signaling pathways, synaptic function, development, circadian rhythms, and various other vital processes. These dysregulated genes potentially hold developmental significance in the *Mecp2* brain, which may underlie the fundamental pathophysiology of RTT.

1807F **Genetic testing in children with developmental delay** Junghyeon Park[1], Ah Yeon Lee[1], Hye Jung Park[1], Myungshin Kim[2], Hoon Seok Kim[2], Seung Bin Lee[3], Joo Hyun Park[1] [1]Department of Rehabilitation Medicine, Seoul St. Mary’s Hospital, College of Medicine, The Catholic University of Korea, [2]Department of Clinical Laboratory Medicine, Seoul St. Mary’s Hospital, College of Medicine, The Catholic University of Korea, [3]Industry-Academic Cooperation Foundation, The Catholic University of Korea

Background

In recent years, molecular advancements greatly enhanced our capacity to identify genetic factors contributing to developmental delays in children, particularly in cases that were previously unexplained. This single-center study in South

Korea focused on reviewing cases of pediatric patients with developmental delays, with the aim of identifying the conducted genetic tests and assessing the results for children whose developmental delays had unclear origins.

Methods

We reviewed the records of pediatric patients who were genetically tested with developmental delays, hypotonia, or facial dysmorphism from 2009 to 2022. We enrolled 306 patients who underwent genetic testing, including karyotype analysis, chromosomal microarray analysis (CMA), targeted Next Generation Sequencing (NGS)-based gene panel (985 genes), Multiplex Ligation-dependent Probe Amplification (MLPA), and Fluorescence In Situ Hybridization (FISH).

Results

Among the 323 patients, 211 (65.3%) were male, and 112 (34.7%) were female. The average age at which genetic testing was conducted was 3.89 years old. Seventeen patients did not undergo the testing despite it being prescribed. The remaining 306 patients completed the tests as recommended. Sixteen patients carried karyotypic abnormalities (16/301). Abnormal CMA results were found in a total of 84 patients (32.7%, 84/257). Among these, 42 had microdeletions, 33 had microduplications, and 9 had both abnormalities. In the targeted NGS panel, mutations were detected in 50 out of 97 patients (51.5%). Among these, 4 were classified as pathogenic, 12 as likely pathogenic, and 34 as variants of uncertain significance (VUS). In MLPA, 2 out of 12 patients exhibited anomalies, while in FISH, anomalies were observed in 6 out of 7 patients. Parental testing was recommended for a total of 98 cases, and it was conducted in 77 cases.

Conclusion

Various genetic tests have demonstrated their utility in identifying the underlying causes of unexplained developmental delays. In children with developmental delay, if a genetic disorder is suspected based on the phenotype, more comprehensive testing such as WES (Whole Exome Sequencing) or WGS (Whole Genome Sequencing) may be necessary.

1808F **Multi-omic interactions of multi-generational early life stress in developing zebrafish** Erik D Norloff[1], Yingning Sang[1], Oksana Kosyk[2], Darius Thompson[1], Anthony S Zannas[2,3,4], Christina L Graves[1,4] [1]Oral and Craniofacial Health Sciences, University of North Carolina at Chapel Hill, [2]Psychiatry, University of North Carolina at Chapel Hill, [3]Genetics, University of North Carolina at Chapel Hill, [4]Carolina Stress Initiative, University of North Carolina at Chapel Hill

Background: Chronic early life stress (ELS) is appreciated to be a powerful force in shaping biological outcomes later in life and is associated with the onset of gastrointestinal disease in humans. Further, recent longitudinal cohort studies demonstrate that multigenerational adversity impacts the gut microbiome composition in early childhood, highlighting the gut-brain axis as an important target of ELS. Building on our recently published work demonstrating that chronic ELS alters the neuroimmune profile and functioning of the developing zebrafish gut, our goal in this study was to establish a model of multigenerational ELS in zebrafish and determine cumulative stress impact on multivariate outcomes. **Methods and Results:** Wild-type AB zebrafish were exposed to chronic mild environmental stressors beginning at 6 dpf until 30 dpf according to our recently published stress paradigm for a total of four successive generations. We compared stressed and unstressed groups from either stressed or unstressed ancestors and found that chronic ELS was associated with reduced reproductive fitness, smaller size, and increased whole body cortisol with effects largely dependent on within-generation stress exposure. RNA-sequencing of gut tissue revealed ELS-associated differential expression of more than 800 genes in founder generations, some of which have been identified as susceptibility loci in human inflammatory bowel disease. **Conclusions:** Our data demonstrate that zebrafish are a powerful model for exploring neuroimmune interactions at mucosal surfaces across generations.

1809F **Motor Circuit Critical Period Closure in a Highly Regenerative Vertebrate** Haley Jetter, Jacob P Brandt, Sarah D Ackerman Pathology and Immunology, Washington University School of Medicine

An essential feature of nervous system development is the remodeling of circuits during critical periods of plasticity, brief developmental windows when the activity of neurons can modify circuit architecture and function to produce sustained changes in animal behavior. In *Drosophila,* astrocytes have been identified as key regulators of critical period closure in the invertebrate motor circuit, where astrocytes signal to motor neurons via a Neuroligin-Neurexin signaling axis to stabilize the developing motor circuit. Here we seek to characterize motor plasticity in zebrafish, an animal capable of complete motor circuit regeneration following injury. Whether a critical period exists, and what roles astrocytes have in regulating motor plasticity, remains to be investigated in a highly regenerative vertebrate model like zebrafish. In both *Drosophila* and mouse,

astrocyte-synapse contact is predictive of critical period closure. In zebrafish, astrocytes extend their initial processes at 2 days post fertilization (dpf) and show a mature morphology by 6 dpf. Thus, we utilize *in vivo* timelapse imaging and optogenetics in zebrafish between 2- and 6dpf to characterize activity-dependent motor neuron dendrite dynamicity. We hypothesize that it is during this developmental window, plasticity will be enriched, and that beyond 6 dpf, the presence of mature astrocytes will limit motor plasticity. We will then use CRISPR/Cas9 to knock out Neuroligins in astrocytes and measure the consequence to motor plasticity. We expect that loss of this astrocyte anti-plasticity cue will enhance motor plasticity, irrespective of whether plasticity is developmentally restricted. Together, we work toward identifying the roles of astrocytes during critical period closure in a highly regenerative vertebrate system.

1810F **The transcription factors *prdm16* and *prdm3* antagonistically regulate acoustic startle response thresholds** Zackary Q Marshall[1], Nicholas Santistevan[1], Susannah Schloss[1], Lomeli Shull[2], Kristin Artinger[3], Jessica C Nelson[1] [1]Cell and Developmental Biology, University of Colorado Denver, [2]Craniofacial Biology, University of Colorado Denver, [3]Diagnostic and Biological Sciences, University of Minnesota

An organism's survival depends on its ability to appropriately filter relevant sensory stimuli from the environment. Differences in sensory filtering exist in many neurological disorders such as migraine, schizophrenia, and ADHD. More specifically, migraine sufferers exhibit altered brain activity and decreased thresholds for visual, thermal, and acoustic stimuli even during interictal periods that intervene migraine attacks. Despite migraine being a leading cause of disability among women, the underlying genetic mechanisms remain elusive. From a pilot screen of putative migraine-associated genes, we uncovered a novel function for the transcription factor *prdm16* in regulating acoustic startle sensitivity. Previous work demonstrated that *prdm16* and *prdm3* orchestrate craniofacial development despite *prdm16* promoting Wnt/ß-catenin signaling and *prdm3* antagonizing Wnt/ß-catenin signaling. In a similar manner, we show *prdm16* homozygous mutants and crispants exhibit heightened acoustic startle sensitivity while *prdm3* crispants display severely reduced acoustic startle sensitivity. Interestingly, *prdm16* homozygous mutants injected with *prdm3* guides have startle thresholds that resemble their wild-type, control guide-injected siblings, indicating that an appropriate balance between *prdm16* and *prdm3* activity is required to tune sensory thresholds. Finally, to investigate which brain regions *prdm16* and *prdm3* modulate, we performed an unbiased whole brain activity mapping experiment, and found that whole brain activity of *prdm16* mutant larvae display hyperactivity in the habenula and the medial rhombencephalon as compared to their siblings. In contrast, we observe wide-spread hypoactivity in *prdm3* crispants, including within the habenula and the medial rhombencephalon. This work reveals a role for genes that balance Wnt/ß-catenin signaling in establishing appropriate sensory thresholds and provides proof of concept for a more comprehensive screen of migraine-associated genes, investigating how they might impact sensory thresholds *in vivo.*

1811S **Understanding the Impact of Superoxide Dismutase on Extracellular Vesicle Biogenesis and Cargo Sorting** Nahin Siara Prova[1], Jessica Tanis[2] [1]Biological Sciences, University of Delaware, [2]Biological Sciences, University Delaware

Extracellular vesicles (EVs), released by nearly all cell types, mediate intercellular transport of protein, RNA, metabolite, and lipid cargo that cannot readily cross the plasma membrane to recipient cells. Dictated by the site of origin, the cargoes packaged into EVs regulate normal physiological processes and propagation of pathological conditions. The cellular factors that modulate EV biogenesis and the enrichment of cargoes into distinct EV subpopulations remain unclear. EVs are released from cilia of *C. elegans* male sensory neurons, then are taken up by surrounding glia or released into the environment. The ion channel CLHM-1 is packaged into EVs shed from the periciliary membrane compartment of the ciliary base, while the TRP polycystin channel PKD-2 is found in EVs that bud from the cilium distal tip. To define factors that impact EV cargo loading and biogenesis, we image and quantitate the number of EVs released from animals that express tdTomato-tagged CLHM-1 and GFP-tagged PKD-2 at single copy. Accumulation of reactive oxygen species (ROS) is a byproduct of both physiological and pathophysiological processes in eukaryotic cells. If not neutralized, aging or pathogen-induced ROS production could potentially disrupt EV biogenesis and cargo sorting. Superoxide dismutase (SOD-1) is an antioxidant enzyme that acts as a ROS scavenger to help reduce oxidative stress. I found that loss of *sod-1* increases shedding of CLHM-1, but not PKD-2, EVs. CLHM-1 abundance in the ciliary base, but not cilium proper, was reduced in *sod-1* mutants. Thus, loss of *sod-1* differentially regulates release of different EV subpopulations, specifically increasing EV shedding from the ciliary base, which could impact neuron-glia communication. Achieving an understanding of how ROS impact EV biogenesis and cargo sorting is important because oxidative stress is an underlying factor for numerous pathological conditions which are impacted by EV release.

1812S **EGL-4 Protein Kinase G modulates the Hypoxia Stress Response and GLR-1 glutamate receptor synaptic trafficking** Tatiana Popovitchenko[1], Eunchan Park[2], Yeshaswi Pulijala[3], Christopher G Rongo[2] [1]Genetics, Rutgers University, [2]Department of Genetics, Rutgers University, [3]Rutgers University

Hypoxia (oxygen deprivation) plays a central role in diverse human diseases, including ischemic stroke, myocardial infarction, and cancer. Metazoans respond to hypoxia using the conserved hypoxia stress response pathway, which regulates

gene expression and metabolism to allow for survival in low oxygen conditions. For the model organism *Caenorhabditis elegans*, exposure to hypoxia tends to be environmental (e.g., hypoxic niches in the soil). Hypoxia results in changes in *C. elegans* metabolism and behavior. Here, we describe a novel role for the Protein Kinase G (PKG) ortholog EGL-4 in the hypoxia response. EGL-4/PKG has a well-established role in sensory integration and adaptation, particularly regarding the sensation of food and control of foraging behavior. Using genomic editing to introduce fluorescent tags into the endogenous *egl-4* locus, we confirmed the diverse neuronal profile of EGL-4 expression. EGL-4 is expressed in the command interneurons, which regulate direction of locomotion and roaming versus dwelling locomotory behavior. A key mediator of command interneuron function is the AMPA-type glutamate receptor GLR-1, which is localized to synapses along the ventral cord of the command interneurons. Our lab previously showed that hypoxia exposure or *egl-9* loss of function mutations block the endosomal recycling of GLR-1 receptors to synapses, resulting in reduced GLR-1 synaptic localization and GLR-1-mediated reversals in locomotory behavior. We observed similar defects in GLR-1 synaptic localization and GLR-1-mediated behavior in *egl-4* mutants. Using an auxin inducible degron sequence, we have modified the endogenous *egl-4* locus to respond to TIR1/auxin-mediated protein turnover, which we are using to examine the site and timing of action of this kinase in the command interneurons. Taken together, our results suggest that EGL-4/PKG signaling modulates the hypoxia stress response by regulating neurotransmitter receptor synaptic trafficking, which increases our understanding of how the hypoxia response pathway is integrated with signaling systems that respond to other environmental cues.

1813S **The neuropeptide nlp-50 regulates stress-induced sleep in C. elegans** Caroline Curtin Saint Joseph›s University

Caroline Curtin (Saint Joseph's University)
Advisor: Matthew Nelson (Saint Joseph's University)

Sleep is evolutionarily ancient, conserved, and likely occurs in all animals with nervous systems. Essential functions have preserved it throughout evolution despite its disadvantages, most notably it renders animals vulnerable to threats. Survival is predicated on the ability to regulate transitions between sleep and sensory readiness; these mechanisms are not well understood. The stress response of the genetically-tractable nematode Caenorhabditis elegans consists of threat avoidance, followed by stress-induced sleep, thus models this broader question. The paired ADL sensory neurons regulate avoidance behaviors and sleep and we have shown that the G-protein coupled receptor npr-38 functions in the ADL neurons to regulate these opposing behaviors. npr-38 mutants initiate sleep later than wild-type controls and display less total sleep; both phenotypes are restored when npr-38 is expressed specifically in the ADL neurons. nlp-50 neuropeptides are expressed in the ADL neurons, and are required for sleep, however when nlp-50 was rescued in the ADL neurons, the total amount of sleep was even further reduced. This suggests that nlp-50 promotes arousal and possible avoidance from the ADL neurons. Currently, my project is focused on determining the site of action for nlp-50 during sleep by measuring sleep in animals in which nlp-50 is restored in a cell-specific manner.

1814S **Investigating a simple neural circuit regulating stress responses in C. elegans** Mary Frattara[1], Matthew Nelson[2] [1]Biology, Mary Frattara, [2]Biology, Saint Joseph's University

C. elegans exhibit a two-fold stress response featuring threat avoidance followed by a state of stress-induced sleep. These represent opposing yet essential behaviors; how animals coordinate them is unclear. Avoidance requires sensory neurons like the ADL and ASH, and a hub interneuron called RMG. Stress-induced sleep requires the ALA and RIS interneurons; the RMG may also regulate arousal from sleep. Our lab has identified a G-protein coupled receptor, npr-38, that is expressed in each of these cells and is required for avoidance, sleep, and arousal. We propose that a circuit composed of 6 cells (ADL, ASH, ALA, RIS, AIB, and RMG) coordinates the stress response and the transitions between opposing behavioral states. As a first step of testing this hypothesis, we expressed the histamine-gated chloride channel HisCl1 in the ADL and RMG. We are currently measuring each aspect of the stress response following chemogenetic silencing of the ADL, the RMG, and both the ADL and RMG. This research will set the groundwork for future studies to delve into other relevant neurons in the circuit.

1815S **Small size correlates with reduced running in response to alternating current in *C. elegans*** Annalise I Totten[1], Victoria Lam[1], Shane Calle[1], Zoe Midthun[1], Ling Fei Tee[2], Gabrielle Martin[1], Kotarou Kimura[2], Jared Young[1] [1]Mills College at Northeastern University, [2]Nagoya City University

In response to alternating current of 30V applied to the agar substrate, C. elegans increases movement speed (Tee et al., Genetics, 2023). This response could be a manifestation of a fear emotion in the worms, causing them to panic and attempt to escape. Previously, sma-1 had been identified as a likely contributor to this behavior. Three alleles of sma-1(e934, e30, and ru18) were tested for electricity response and all were found to be defective. On average, these sma-1 worms showed less increase in their movement speed compared to wild-type worms, and were less likely to leave a food lawn when exposed to electricity. We have tested hypotheses regarding the specific biological contribution of sma-1 to the electricity response,

including testing of other C. elegans mutants that share phenotypic similarities to sma-1 mutants. These phenotypes include small size and defective excretory canals. The effect of size on the electricity response was tested using different ages of wildtype N2 strain and mutants of different sizes, with smaller size correlating with decreased electricity response.

1816S **The role of GPCRs in regulating sleep through Notch signaling in C.elegans** Manuel F Lamela[1], Adam Michael Friedberg[2] [1]Neuroscience, Brown University, [2]Brown University

Sleep is an essential behavior observed across species and is characterized by behavioral quiescence, including reduced sensory responsiveness and decreased activity. In C. elegans, Notch signaling regulates developmentally timed sleep (DTS) which occurs in the transition between developmental stages during periods known as lethargus. A double knock-out of the two Notch co-ligands (osm-7 and osm-11) leads to a decrease in DTS, whereas overexpression of OSM-11 in adult C. elegans results in anachronistic sleep, a temporary, reversible behavioral quiescence similar to lethargus sleep (Singh 2011). With this knowledge, a forward genetic screen was undertaken to identify genes whose perturbation disrupts anachronistic sleep in C. elegans, and goa-1, a gene that encodes a G-alpha(o), was identified (Huang 2017). However, the GPCR receptors that may interact with GNAO1 to regulate sleep are still unknown. Notably, the orthologous human gene GNAO1 was associated with insomnia in a large-scale, human genome-wide association study, suggesting GNAO1 may be important in sleep across species (Lee 2019). To study this receptor in C. elegans, I (1) optimized the sleep assay for assaying anachronistic sleep presented in Huang et al. 2017, (2) CRISPR individuals with the transgene that I wanted to test (3) tested this mutant strain for sleep defects. The results will provide insight into interactions between GPCR and Notch signaling in regulating sleep, demonstrate conservation of GPCRs in C. elegans, and may provide mechanistic insights into the importance of GPCR signaling in sleep and insomnia.

1817S **A genetic screen for modifiers of stress-induced sleep in *C. elegans* using a worm picking robot** Zihao John Li[1], Kerry FY Lecure[2], David M Raizen[2], Chris Fang-Yen[3] [1]Bioengineering, University of Pennsylvania, [2]Neurology, University of Pennsylvania, [3]Biomedical Engineering, Ohio State University

Animals sleep more when they are sick. In *C. elegans*, stress-induced sleep (SIS) is regulated by epidermal growth factor (EGF) activation of the ALA and RIS neurons, which then release neuropeptides to trigger sleep. However, the mechanisms by which EGF is regulated and components acting downstream of ALA/RIS signaling are poorly understood. To gain insight into the mechanism of SIS, we conducted a genetic screen for modifiers of UV-induced sleep. We used the Million Mutation Project (MMP), a library of 2007 mutagenized and sequenced strains. The screen requires manipulating and phenotyping a large number of clones, making the experiments labor intensive. To increase throughput, we used our recently developed worm-picking robot to maintain the strain library, prepare sleep assays in the multi-well WorMotel platform, and perform other manipulations. Using the resulting sleep data from MMP strains, we developed statistical methods for determining the associations between the genes and sleep phenotypes. Our analysis unveiled a set of novel candidate genes associated with SIS in *C. elegans*. Further analysis of these genes holds promise to deepen our understanding of sickness sleep. In addition, our screening pipeline serves as a model for accelerating other genetic screens through robotic automation.

1818S **Response to two attractive odorants relies on distinct regulators of RNA silencing** Samiha Tasnim, Antony M Jose University of Maryland

Behavioral adaptation to dynamic environments is a hallmark of all animals. Although such adaptation has been proposed to require gene regulation, the underlying mechanisms are not well understood. The nematode *C. elegans* is a useful model for analyzing adaptation upon prolonged exposure to attractive odorants. It uses the AWC pair of amphid sheath neurons to respond to the attractive odorants butanone and benzaldehyde. It can adapt to each odorant independently such that prolonged exposure to either odorant leads to loss of attraction to that odorant. Inspired by prior reports on the role for RNA silencing in the response to butanone, we examined both sensation upon acute exposure and adaptation upon prolonged

exposure to butanone or benzaldehyde by animals lacking different regulators of RNA silencing. We generated null mutants of each regulator using Cas9-mediated genome editing and tested their behavior using a choice assay that we adapted to ensure a large effect size. Surprisingly, two proteins with roles in the germline were required for the response to both odorants. The nuclear Argonaute HRDE-1 was required for sensing both odorants and the Maelstrom-domain protein RDE-10 was required for adapting to both odorants. This requirement either reflects additional roles for these proteins in neurons or altered neuronal development resulting from loss of RNA regulation in the parental germline. Furthermore, the adaptation to benzaldehyde but not to butanone required the primary Argonaute RDE-1 and the somatic nuclear Argonaute NRDE-3. This selectivity suggests that the changes in RNA regulation required for adapting to butanone could be different from those required for adapting to benzaldehyde. Together, our results reveal that the response to two attractive odorants sensed by AWC neurons share RNA regulators with known roles in the germline and additional distinct RNA regulators.

1819S **Neurofibromin deficiency alters the initiation and perseveration of temporally-sequenced behaviors** Genesis Omana Suarez[1], Divya S Kumar[2], Hannah Brunner[1], Jalen Emel[1], Valentina Botero[1], Connor Broyles[1], Aaron Stahl[1], Salil S Bidaye[2], Seth M Tomchik[3] [1]University of Iowa, [2]Max Planck Florida Institute for Neuroscience, [3]Neuroscience and Pharmacology, University of Iowa

Neurofibromatosis type 1 (NF1) is a genetic disorder that drives tumor formation and affects brain function in some patients. The disorder produces a range of symptoms, including increasing susceptibility to cognitive and behavioral symptoms such as autism spectrum disorder and attention-deficit/hyperactivity disorder. This suggests that NF1 affects neuronal function, leading to changes in behavior. NF1 is caused by loss of function mutations in the *NF1* gene and its protein product, neurofibromin. To dissect the mechanisms of how NF1 affects neuronal function, we have examined the effect of neurofibromin deficiency (mutants/RNAi) on motor function in *Drosophila*. Loss neurofibromin generates behavioral phenotypes, including increasing the frequency of spontaneous grooming. Here we report that neurofibromin deficiency alters the patterning and prioritization of temporally-sequenced motor behaviors. Spontaneous grooming was increased in a nonlinear spatial and temporal pattern, with grooming of certain body parts selectively elevated in a time-varying manner. This was state-dependent, as food deprivation resulted in a genotype-dependent behavioral switch from a grooming- to foraging-dominant behavioral mode over time. Loss of Nf1 in discrete sensory circuit and/or command neurons did not alter grooming frequency, though in some cases, it biased spontaneous grooming toward a specific body part. Walking patterns were altered - flies lacking Nf1 walked faster, but without significant alteration in leg kinematics or interleg coordination. Overall, these data suggest that neurofibromin deficiency modulates neuronal network activity nonlinearly, altering the selection of temporally-sequenced behaviors.

1820S **Long non-coding RNA Statera regulates synaptic plasticity at the *Drosophila* neuromuscular junction** Shuhao Wang, Gimena Alegre, Travis Thomson UMass Chan Medical School

It is widely accepted that synaptic plasticity is the foundation of learning and memory and perturbation of plasticity is implicated in many neurological and psychiatric diseases. Our lab previously described a protein and RNA trafficking pathway ViSyToR (Viral Synaptic Transfer of RNA) required for synaptic plasticity at the Drosophila neuromuscular junction (NMJ). Central to this pathway are two capsid genes, dArc1, a Drosophila homolog of Arc (Activity-Regulated Cytoskeleton-Associated protein) which is a positive regulator of plasticity, and Copia, a retrotransposon which is a potent negative regulator of plasticity. Using RNA immunoprecipitation, we found that the long non-coding RNA Statera is bound by dArc1 and Copia proteins. By analyzing existing single-cell RNA-Seq datasets, we found that Statera is universally expressed in Drosophila and induced during aging. RNA FISH data shows that Statera is localized to the CNS, as well as the nucleolus of muscle cells. Neuron-specific Statera knockdown by RNAi and whole-body Statera knockout by CRISPR both lead to a decrease of bouton numbers at the NMJ, suggesting a role of Statera in synaptic plasticity. Furthermore, RNA-Seq and dPCR data show that Statera knockout leads to an increase of a group of transposable elements including Copia. Taken together, our results point to an unexpected role of a long non-coding RNA in synaptic plasticity, possibly by regulating the levels of transposable elements.

1821S **Recurrent spontaneous seizures caused by glial-*Dube3a* overexpression can be suppressed through modulation of 5-HT signaling** Saul Landaverde[1], Reid Schuback[1], Megan Sleep[1], Selene Tan[1], Andrew Lacoste[1], Lawrence T. Reiter[2,3], Atulya Iyengar[1] [1]Department of Biological Sciences, The University of Alabama, [2]Department of Neurology, The University of Tennessee Health Science Center, [3]Department of Anatomy and Neurobiology, The University of Tennessee Health Science Center

The E3 ubiquitin ligase *UBE3A* catalyzes the transfer of ubiquitin to substrate proteins marking them for proteolysis. Over-expression of *UBE3A* is thought to contribute to Duplication 15q syndrome since *UBE3A* is located within the 15q11.2-q13.1 duplication. Dup15q patients often display autism, muscle hypotonia, and epilepsy. In vertebrate models, overexpressing *UBE3A* in neurons recapitulates several aspects of Dup15q syndrome, but not epilepsy phenotypes. Previous work in Drosophila indicates that overexpression of *Dube3a* (homolog of *UBE3A*) in glia leads to a “bang-sensitive”

hyperexcitable phenotype. Here, we used the Gal4-UAS system to compare overexpression of *Dube3a* in glial and neuronal cells (using the *repo*-Gal4 and *nsyb*-Gal4 drivers respectively) to determine if either manipulation led to spontaneous seizure phenotypes. In an intact tethered fly preparation, we recorded action potentials from the indirect flight muscles (dorsal longitudinal muscles, DLMs). We found recurrent, spontaneous spike discharge in *repo* > *Dube3a* flies ($\bar{x}$ = 2.19 Hz; 0.387 burst freq. min^{-1}) but not *repo* > w^{1118} control flies ($\bar{x}$ = 0.11 Hz; 0 burst freq. min^{-1}). These bursts originated centrally and were correlated between the left and right sides. Furthermore, blocking central excitatory neurotransmission (via the nAChR antagonist Mecamylamine) stopped bursting activity. In contrast, we did not observe spontaneous spike discharges in *nsyb* > *Dube3a* flies. These studies confirm previous work suggesting that glial rather than neuronal overexpression of *Dube3a* is the main contributor to spontaneous seizure activity. The lack of effective treatment options for Dup15q-associated epilepsy presents a hurdle in seizure management. Previous work has identified, Vortioxetine (a 5-HT1A agonist) and Ketanserin (5-HT2A receptor antagonist) as potential treatment options for Dup15q-associated epilepsy. We reared *repo* > *Dub3a* and *repo* > w^{1118} flies with these pharmacological agents (40nM and 400nM) to evaluate their efficacy in treating the seizure phenotype. We found both pharmacological agents were successful in eliminating spontaneous spike discharges in *repo* > *Dube3a* flies. Our findings highlight the potential for glial pathophysiology in underpinning seizures associated Dup15q syndrome.

1822S **Distinct growth property of *Drosophila* primary embryonic neurons derived from hyperexcitable K_v and Na_v channel mutants** Yeo Rang Lee, Jessie Shirley, Cameron Mahanke, Atulya Iyengar Department of Biological Sciences, The University of Alabama

Ion channels play essential roles in action potential propagation and cellular homeostasis in neurons. In *Drosophila*, mutations in genes that encode voltage-gated ion channels can lead to excessive and abnormal neuronal activity. Both loss-of-function mutations in voltage-gated potassium (K_v) channel genes *ether-a-go-go* (*eag*) and *Shaker* (*Sh*) as well as recently-identified gain-of-function mutations in the sole voltage-gated sodium (Na_v) channel gene *paralytic* (*para*) show hyperexcitable phenotypes such as vigorous leg shaking under ether anesthesia and impaired flight. Hyperexcitable K_v channel mutations also affect the growth and maturation of neurons, with primary cultured *eag Sh* neurons displaying elevated branching and growth cone complexity. Although effect of K_v channel mutations on neuronal growth are documented, it is unclear whether hyperexcitable Na_v channel mutants also display similar neuronal development features or if new neuronal growth phenotypes emerge. We undertook longitudinal studies of neuronal morphology comparing embryonic primary neuronal cultures of hyperexcitable Na_v and K_v channel mutants. Consistent with previous reports, we found *eag Sh* K_v double mutant neurons showed enhanced neurite terminal complexity and growth cone size. These phenotypes were exaggerated upon rearing at high temperature (30℃). In contrast, hyperexcitable *para* alleles displayed heterogenous collection of phenotypes. We found the hyperexcitable Na_v mutant, $para^{bss1}$, showed increased neurite terminal complexity while $para^{GEFS+}$ and $para^{Swd}$ did not show this phenotype. Unlike *eag Sh*, at room temperature, none of the Na_v mutants showed changes in growth cone size. However, at high temperature, both $para^{GEFS+}$ and $para^{Swd}$ mutants showed enlarged growth cones while $para^{bss1}$ did not. Together, our results highlight the complex relationship between excitability properties and neuronal development.

1823S **Investigating variability in learning and memory phenotypes using the *Drosophila* Synthetic Population Resource** Victoria Hamlin[1], Elizabeth King[2] [1]Biological Sciences, University of Missouri, [2]University of Missouri

Learning and memory are complex cognitive traits with function impacted by many factors including genomic makeup, environmental factors, and gene-environment interactions. These traits are vital for an organism's survival in an ever-changing environment by allowing for behavioral modifications in response to a stimulus. Within a given population, we see a wide range between individuals' ability to perform different cognitive tasks, however, the mechanisms underlying this variability are still largely unknown. Our goal is to identify the genomic regions contributing to cognitive performance and the effects of genomic variation on synaptic morphology and plasticity in the neural networks involved.

In our work we use a multifaceted approach to identify the important genomic regions contributing to the variability in cognitive traits. Our first approach uses Recombinant Inbred Lines (RILs) from the *Drosophila* Synthetic Population Resource (DSPR), a multiparent population consisting of about 1800 RILs, which provides us with the ability to perform high resolution genome wide scans. Through behavioral phenotyping of the RILs, we can identify genomic regions which significantly contribute to both the mean of a phenotype (mQTL), the residual variance of a phenotype (vQTL), or a combination of the two (mvQTL). Second, we took an evolve and resequence approach to identify changes in allele frequencies in our selected and control population lines. Both approaches used an appetitive olfactory conditioning Y-maze assay in which flies were trained to associate a specific odor with a sugar reward after dietary restriction. So far, we have identified several suggestive QTLs to investigate further to identify potential candidate genes. By linking genotype to phenotype, we will further our insight into the mechanisms of variability within the nervous system leading to a greater understanding of formation, function, and dysfunction of circuits involved in cognitive tasks.

1824S **The conserved microRNAs *miR-34* and *miR-277* regulate proportional growth of the neuromuscular junction in *Drosophila melanogaster* larvae** Mala Misra, Lauren T Maynor, Jackson J Sopa, Hillary P Hwang, Zeeta A Abubakar Biology, Washington College

As organisms grow, neurons maintain innervation of target tissues through proportional growth and elaboration. This scaling growth is regulated by a combination of global hormone signaling and cell-autonomous gene regulation, but our understanding of the interplay between these mechanisms and the genes involved is incomplete. In *Drosophila melanogaster,* the neighboring microRNAs *miR-34* and *miR-277* are part of a negative signaling loop with ecdysone, a circulating hormone linked to growth arrest during the larval-to-pupal transition. We examined the expression and function of these two microRNAs in the regulation of scaling growth of the neuromuscular junction (NMJ) during larval development. Quantitative PCR analysis in whole larvae and in isolated larval central nervous system tissue suggested that expression of *miR-34*, *miR-277*, and primary isoforms containing these microRNAs is higher during growth phases of larval development and drops off during late third instar, when larval growth is suspended at the onset of pupariation. Suppression of *miR-34* and *miR-277* function in motor neurons during larval development disrupts coordination of proportional NMJ growth by causing overgrowth of motor neuron axon terminals and by non-cell autonomously impairing target muscle growth. Our observations suggest that *miR-34* and *miR-277* act as signaling nodes in the regulation of proportional growth at the NMJ.

1825S **Matching transcription factor codes with morphological neuron types by lineage origin, neuron birth order, and spatial transcriptomics** Angelica Previero[1,2], Tzumin Lee[1,2] [1]Molecular, Cellular, and Developmental Biology, University of Michigan, [2]Life Science Institute, University of Michigan

In the brain, distinct neuron types express different combinatorial transcription factors (TF) codes, the identification of which is essential for elucidating the mechanisms of neuronal diversification and specification. While scRNA-seq permits comprehensive discovery of putative TF codes, finding their corresponding neuronal types in the complex brain remains tedious and often unachievable. In the Drosophila brain, which develops through stereotyped neuronal lineages, we conceived a strategy to match neurons' TF codes and morphologies systematically by placing gene expression patterns in the context of cell lineages. To realize this, we explore combining multiplexed smFISH with CLADES, a genetic cascade to label serially derived neurons with a predefined color sequence. I will present the application of this system to the mapping of the combinatorial TF codes for the 50 neuron types serially made by a common neural stem cell in the Drosophila central brain.

1826S **m6A-inhibitory RNA binding protein Nab2 Regulates Lipid Storage and Metabolic Pathways** Jordan Goldy, Anita Corbett, Kenneth H Moberg Emory University

The brain plays a critical role in regulating metabolism by sensing metabolic status and modulating release of metabolic hormones and regulators. This link is evident in clinical data as an elevated risk among individuals with intellectual disability (ID) for metabolic defects, including obesity, abnormally high triglycerides, and elevated blood sugar. One group of heritable forms of ID are caused by mutations in genes encoding RNA binding proteins (RBPs), which control RNA 5'-capping and polyadenylation, splicing, nuclear export, localization, and turnover. In some cases, RBPs with important and conserved roles in development of the central nervous system (CNS) also modulate metabolic status of distant organs, consistent with regulation of neuronal RNAs encoding secreted factors that modulate systemic metabolism. Notably, loss of function mutations in the RBP *ZC3H14* are linked to a form of non-syndromic, autosomal recessive human intellectual disability. Studies of the ZC3H14 ortholog Nab2 in *D. melanogaster* show that loss of Nab2 results in behavioral impairments, short-term memory deficits, reduced survival, altered brain morphology and increases in steady-state levels of various transcripts. Previous studies reveal a role for Nab2 in modulating the levels of N^6-methyladenosine(m^6A) deposition by Mettl3, the catalytic component of m^6A methyltransferase complex, on specific mRNAs. RNA-seq data indicate that two transcripts altered in *Nab2* null females are the insulin-like peptides *dilp2* and *dilp5*, which regulate systemic *Drosophila* metabolism and lipid storage. dIlp2 and dilp5 are synthesized in IPCs (insulin-producing cells), analogs of pancreatic beta cells in humans, and signal to cells in the fat body (FB) to promote lipid storage. Consistent with female-specific *dilp2/dilp5* data, preliminary analysis of *Nab2* null 3rd instar larvae reveals increased size of lipid droplets in female FBs, arguing that Nab2 is a female-specific inhibitor of lipid storage by virtue of its role in a brain-FB adipose storage circuit. Interestingly, a loss of Mettl3 in females results in an increase in *dilp2* transcript levels and increased average lipid droplet size comparable to the *Nab2* null females. Thus, we hypothesize that Nab2 regulates mRNA transcripts critical for proper metabolic function and lipid storage. We will discuss this evidence and present data on the mechanistic basis for this metabolic phenotype in *Nab2* null females.

1827S **Disruption in calcium conductance of cacophony channels alters VGCC abundance and retention at active zones** Chhavi Sood[1], Karen L Cunningham[2], Hannah B Hicks[2], J. Troy Littleton[1] [1]Picower Institute of Learning and Memory, Massachusetts Institute of Technology, [2]Massachusetts Institute of Technology

Active zones (AZ) are specialized presynaptic sites where voltage-gated calcium channels (VGCCs) mediate Ca^{2+} influx to trigger synaptic vesicle (SV) fusion and neurotransmitter release. A major determinant of SV release probability (P_r) and presynaptic output is the amount of presynaptic Ca^{2+} influx, which is correlated with the abundance of VGCCs at release sties. To better understand how VGCCs traffic, accumulate and recycle at AZs, we are using the *Drosophila* neuromuscular junction to characterize how the abundance of Cacophony (Cac), the sole AZ-localized VGCC in *Drosophila*, is set and regulated at individual release sites. We found that AZs accumulate Cac to a capped upper limit during AZ maturation, in contrast to the core AZ scaffold Bruchpilot (BRP), whose AZ abundance increases given extended developmental time. During larval development, Cac abundance varies across the AZ population and correlates with AZ size and synaptic output, and its delivery is rate-limited by the accessory subunit α2δ. Using photoconvertible mMaple-tagged endogenous Cac, we observed individual channels are largely confined to single AZs and their turnover is promoted by delivery of new Cac, which sets an upper limit on AZ Cac accumulation. In vitro studies in other models have suggested Ca^{2+} conductance properties may regulate VGCC trafficking and synaptic abundance, however, whether channel conductance also regulates in vivo trafficking and synaptic abundance of VGCCs is less clear. To assay if alterations in Ca^{2+} conductance provides additional layers of control for Cac abundance and turnover at AZs in vivo, we generated GFP and mMaple-tagged Cac conductance mutants (cac^{F} and cac^{NT27}) to compare their AZ dynamics to wildtype channels. We found that heterozygotes and homozygotes of *cac* conductance mutants showed increase in AZ abundance of both the mutant and wildtype channels. Furthermore, there was a concomitant increase in AZ area and abundance of BRP in the *cac* conductance mutants compared to wildtype. Ongoing studies will examine whether alterations in AZ abundance of Cac in the *cac* conductance mutants are due to disruptions in synaptic delivery, AZ retention and/or recycling of Cac during synaptic development and AZ maturation.

1828S **A conserved gene network enables decisions by regulating the distribution of an excitatory receptor** Kexin Zhang[1], Ornella P T Meko[2], Mandy Wong[2], Claudia M Mizutani[1], Rui Sousa-Neves[2] [1]Biology, Case Western Reserve University, [2]Genetics and Genome Sciences, Case Western Reserve University School of Medicine

Decisions plays a fundamental role for the survival of animals but little is known about the mechanisms that generate them. Previously we showed that the transcription factor DATILÓGRAFO (DATI) is required in cholinergic neurons in three brain regions of Drosophila females for the decision to accept courting males. Recently, we identified computationally the gene network regulated by DATI and validated several genes for their requirement in female acceptance using RNAi knockdown in cholinergic neurons. Among these genes, we find the receptor anchor CORACLE (CORA), the excitatory acetylcholine receptor nAChRa6, the translational repressor Bruno 3 (Bru3), and the regulator of transcription and RNA degradation, CG1677, here renamed *dati switch* (*ditch*). Here we tested if CORA and/or Bru3 are required for the localization of nAChRa6 in cholinergic neurons. We analyzed the expression patterns of nAChRa6 using 3D hotspots analyses and depth maps that provide 3D distribution statistics. Our data shows that CORA does not anchor nAChRa6 but it limits the access of this excitatory receptor to certain regions of dendritic neuropiles in the antennal lobe. Like CORA, Bru3 also limits the distribution of nAChRa6, suggesting that Bru3 and CORA are both part of a mechanism that prevents the expression of this excitatory receptor in specific regions of the antennal lobe and thus prevent the possibility of generating abnormal excitation. Finally, we show that DITCH is frequently found colocalized with Bru3 in the dendritic neuropile, suggesting an association between RNA repression and degradation. Together, these data identify conserved genes involved in decision making and show that they are part of a mechanisms that enables the allocation of receptors within neurons.

1829S **Defining Locomotor Deficits in KDM5 Loss of Function Mutants** Aubrey Siebels[1], Bethany Terry[2], Matanel Yheskel[2], Julie Secombe[2] [1]Neuroscience, Albert Einstein College of Medicine, [2]Genetics, Albert Einstein College of Medicine

The lysine demethylase 5 (*KDM5*) family of histone demethylases are crucial regulators of transcription. Loss of function mutations in the genes encoding the *KDM5* family of transcriptional regulators are associated with neurodevelopmental disorders. Among the observed missense mutations in the *KDM5* family, mutations in the *KDM5C* gene are among the best described. In the largest caregiver-reported questionnaire on the symptoms of patients with *KDM5C* variants, 87% and 81% of patients exhibit fine and gross motor delays, respectively. Drosophila offer an excellent opportunity to investigate the consequences and mechanisms of this phenomenon because they encode a single *KDM5* gene that likely reflects functions of all mammalian paralogs. It is unclear which components of locomotion planning and execution may be affected by *KDM5* mutations. To address this open question, we will begin by investigating the effects of cell-type specific KDM5 knock-down on Drosophila locomotion. Although the exact role of the *KDM5* family is not fully understood, it is increasingly evident that demethylase-independent functions of KDM5 may also play an important role in determining what genes are transcribed. We have developed a suite of *Drosophila* lines that carry missense mutations in different domains on the orthologous *KDM5* gene, some mutants have disrupted demethylase function, and some have intact demethylase domains. We will also examine variations in locomotion across these missense mutation strains to parse out the domains of *KDM5* that may be required for normal locomotor planning and execution. Establishing the nuances in locomotor functionality across the various missense mutation lines, serves as a crucial step into and we intend to expand into examining which domains and

functions of KDM5 may contribute to the motor delays seen in *KDM5C* variant patients.

[JS1]I would have this as a separate sentence, and perhaps start with the fact that the phenotypes associated with X-linked KDM5C are the best described (or something) … with 87/81% etc…

1830S **Effects of a Differential Overexpression of the Vesicular Acetylcholine Transporter on Synaptic Activity and Behavior in *Drosophila melanogaster*** Katarzyna D Rosikon, Benjamin D Church, Hakeem Lawal Delaware State University

Impairment in cholinergic neurotransmission is associated with normal and pathological aging, making cholinergic release a subject of sustained interest. However, the precise role of changes in central acetylcholine (ACh) release in mediating behaviors that range from locomotion to cognition has not been fully elucidated. The vesicular acetylcholine transporter (VAChT) is present in many species, including worms, flies, and humans, and is responsible for the packaging of ACh for exocytotic release. Although there is a plethora of knowledge about the molecular machinery that regulates ACh, the exact manner in which VAChT, an essential component of ACh regulation, alters ACh-linked neuronal function remains a subject of active investigation. Here, we use the overexpression of VAChT as a tool to increase the amount of ACh released into the synaptic cleft. And we are measuring the effect of that altered state on synaptic activity using two key behavioral circuits, locomotion and cognition. Previously, we showed that vast increases in VAChT expression cause severe behavioral deficits, including a sharp decline in lifespan. Our current study is focused on testing the hypothesis that more moderate increases in VAChT expression will not only lead to less severe effects but also beneficial ones. To test this idea, we used four VAChT overexpressing lines with varying levels of increased expression. We report the intriguing results that while strong increases in VAChT produced a corresponding decrease in lifespan, a less drastic overexpression of the protein led to a less steep decline in lifespan. Moreover, we show that in agreement with our previous published findings, our preliminary data show that VAChT overexpression caused an age-dependent decrease in locomotion ability in all lines tested. Further, immunohistochemical analysis showed that at least one VAChT overexpressor showed a strong increase in localization of the protein to punctate in the optic lobe, indicative of increased presence in synaptic vesicles. Taken together, these data indicate that morphological and behavioral effects of VAChT overexpression are driven by the levels of the protein's expression and inform further studies to be aimed at identifying precisely which dial in VAChT expression could lead to a beneficial effect on synaptic neurotransmission.

1831S **Effect of larval diet on adult feeding preference in *Drosophila Melanogaster*** Vaibhav D Menon[1], Christopher Creighton[1], Mayra Vazquez-Muñoz[2], Anupama A Dahanukar[1,3] [1]Neuroscience Graduate Program, University of California, Riverside, [2]Division of Biomedical Sciences, University of California, Riverside, [3]Department of Molecular, Cell and Systems Biology, University of California, Riverside

An animal's ability to taste is critical, underlying its selection for food sources that fulfill energetic and physiological needs, as well as rejection of potentially toxic substances. While the role of innate taste perception is well established, it is becoming increasingly clear that factors such as environment and internal state can influence taste-mediated behavioral outcomes. Yet, exposure to taste cues early in life remains a subject of limited analysis. We present a model for evaluating the role of larval taste input on adult feeding preference in *Drosophila melanogaster*. Our preliminary analysis identifies a pathway through which chemosensory stimuli elicit long-term modifications to feeding behaviors via exposure during a critical developmental period. We find that dietary exposure of larvae to known aversive taste compounds attenuates feeding avoidance of those same compounds in adult flies. The behavioral modification is specific in that it occurs with some compounds and not others, and selective in that its feeding preferences for other tastants, including closely related ones, are not affected. Notably, experience-dependent attenuation of feeding avoidance persists well into adulthood. Interestingly, proboscis extension responses show parallel changes, raising the possibility that developmental dietary experience with certain bitter tastants may impact the function of taste sensory function or circuits in a way that selectively reduces avoidance of those tastants. To understand developmental exposure-induced changes in bitter taste, we are taking a two-pronged approach by testing mutants of chemosensory genes that mediate bitter neuron activation and sweet neuron inhibition, and identifying chemosensory genes that are differentially expressed under naïve and tastant-exposed conditions. We find that bitter neuron activation and sweet neuron inhibition are both required to elicit experience-dependent changes to feeding preference. We are also investigating the role of long-term memory in shifting feeding behavior outcomes, using flies lacking neuronal activity in various mushroom body neuron populations. Together, our findings suggest a role for the gustatory system in eliciting persistent, robust changes in feeding behavior across metamorphosis and point towards a putative critical period for shaping taste preferences.

1832S **The DATI Neuroprocessor Enables Mating Decisions in *Drosophila* Female Through a Molecular and Cellular Mechanism that Eliminates Competing Behaviors** Mandy Wong[1], Ornella P T Meko[1], Kexin Zhang[2], Megan L Miller[1], Claudia M Mizutani[2], Rui Sousa-Neves[1] [1]Genetics and Genome Sciences, Case Western Reserve University School of Medicine, [2]Biology, Case Western Reserve University

Previously we identified DATILÓGRAFO (DATI) and showed that this transcription factor is required for decision of accepting male courtship in cholinergic neurons in three regions of *Drosophila* female brain. More recently, we screened the *Drosophila* and human genomes for genes containing DATI binding sites and found that 89% of the genes found in Drosophila are also present in the human genome. A systematic validation with RNAi interference in cholinergic neurons of 10% of these genes identified 12 novel genes involved in decision making. Remarkably, 41% of the genes validated either interact physically with the Amyloid Precursor Protein implicated in familial Alzheimer's Disease (AD), or are themselves candidates of other forms of AD, a disease characterized by memory loss, and decision-making deficits.

This validated blueprint equips neurons with the genes required to make decisions which we here refer to as the DATI neuroprocessor. This neuroprocessor contains two excitatory receptors (nAchRα6, nAchRα7), two inhibitory receptors (GluClα, Dop2R), a receptor anchor (CORA) and a low voltage calcium channel (Ca-α1T). Noteworthy, the loss of either the excitatory receptors that generate current or the inhibitory receptors that interrupt current results in rejection. It is then evident that these receptors excite and inhibit different parts of the neurons, working together to produce acceptance. Using 3D spatial analyses with spatial statistics, we show that these receptors have different localizations, and that CORA regulates the localization of nAchRα7, GluClα and Dop2R. In addition, we show that Ca-α1T is needed to secrete glutamate in the same cholinergic neurons that receive glutamate. This glutamate binds to GluClα, causing inhibition. Thus, the picture that emerges from these experiments is these are auto-inhibitory cholinergic neurons with an excitatory path that leads to acceptance and a separate path where signal must be blocked by an inhibition in order to prevent rejection from occurring. When uninterrupted, this separate pathway leads to signal loss through ShakB electrical synapses to neurons that process information about food. With this knowledge, we designed experiments that generate abnormal but predictable decisions and the results validated our arrangement of this neuroprocessor. Finally, we found that the Amyloid Precursor protein of *Drosophila*, Appl, not only interacts with proteins in this circuit but also is also required to make these decisions in this circuit. These findings reveal a conserved mechanism of decision making with direct relevance to our understanding of AD.

1833S **Dissecting the transcriptional networks driven by the Fra/DCC intracellular domain** Camila M Barrios-Camacho, Greg J Bashaw Neuroscience, University of Pennsylvania

Midline circuit assembly relies on the temporally- and spatially- regulated expression of axon guidance receptors. In *Drosophila*, the Frazzled receptor promotes midline crossing through netrin-dependent and netrin-independent mechanisms. In the former, commissural axons respond to Fra's chemoattractive ligand Netrin to project towards the midline. In the latter, γ-secretase cleaves the Fra intracellular domain (ICD), allowing it to translocate to the nucleus and induce the expression of *commisureless* (*comm*). *Comm* desensitizes crossing axons to the midline repellant Slit by inhibiting the trafficking of its Robo receptor to the plasma membrane. Once neurons have crossed, *comm* expression is down-regulated and sensitivity to repellants is re-established, thus facilitating commissural axon exit from the midline and simultaneously preventing their re-crossing. It is unknown if this *in vivo* transcriptional output of Fra is conserved in the human homolog, DCC, despite evidence that the ICD of Fra's vertebrate orthologs, Neogenin and DCC, also undergo γ-secretase-mediated cleavage and enter the nucleus to regulate transcription *in vitro.*

The P3 domain of the ICD functions as a transcriptional activation domain and in *Drosophila*, specific point mutations within this region render the receptor transcriptionally inactive, unable to induce *comm* expression. However, it is not known whether the role of these residues are conserved in the DCC-ICD. To test this, we generated various HA-tagged DCC-ICD mutant plasmids: 1) an ICD over expressor (ICD-OE) 2) a point mutant L1433A 3) a point mutant Q1426A 4) a dual point mutant L1433A/Q1426A, 5) a ΔP3 domain mutant and 6) an HA-tag negative control. With these plasmids, we generated stably transfected HEK293 cell lines and subjected these to bulk-RNA sequencing. Bioinformatic analyses show that transcriptomes of the ICD mutants are equivalent to that of the HA-tag negative control; however, over-expression of the wild-type ICD induces a distinct transcriptomic profile. We apply network topology approaches to this transcriptomic profile and identify mechanistically testable candidates. We are currently evaluating the expression patterns of these candidates and testing their roles in midline crossing.

1834S **Investigating the role of *NLGN3* in autism spectrum disorder and sleep disruptions** Rebekah Townsley[1,2], Jonathan Andrews[1,2], Sharayu Jangam[1,2], Michael Wangler[1,2] [1]Molecular & Human Genetics, Baylor College of Medicine, [2]Dan & Jan Neurological Research Institute, Texas Children's Hospital

Autism spectrum disorder (ASD) is a common neurodevelopmental disorder that is highly comorbid with sleep disorders; however, the etiology of this co-occurrence is unknown. Recently, variants in the *Neuroligin* (*NLGN*) gene family have been identified in patients with both ASD and sleep disorders. NLGNs (NLGN1-5) are a family of postsynaptic cell adhesion molecules that interact with their presynaptic partner, Neurexins (NRXNs), to regulate synapse formation and maturation. They also indirectly recruit GABAergic and glutamatergic receptors to the postsynaptic membrane to establish the mature

neuron. *NLGN* members have unique expression patterns at either GABAergic or glutamatergic synapses; however, only *NLGN3* is expressed in both. We hypothesize that *NLGN3* variants impact GABA and glutamate activity resulting in ASD phenotypes and sleep disturbances. It is well known that the loss of *Nlg3*, the *Drosophila* homolog of human *NLGN3*, results in viable flies that have reduced locomotor activity; however, its effect on sleep and circadian rhythm is still unknown. We generated three *Nlg3* mutant alleles and found that two of the mutant lines exhibited a reduction in locomotor activity under a light/dark cycle. Furthermore, these same mutant flies also showed a decrease in the number of inactive periods and the periods of inactivity were longer compared to controls. Expression analysis also revealed that *Nlg3* is primarily colocalized to neurons and not to glia. Since human *NLGN3* variants have been reported to be associated with ASD and/or sleep disorders, we also functionally assessed these variants in the *Drosophila* model by generating transgenic flies expressing the human reference and variant cDNA. Leveraging the UAS-GAL4 system, we found that overexpressing either the human reference or variant cDNA did not cause any gross toxicity and the mendelian ratio was consistent for both males and females. Furthermore, the human reference and variant was unable to rescue the loss-of-function phenotypes. For future directions, we will be assessing the morphology and physiology of the neuromuscular junction. Our goal is to provide a functional link between ASD and sleep disturbances in order to identify potential therapeutic approaches to lessen the impact of sleep abnormalities in individuals with ASD.

1835S **Expression Analysis of cell-type-specific split-GAL4 lines in developing Drosophila visual system** Angelina Fordjour[1], David Chen[2], Claude Desplan[1] [1]Biology, New York Univeristy, [2]Biology, New York University

The identification and characterization of neuronal cell types in the optic lobe of Drosophila melanogaster is significant for unraveling visual processing mechanisms, with a potential understanding of similar processes in humans. There are over 200 different neuronal cell types within the fruit fly's visual circuit. To understand individual neuronal function and development, the generation of cell-type-specific genetic tools for labeling neurons is an essential first step. Prior studies utilized active enhancer-GAL4 lines to label diverse cell types. However, the limited specificity of the tool prompted the development of an innovative approach. The split-GAL4 lines take advantage of the intersectionality of the cells to refine the cell-type-specific expression; however, these enhancer-based split-GAL4 lines require time and resources to screen all the different enhancer patterns. In this study, we utilize the single-cell RNA sequencing (scRNAseq) of all the individual cells in the optic lobe at different developmental stages to select gene pairs for the generation of gene-specific split-GAL4 lines. This novel technique shows effective labeling of both known and previously unidentified cell types within the Drosophila visual system. I evaluated the effectiveness of this technique by testing two distinct split-GAL4 lines targeting different cell types, guided by data derived from the developmental scRNAseq dataset. One split-GAL4 line tested was bi-DBD + Rx-AD, which is predicted to label cluster LC14. Another line tested was CG9896-DBD + Dop1R2-AD predictably labeled cluster 45, which is an unannotated cell type. The result of the studies showed that bi-DBD+ Rx-AD does label LC14 at three different stages tested. CG9896-DBD + Dop1R2-AD labels a TmY-like neuron from early pupal stage to adult. Our study showed the promise of cell-type-specific tools to effectively label established cell clusters but also unveiled the identity of unannotated clusters. This breakthrough methodology thus paves new ways for investigating the heterogeneous cell types within the optic lobe and providing further understanding of the visual system and its functioning. In the upcoming semester, I plan to create more Split-Gal4 lines and use MCFO and GFP staining to not only observe cell types in adult flies but also track their development across different stages of fly growth. We will be analyzing our data using confocal microscopy to assess the morphology and location of the neurons that are expressed with each generated split-Gal4 line.

1836S **Structure-function of *Drosophila* Robo3 using CRISPR gene replacement** Ayawovi Selom Ametepe[1], Abigail Carranza[1,2], Timothy Evans[1] [1]Department of Biological Sciences, University of Arkansas, [2]Texas A&M University School of Medicine

At the midline of bilaterians, multiple decisions involve neuronal extensions called axons. They are capable to sense chemical cues through transmembrane proteins named axon guidance receptors. One of the key components of axon guidance is the Roundabout (Robo) family. They are found in many animal groups, including insects and vertebrates, and they regulate many important axon guidance decisions. In Drosophila, there are three Robo receptors: Robo1, Robo2 and Robo3; all of them bind to a common ligand, Slit. The repellent ligand Slit, and its receptors regulate midline crossing of axons during development of the embryonic central nervous system (CNS). And each receptor plays a specialized role during development of the embryonic CNS Drosophila Robo3 has 5 immunoglobulin (Ig), 3 fibronectin type III repeats and 2cytoplasmic motifs. It is expressed in the lateral-most two thirds of the embryonic ventral nerve cord. It has been proposed that Robo3 regulates axon pathway formation in response to Slit, perhaps by conferring sensitivity to a Slit gradient emanating from the midline, but this hypothesis has not been directly tested. It is also unknown which other domains within the Robo3 receptor, if any, are required for its role in intermediate pathway formation. To determine which structural domains within the Robo3 receptor are required for its role in intermediate pathway formation, we used a CRISPR/Cas9-based approach to replace the robo3 gene with modified versions in which individual domains have been deleted. We generated variants of the Robo3 in which the N-terminal

Ig1 domain and Ig4 are deleted: we constructed CRISPR donor plasmids and a corresponding guide RNA plasmid to target the robo3 gene and replace it with our domain deletion variants. Drosophila flies expressing Cas9 were injected with the gRNA plasmid and robo3 variant donors, and we recovered the modified alleles by screening the injected flies' progeny via PCR. We observed that intermediate pathways failed to form properly in the variants lacking Ig1 and Ig4. This shows that Ig1 and Ig4 are required for proper localization of the Robo3 protein. We also found that in both knock-in allele that expression is not only limited to the two third lateral as it appears in the homozygote embryos and full length Robo3 protein, rather it is spread all over the axonal pathway. We further notice an abondance of HA tagged Robo3 lacking Ig1 and Ig4 respectively in neuronal cell bodies. This suggests that Robo3 Immunoglobulin domain Ig1 and 4 are essential for axonal localization of the Robo protein. We finally showed that Slit binds robustly to cells expressing full length Robo3 but does not bind to variants lacking Ig1. This suggests that Ig1 is required for Slit binding.

1837S **Multiple glial subtypes interact and compensate for the loss of nearby glial function** Gabby Salazar[1], Allison N Beachum[2], Kevin Krause[1], Amelia Nachbar[1], Hannah Klose[1], Hayes Miller[1], Jaeda Coutinho-Budd[2] [1]University of Virginia, [2]Neuroscience, University of Virginia

Glia not only form close associations with neurons throughout the CNS, but they also interact closely with each other. As these cells mature, they undergo glial tiling to neighbor one another without invading each other's boundaries. While glial tiling is a common phenomenon in the animal kingdom, little is known about the interactions that lead to and maintain this process. Through an RNAi-based screen in *Drosophila*, we discovered that the loss of the secreted neurotrophin Spätzle 3 (Spz3) resulted in the transformation of cortex glia from a lace-like morphology that surrounds neuronal somas, to globular cells that lose the ability to ensheath these neurons. Our previous research revealed that the loss of Spz3 in cortex glia led to astrocytic processes infiltrating the cortex beginning in late larval stages. More recently, we observed similar outgrowth in other glial subtypes, such as ensheathing glia and subperineurial glia (SPG). Our developmental analysis demonstrated that cortex glia are initially established correctly, and only begin to exhibit altered morphology in late larval stages. Surprisingly, restricting animal growth prevented both cortex glial disruption and infiltration from other glial cell types even with the loss of Spz3, suggesting that this infiltration is not simply due to reduced Spz3 signaling but also the loss of cortex glial function as the CNS grows. We hypothesize that this aberrant infiltration is a compensatory mechanism of other glial subtypes for glial roles, such as clearing neuronal corpses throughout development. We therefore blocked engulfment in neighboring glia by reducing the engulfment receptor Draper in each subtype, and showed that astrocytes, ensheathing glia, and SPG contribute to the encapsulation and degradation of neuronal debris in the absence of functional cortex glia. Our data also demonstrate that peripheral phagocytes, such as macrophages, can infiltrate the CNS in these mutants. Remarkably, our findings suggest that even when astrocytes, ensheathing glia, and SPG divert their cellular resources from their normal positions, they are still capable of performing their usual functions. This work illustrates that when one glial subtype is disrupted and unable to perform its functions, surrounding healthy glia infiltrate beyond their natural barriers and perform compensatory actions alongside their normal functions to maintain CNS homeostasis.

1838S **Dissecting the Causal Role of Insomnia in Cardiovascular Disease** Torrey RP Mandigo[1], Farah Abou Daya[2], Suraj Math[3], Dev Patel[2], Lily Ober[2], Matt Maher[3], Girish Melkani[2], Richa Saxena[3], James Walker[3] [1]Center for Genomic Medicine, Massachusetts General Hospital, [2]University of Alabama at Birmingham, [3]Center for Genomic Medicine, Massachusetts General Hospital/Harvard University

Insomnia disorder occurs in 10-20% of the population and is an important risk factor for incident cardiovascular disease (CVD) conferring a >2-fold increased causal risk of incident. However, the underlying pathways and mechanisms linking the two remain poorly understood. We utilized the recent advances in large-scale sleep GWAS to identify human genes on haplotypes associated with insomnia and other sleep traits. From these candidate loci, we prioritized those with only one or two genes located within the haplotype and/or, with prior evidence of links to CVD, coronary artery disease (CAD), or cardiometabolic disease (CMD). After identifying *Drosophila* orthologs of these candidate genes, we used RNAi to knock down the expression of each ortholog in neurons to assess their cell-autonomous effects on sleep. Since mendelian randomization studies in humans have found insomnia symptoms causally contribute to CAD, we also looked at cell non-autonomous effects of neuronal KD on cardiac function and heart KD on sleep. These cell non-autonomous experiments highlight various pathways that are essential for the functions of both tissues as well as potential pathways conferring cell non-autonomous regulation of sleep and cardiac function, providing a shortlist of therapeutically relevant genes and pathways that link insomnia, sleep and CVD.

1839S **Postnatal normalization of *Dyrk1a* in a mouse model of Down syndrome impacts adult behavior and cognition** Elysabeth Otte[1], Drew Folz[1], Nicole Gordon[1], Charles R Goodlett[2], Randall J Roper[1] [1]Biology, Indiana University-Purdue University Indianapolis, [2]Psychology, Indiana University-Purdue University Indianapolis

Down syndrome (DS) is the most common genetic cause of cognitive disability, affecting approximately 1 in 700 individuals. DS is caused by the triplication of human chromosome 21 (Hsa21), leading to the overexpression of over 200 protein-coding

genes, including dual-specificity-tyrosine-phosphorylation-regulated kinase 1A (*DYRK1A*). *DYRK1A* catalyzes phosphorylation on serine/threonine and tyrosine residues and plays a role in cellular proliferation and neural development. Studies have linked *DYRK1A* to the cognitive deficits seen in individuals with DS, and further understanding the role of *DYRK1A* in cognitive development and functioning is crucial to understanding this disorder. We hypothesize that normalization of *Dyrk1a* beginning at postnatal day 0 (P0) will alleviate cognitive and motor deficits in a mouse model of DS. Using a DS mouse model with a temporally-activated *Dyrk1a* normalization, we are able to study the effects of disomic *Dyrk1a* expression in an otherwise trisomic animal. We tested these mice at P45 in a battery of behavioral analyses, including locomotion, gait, balance beam, and Morris Water Maze (MWM) to examine behavioral and cognitive function. Preliminary analyses indicate a significant increase in activity levels in female trisomic animals, and that trisomic females with two copies of *Dyrk1a* decreases this hyperactivity, but not to euploid levels. Male trisomic animals with a *Dyrk1a* normalization have similar activity patterns to those seen in euploid animals. Preliminary data show an increased step angle and slightly decreased total step distance in animals with normalized *Dyrk1a* levels when compared to euploid controls. Initial analysis of spatial learning and memory abilities of these animals show increased latency to locate visible platforms in trisomic females, and that trisomic females with two copies of *Dyrk1a* have latency values more closely resembling euploid counterparts. Normalization of *Dyrk1a* in an otherwise trisomic model seems to directly impact behavior associated with cognition and movement in a mouse model of DS, but does not rescue all deficits seen in trisomic animals. These data suggest that triplicated *Dyrk1a* may act in conjunction with other genes in the development of cognitive deficits in DS.

1840S **Expression Characterization of a Putative Novel Neuropeptide** Vicki J Wong, Jenny Chen, Sean Eddy Department of Molecular and Cellular Biology, Harvard University

Neuropeptides are signaling molecules that play a key role in the regulation of both behavioral and physiological processes, and it is believed that more neuropeptides remain to be discovered. We implemented a computational screen to discover putative novel neuropeptides and identified one gene that appears to be expressed and secreted in the brain. To understand the functional significance of this gene, we compiled and analyzed terabytes of publicly available RNA-sequencing data, with a focus on development and reproduction. The analysis sought to investigate expression patterns across species and pinpoint conditions associated with unregulated expression. To streamline these processes, an automated pipeline was developed, encompassing data scraping, read alignment, and expression calculation. We find this gene is expressed across vertebrates, specifically in the hypothalamus and pituitary. To experimentally validate these computational predictions, we plan to create knockout mouse models to understand the physiological consequences of its absence.

1841S **Antennal RNAseq reveals candidate genes associated with host preference in the Northern house mosquito *Culex pipiens*** Theresa N Menna, Katherine Bell, Anna Noreuil, Megan L Fritz University of Maryland

Culex pipiens, the Northern house mosquito, is the primary vector for West Nile virus (WNv) in North America. Its two distinct bioforms, *Cx. p. pipiens* and *molestus*, have divergent host preferences—*pipiens* prefers avian hosts, while *molestus* prefers mammals. However, hybrid offspring display indiscriminate host choice. Host preference dynamics crucially impact transmission rates for many vector-borne diseases, so it is therefore critical to identify the genetic underpinnings of this trait in *Culex*. In this study, we used a host landing assay to phenotype individual host-seeking females from three field-isolated strains of *pipiens* and *molestus* by their host preference. We then dissected and pooled antennae by phenotype for RNA sequencing in order to observe differences between human- and chick-seeking antennal transcriptomes. Our differential expression analysis focused on four chemosensory gene families recently annotated for *Culex*, known to play important roles in olfaction: odorant-binding proteins (OBPs), odorant receptors (ORs), ionotropic receptors (IRs), and gustatory receptors (GRs). Through comparative analyses between the antennal transcriptomes of human- and chick-seeking pools of *Culex*, we have identified 59 strong candidate genes associated with host preference, across 3 gene families known to detect host-specific odors. IRs from the understudied IR20a clade were strongly represented among differentially expressed chemosensory genes, indicating a promising avenue for future research. These results contribute to a deeper understanding of host preference genomics in *Culex* and lay the groundwork for future functional studies, moving us closer to improved vector surveillance for WNv in North America.

1842S **Paternal inheritance of SLC52A1 Gene Mutation in the infant presenting with developmental delay: a case report** Ah Yeon Lee[1], Hye Jung Park[1], Junghyeon Park[1], Myungshin Kim[2], Hoon Seok Kim[2], Joo Hyun Park[1] [1]Department of Rehabilitation Medicine, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, [2]Department of Clinical Laboratory Medicine, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea

Introduction

Riboflavin, also known as vitamin B2, plays a critical role in the metabolism of various substances, such as fatty acids and

amino acids, serving as major energy sources. The body does not produce riboflavin, so any deficiency in its absorption can lead to pathological conditions. In severe cases, like riboflavin transporter deficiency (RTD), it can result in progressive neurodegeneration. RTD is associated with mutations in the SLC52A1 to SCL52A3 genes, each encoding a riboflavin transporter (RFVT1 to 3), leading to three different types of RTD (RTD 1 to RTD 3). While RTD2 and RTD3 are well-documented, RTD1 and mutations of the SLC52A1 gene are less common. Most cases are related to maternal inheritance due to the significant presence of RFVT1 in the placenta, affecting fetal riboflavin absorption.

Case Report

A 25-month-old male was born at term via cesarean section with a birth weight of 3600g following in vitro fertilization. At 15 months, he was referred to our rehabilitation medicine department due to developmental delay, despite no family history of developmental delay in naturally conceived siblings. Bayley-III Scales assessments at 15 and 25 months showed severe delays in all areas. An 18-month brain MRI revealed chronic periventricular leukomalacia, unmyelinated white matter, and thinning of the corpus callosum. Diffusion tensor tractography indicated that bilateral corticospinal tracts and the corticopontocerebellar tract from the left cortex to the right cerebellum couldn't be traced, explaining his severe gross motor delay and hypotonia. Genetic evaluation, including chromosomal analysis, chromosomal microarray analysis (CMA), and targeted next-generation sequencing (NGS), detected an SLC52A1 gene (c.1164_1165del) mutation. Since the mutation was of uncertain significance and RTD1 is less understood, segregation analysis was performed, identifying the same mutation in the asymptomatic father. This is intriguing as maternal inheritance is typically associated with RTD1 due to RFVT1 dominance in the placenta. Although the patient's symptoms do not align with typical RTD cases, his muscle tone reduction and impaired cognitive function may be related to a neuronal generation defect. As a result, the patient was referred to another clinic for further evaluation of riboflavin deficiency and potential treatment.

Conclusion

We presented a case of paternal inheritance of an SLC52A1 gene mutation in a patient with severe developmental delay, along with an asymptomatic father carrying the same mutation. While most RTD1 cases are associated with maternal inheritance, our case suggests that the paternal inheritance of the mutation itself may be the cause of developmental delay. However, given the limited knowledge about RTD1 and the SLC52A1 gene, further research is needed to fully understand this case.

Examining the role of *cadherin 16* (*cdh16*) in the establishment of sensory thresholds Susannah S Schloss, Zackary Q Marshall, Nicholas J Santistevan, Jessica C Nelson Cell and Developmental Biology, University of Colorado Denver

An organism's ability to appropriately respond to environmental stimuli hinges on a precise combination of genetic and molecular factors that influence early neurodevelopmental processes. In particular, sensory thresholds, which dictate the level of stimulus required to elicit an animal's response, whether visual, auditory, or otherwise, are established during development. To explore sensory thresholds and their underlying genetic and circuit mechanisms, we use the acoustic startle response in larval zebrafish. Through a forward genetic screen, we identified a gene called *cadherin 16* (*cdh16*) as an important regulator of acoustic sensory thresholds and threshold plasticity through habituation. How *cdh16*, which encodes an atypical cadherin, exerts these functions is not yet known. To examine this question, we first assessed *cdh16* expression in the brain via *in situ* hybridization chain reaction. Next, we created a heat shock transgenic construct to test if ubiquitous expression of *cdh16* in mutant animals would rescue their sensitivity and habituation phenotypes. We found continuous expression of *cdh16* later in development, when the acoustic startle has been established, was sufficient to induce wild-type levels of responsiveness in mutants. Finally, we hypothesized based on a previous study that *cdh16* expression might be regulated by Wnt signaling, leading us to investigate the effects of pharmaceutical agonists and antagonists of Wnt-signaling on acoustic startle thresholds and habituation. We discovered that a Wnt agonist, XV, causes decreased sensitivity to acoustic stimuli, but has no impact on sensory thresholds in *cdh16* mutants. These data are consistent with *cdh16* functioning downstream of Wnt in the establishment and plasticity of sensory thresholds.

1844S **Identifying molecular targets of CHD7 that mediate CHARGE syndrome phenotypes in a zebrafish mode** Melody Hancock[1], Dana Hodorovich[2], Rachael Bieler[1], Chris Cole[1], Kurt Marsden[1] [1]North Carolina State University, [2]National Institute of Environmental Health Sciences

CHARGE syndrome is a developmental disorder that affects 1 in every 10,000 births, and patients exhibit ear, eye, craniofacial abnormalities, and behavioral characteristics that include autistic-like behaviors, intellectual disabilities, and sensory

disorders. A de novo mutation in CHD7 (chromodomain helicase DNA binding protein 7) causes 70% of CHARGE syndrome cases. The Chd7 protein is a chromatin remodeler and has thousands of predicted binding sites in the genome. Our lab created a zebrafish model of CHARGE syndrome with a CRISPR/Cas9-induced 7 bp frameshift mutation in exon 9. This model recapitulates CHARGE-like phenotypes including craniofacial defects, ear defects, cardiac defects, and defects in both acoustically- and visually-driven behaviors. But the neural and molecular pathways that underlie these behavior defects are unknown. To determine the specific parts of the brain that require Chd7, we used brain-wide imaging to identify regions with altered activity patterns as well as altered numbers of inhibitory and excitatory neurons. Here we will show that, consistent with our behavioral data, chd7 mutant larvae have reduced activity in hindbrain areas required for specific responses to acoustic stimuli. We also show that chd7 heterozygotes have an increase in inhibitory neuron labeling in this same region. To identify Chd7 target genes that mediate CHARGE-like behavioral phenotypes, we are currently analyzing transcriptomic and proteomic data from chd7 wild type, heterozygous, and homozygous mutant zebrafish brain tissue at two developmental time points. We are using differential expression analysis, ingenuity pathway analysis (IPA), and machine learning approaches to define a set of strong candidate genes that link Chd7 with disease-related phenotypes. To determine if the identified pathways impact CHARGE-like phenotypes in our zebrafish model, we will design CRISPR gRNAs to knockdown or enhance expression of candidate genes and measure morphological and behavioral phenotypes and assess whether they phenocopy or rescue CHARGE-like phenotypes. Together these analyses will bridge a key gap and allow us to define molecular and cellular pathways that may be targets for potential therapeutic intervention to alleviate specific aspects of CHARGE syndrome.

1845S **Serotonin acutely regulates acoustically-evoked behavior selection in zebrafish through multiple HTR2 receptor subtypes** Rebecca Osbaldeston[1], Kevin Villafañe[1], Matthew Curran[1], Nicholas Roland[1,2], Eva Shin[1], Roshan Jain[1] [1]Biology, Haverford College, [2]Neurobiology and Behavior, Cornell University

Neuromodulators such as serotonin (5-HT) regulate many aspects of behavior including mood, social interactions, sleep, and decision-making, to allow animals to flexibly respond to their changing environment. We focus on simple acoustically-evoked behavioral selection in zebrafish to model and understand the impact of serotonin on decision-making and behavioral flexibility. Following sudden acoustic stimuli, zebrafish larvae select between two stereotyped escape behaviors: an explosive short-latency response or a kinematically distinct and weaker long-latency response, biasing their selection based on the perceived threat of the stimuli, environmental context, and recent stimulus history. Through an array of pharmacological antagonists and agonists of various serotonin receptors, we have identified distinct serotonin receptor subsets that acutely bias which escape behaviors zebrafish select in response to acoustic stimuli. To pinpoint the specific serotonin receptors responsible for biasing this behavior selection, we designed CRISPR/Cas9 gene knockout tools to target candidate serotonin receptor subtype genes. Through combined pharmacology and genetics, we demonstrate that 5-HT_{2B} and 5-HT_{2CL2} receptor activity promotes the selection of long-latency escape behaviors over short-latency responses. Surprisingly we also find that the related paralogous 5-HT_{2CL1} receptor biases behavior selection in the opposite direction, promoting short-latency escape behavior. To identify the neuronal changes underlying these functions, we have begun mapping whole brain neural activity changes using the photoconvertible CaMPARI2.0 sensor. Together this work reveals multiple 5-HT receptor mechanisms through which serotonin bi-directionally modulates simple and ethologically relevant vertebrate decision-making following acoustic threat.

1846V **Characterization of Ultrasound-Induced Mobility Defects and Subsequent Recovery in *C. elegans* Nematode Worms** Louise M Steele[1], Monica Flores[2], Caitlyn McTrustry[2] [1]Biological Sciences, Kent State University at Salem, [2]College of Nursing, Kent State University at Salem

Our lab has reported that exposure to therapeutic ultrasound reduces *C. elegans* worm mobility in a dose-dependent manner. As the ultrasound intensity was increased, fewer worms were thrashing normally, and more worms exhibited a slow, irregular movement that we called «writhing» (Steele *et al*., 2021). At the higher intensities tested, some worms became immobile. To characterize the worms' mobility defects in more detail, we analyzed their movement in S. Basal buffer immediately after ultrasound exposure by using WormLab software. Depending on the severity of the defects, the worms' average and maximum body bend angles were reduced, and different curvature map "signatures" were often observed. Interestingly, many writhing worms appeared to recover their mobility within minutes or hours. To assess whether they made a full or partial recovery, we determined their thrashing rates by using the free ImageJ plugin, wrMTrck. After three hours of recovery time, their average thrashing rate was the same as that of unexposed shams, which suggested that their mobility was fully restored. To explain the transient nature of the defects in movement, we hypothesized that ultrasound may alter neurotransmission. Indeed, writhing worms were hypersensitive to aldicarb, which suggested that acetylcholine signaling was affected. To rule out the possibility that writhing worms were simply more permeable to aldicarb, we stained them with SYTOX Green, a fluorescent dye that only enters cells with compromised membranes. Based on those results, at least some writhing worms were unlikely to be taking up aldicarb more readily. Future work will determine if the neurotransmission defect is pre or postsynaptic. This study has the potential to deepen our understanding of ultrasound's bioeffects in the nervous system at the cellular and molecular levels.

This information could contribute to the development of exciting new laboratory techniques and therapeutic procedures.

1847T **Creating a course based undergraduate research experience (CURE) genetics laboratory course at Xavier University of Louisiana.** Joanna E Haye-Bertolozzi Biology, Xavier University of Louisiana

Course-based Undergraduate research experiences (CUREs) are important for providing undergraduates with authentic research experiences. We developed a CURE course for an undergraduate Genetics Laboratory at Xavier University of Louisiana. The goals of developing this Genetics CURE laboratory course were: 1) to provide an opportunity to participate in a hypothesis driven research project for a large number of students, 2) to analyze different alleles of *MSH6* and determine the effect of each variant on DNA mismatch repair (MMR), 3) to provide opportunities to develop scientific writing skills, and 4) to assess student learning. Our long-term goal is to assess the impact of the CURE course on student confidence, interest in science, and persistence in STEM. Examination of course evaluations indicated that students appreciated working on a single project for the semester and gained understanding of the effect of different mutations on the DNA MMR process. Analysis of pre- and post-course surveys demonstrated an increase in student sense of belonging in the field of science and perception of themselves as scientist.

1848T **Theory, Design, and Outcomes for routine DEIJ discussion during Department Meetings** Katherine Furniss[1], Catherine Kirkpatrick[1], Bhaskar Upadhyay[2] [1]Biology Teaching and Learning, University of Minnesota - Twin Cities, [2]Organizational Leadership, Policy, and Development, University of Minnesota - Twin Cities

Undergraduate institutions are increasingly asking their employees to engage in Diversity, Equity, Inclusion, and Justice (DEIJ) workshops, committees, and programs. Some open questions are which DEIJ efforts will lead to meaningful change in participant attitudes and actions, are scalable, and align with participant interests?

Beginning Fall 2021, the Biology Teaching and Learning (BTL) Department at the University of Minnesota-Twin Cities has engaged in a monthly exploration of a variety of DEIJ topics through the framework of transformative mindfulness. During the planning stage, BTL department members and administrators analyzed change theories to design an approach that: 1) would influence and communicate departmental culture, 2) factored in time limitations for department members, and 3) employed evidence-based practices around individual and community change. The designers based the program goals on the principles of self-awareness and empathy laid out in Dewsbury and Brame's 2019 article on Inclusive Teaching. Over the course of two years and 12 department meetings many DEIJ topics have been discussed including meritocracy, color blindness, achievement vs opportunity gap, and Relational Cultural Theory.

After two years, we wanted to know whether there has been any meaningful change to self-awareness and empathy related to DEIJ concerns, attitudes about departmental culture, or behaviors. Using a theoretical framework by Morris 2020, Incremental Transformative Learning Process Through Mindfulness, we analyzed data from department meeting artifacts (anonymous open-ended and quantitative surveys, jamboards) as well as semi-structured interviews with department members. We have found evidence that the department meeting program interrupts the connection between an individual's frame of reference (how they perceive themself and the world around them) and their behavior (thoughts, judgements, feelings, and actions). We also found evidence that department members recognized their implicit motivational dispositions and that some of them changed their behavior. We will discuss potential modifications to the framework, lessons for implementation in other environments, and project limitations.

Dewsbury and Brame. 2019. doi: 10.1187/cbe.19-01-0021 Morris. 2020. https://files.eric.ed.gov/fulltext/EJ1257177.pdf

1849T **Do I Belong? An Analysis of Black Student Experiences in the Biology/STEM program at Emmanuel College** Samira Fawel[1], Jennika Fevrier[2], Anupama Seshan[1] [1]Biology, Emmanuel College, [2]Emmanuel College

A Belonging in Biology initiative was undertaken by an undergraduate Black-identifying Biology/Health Sciences major at Emmanuel College (EC), a primarily white institution (PWI). Current biology majors and recent alumni from the EC Biology program that also identified as Black were invited to share their experiences navigating the Biology and Biology-related STEM programs. A total of ten interviews were conducted with nine female-identifying, and one male-identifying student. Three participants were alumni of Emmanuel while seven were current Emmanuel students at the time of the interview. Semi-structured interviews were conducted and coded using the Taguette open-source tool. The codes revealed a total of 17 major themes, with eight themes related to exclusion, and nine related to inclusion. The frequency of exclusive codes (199) far outnumbered the frequency of inclusive codes (91). The most frequent exclusive themes mentioned were 1) lack of diversity in the classroom and on campus (n=53) and 2) lack of discussion about student's self-identity and current issues (n=39). The most frequent inclusive themes included 1) participating in established programs created specifically for students of color (n=18) and 2) feeling supported through Black students' and peers' presence and interactions (n=16). A compilation

video was created to highlight the most frequent exclusive and inclusive codes and shown to School of Science and Health (SSH) faculty at Emmanuel College during a professional development workshop. Following the viewing, faculty participants demonstrated increased awareness of major reasons why some students are or are not successful in STEM fields. For example, 59% of participants noted that lack of belonging in STEM courses is a major reason pre-workshop, but this shifted to 83% post-workshop. Pre-workshop, 53% of participants believed that lack of sufficient knowledge in math and/or science was a major reason, while post-workshop this dropped to 25%. Overall, our study presents a set of themes to explain factors that prevent minoritized undergraduate students at PWIs from persisting in their chosen field, as well as those that increase persistence. We investigate how participating in initiatives to raise awareness about systemic injustice increases belonging for minoritized students. This research demonstrates a model for how similar institutions can learn from their own students and share student experiences to change faculty mindsets.

1850T **The Basics of NIH Peer Review** Mollie Manier, Guoqin Yu National Institutes of Health Center for Scientific Review

As the largest funder of biomedical research in the world, NIH supports much research relevant to scientists at TAGC. NIH funds are competitively awarded through a two-stage review process. The first level of review solely evaluates the scientific merit of an application by convening peer reviewers who are experts in the field to adjudicate the potential impact of the proposed research. The second level of review takes into consideration for funding both the scientific impact of a proposal as well as its responsiveness to NIH programmatic objectives. The majority of peer review takes place through the NIH Center for Scientific Review (CSR). CSR conducts the review of 94% of R01s, 84% of NIH NRSA Fellowships, and 96% of SBIR-STTR applications. Outreach efforts by CSR scientific review officers help investigators and reviewers understand important aspects of the grant submission and review process. Key areas for discussion cover the basics of peer review, review criteria, the review timeline, whom at NIH to talk to about your application and when, how to find a potential study section, and recent policy initiatives, such as those pertaining to simplified review criteria, data management plans, and peer review integrity. Outreach efforts help to minimize the influence of grantsmanship and differential knowledge of NIH priorities, policies, and practices, to ensure that review outcomes reflect the strength and scientific merit of applicants' ideas.

1851T **Development of an Oxford Nanopore CURE module for an undergraduate genetics course.** Bryce Taylor Program in Biology, Loras College

It is critical for today's genetics students to gain exposure to genomic tools like next-generation sequencers. Unfortunately, these tools are generally out of reach for most small colleges. The MinION sequencing devices from Oxford Nanopore offer a relatively accessible entry-point for genomic investigations, but to date there are few models of how to incorporate these into classroom instruction.

In my genetics course we are using Minion sequencers to sequence microbial genomes during 4-week CURE modules. I have followed two models for this module:

1. Student groups submit project proposals for consideration. All students participate in sample collection and analysis of data generated from one MinION Mk1B flow cell.

2. I pick a project and have each student collect and sequence samples on individual MinION Flongle flow cells.

I'll report qualitative perspectives on how both models went, data generated from both years, and challenges faced and overcome in developing this CURE module at a low-resourced institution. I would appreciate feedback and perspective from other educators or minion users!

1852F **Structures and Outcomes of Virtual Human Genomics and In-Person *Caenorhabditis* Genetics CUREs** Sosse Kendoyan[1], Joseph Ross[2] [1]California State University, Fresno, [2]Biology, California State University, Fresno

The inclusion of research within the undergraduate academic curriculum is advantageous to students, in part by democratizing access to research opportunities for students. Thus, we redesigned the upper-division undergraduate course Cell Biology and Genetics laboratory (BIOL 104) as two Course-based Undergraduate Research Experiences (CUREs). Here, we share the course designs and their student impacts. Students in the in-person sections developed and conducted *Caenorhabditis* genetics research projects. They first trained in laboratory techniques like microscopy, worm husbandry, crossing, and PCR genotyping. Small groups of student teams then conducted a scaffolded literature review, generated a hypothesis and experimental design, collected and analyzed data, and interpreted and presented their work over the course of a semester. Each group prepared a written reports in the format of a *Micropublication Biology* journal article, so that any projects that support a novel hypothesis or fail to replicate published literature can be easily submitted for peer review and possible publication. Some groups were also selected for oral presentations at a campus research symposium. Student surveys indicated support for this approach.

Students suggest that such research courses be offered earlier in the curriculum and that the potential for publication sustains motivation in course-based research. Our findings suggest useful ways to design CUREs that address issues with resource availability (e.g. time, facilities, and funding), student perceptions of the value of CUREs, and useful approaches for assessing student gains. We also suggest ways to balance student training in knowledge and practical content while providing as much time as possible for their research. Students in the virtual section learned to interpret human ancestry testing datasets. Each student group identified a point mutation that influences a human trait and that is genotyped by ancestry testing companies. The project goal was to research that mutation and to draft a report to the anonymous donor, based on their genotype, predicting their trait or disease risk. Custom videos provided instruction on how to use SNPedia and OMIM and to interpret the raw genotype data files. Students found this approach to be engaging and practical by providing them with knowledge and skills they can apply to their own lives. Students also highlighted how the course contributed to their academic and career aspirations.

1853F **Fly-CURE and connecting curriculum: multi-institutional course-based undergraduate research experiences in genetics and beyond** Kayla Bieser[1], Jacob Kagey[2], Julie Merkle[3], Jamie Siders[4], Joyce Stamm[5], Alysia Vrailas-Mortimer[6] [1]Nevada State University, [2]University of Detroit Mercy, [3]Biology, University of Evansville, [4]Ohio Northern University, [5]University of Evansville, [6]Oregon State University

The Fly-CURE is a multi-institutional course-based undergraduate research experience (CURE) centered on the genetic mapping and characterization of *Drosophila melanogaster* by undergraduate students at 26 institutions (including public, private, community colleges, and minority-serving institutions). To date, undergraduate researchers have successfully mapped and characterized 26 EMS-induced mutants, which has led to local and national scientific presentations by students, as well as eleven peer-reviewed publications with 581 undergraduate co-authors. This project has provided research exposure to greater than 1,500 undergraduate researchers within a classroom setting and student participants report significant gains in their sense of belonging to the scientific community, self-efficacy in research methods, and intent to pursue additional research opportunities. We are expanding the Fly-CURE curriculum through an NSF-funded Research Coordinated Network (RCN) to develop courses in bioinformatics, behavioral genetics, molecular biology/CRISPR, and developmental biology, which can be scaffolded with the genetics Fly-CURE modules or can be implemented as stand-alone CUREs. Through this RCN, we will increase research exposure for students across different courses and provide more opportunities for faculty to incorporate CUREs at their institutions. We are currently recruiting faculty to participate in our RCN. Faculty participants will be provided stipends for curriculum training and implementation, a social network of faculty, a community of like-minded scientists, continued scholarship opportunities, and support for tenure and promotion.

1854F **Inclusivity of the LGBTQ+ community in Emmanuel College biology courses.** Teagan Santoro[1], Janel Cabrera[2] [1]Biology, Emmauel College, [2]Biology, Emmanuel College

Teaching a curriculum that is inclusive and representative of diverse groups of people can result in higher outcomes for students and reduced stigma. However, LGBTQ+ discrimination and lack of inclusion has been growing across the US, and queer representation and education in schools tends to be scarce. While various studies have been conducted, there is little information available regarding implementing LGBTQ+ inclusive curricula, and this is particularly true in STEM fields. This research surveyed students and instructors in biology courses at Emmanuel College in Boston, MA to examine feelings of classroom and curriculum inclusivity on the basis of gender identity and sexuality. In the initial surveys, instructors were asked to answer questions regarding knowledge and understanding of LGBTQ+ terminology and topics, levels of comfort with discussing such topics with students, and personal efforts to make an inclusive curriculum and classroom environment. Students were asked about previous experiences of belonging and representation on the basis of gender identity and sexuality in classrooms, including Emmanuel biology classrooms, and personal desire to learn more about LGBTQ+ topics relating to their science courses. It is hypothesized that the current curriculum is markedly less inclusive towards those in the LGBTQ+ community and identifying students would report feeling less included and represented in the classroom environment than their heterosexual, cisgender peers. Based on the data received after the second set of surveys, which will be more focused on experiences of belonging and inclusion in the given biology course throughout the semester, resources and any necessary further actions will be compiled and planned for instructors to aide in development of more inclusive curricula. The goal is that the information gained through this research will provide a more open understanding of what must change in classroom planning and environment so students in the LGBTQ+ community feel sufficiently represented in material and can cultivate a better sense of belonging. While this initiative is currently localized to the biology department at Emmanuel College, the hope is to expand such research and resources to other departments and institutions.

1855F **Learning genetics by “making a baby” with a deck of cards for majors or non-majors courses** Tina L. Gumienny, Lionel L. Faure Biology, Texas Woman›s University

Genetics can be a difficult topic to master. For some students, the random yet precise segregation of chromosomes during

meiosis and different inheritance patterns are especially hard to grasp. To help students understand these basic genetic concepts, we developed, implemented, and refined a “card baby” active learning activity over eight years. This activity can be done in class or online, and in a non-majors or majors course. After instruction on meiosis, the animal life cycle, and basic inheritance patterns, students get to apply what they learned by “making a baby”. In-class students pair and are given a deck of cards. Each card represents a chromosome. The two black suits are the dad’s two chromosome sets. The two red suits are the mom’s two chromosome sets. Students are instructed to perform meiosis: after laying out cards in order by suit, one student in the group makes the haploid “sperm” chromosome set by randomly selecting one of each card number from clubs and spades. In a similar way, another student makes the “oocyte” chromosome set from heart and diamond cards. The group performs “fertilization” by matching up the two sets of cards. They confirm no aneuploidies. After students have successfully “made a baby”, they get a table with the genotypes associated with each chromosome and the inheritance pattern. Real human traits that generally follow autosomal recessive or dominant, sex-linked, incomplete, and polygenic inheritance patterns are provided for the students to interpret. The majors course includes an example of epistasis. The students’ goal is to interpret the genotype and phenotypes of their “baby” based on the randomly selected card chromosomes their “baby” has. They fill in a paragraph describing their baby’s traits based on the genotype and the given inheritance patterns. At the end of the class (or in a discussion board, if online), groups read their paragraph to the class so students can see the variety in the “siblings” the class made. Students provided overwhelmingly positive responses when asked if this activity helped them understand the patterns of inheritance and if this activity was enjoyable. This activity is adaptable to one’s favorite inheritance patterns, traits, and diploid, sexually reproducing, multi-chromosomal organism. Practically, it is inexpensive, doable in a 50- or 80-minute class, and scalable to large classes (especially with help from teaching assistant(s)).

1856F **‘Genetics & Society’: a non-majors undergraduate case study examining a genetic research study for scientific merit and societal impacts** Nicole M Green Biology, Cornell College

The field of genetics has produced many exciting leaps in knowledge and technology in recent years. However, rapid scientific advances place a high burden on individuals in society to follow current research trends and understand new technologies. In an effort to prepare college students about the role of genetics in their own lives and communities, I designed a non-majors course emphasizing critical skills such as inquiry, source evaluation, decision-making, and intercultural literacy. This course—called Biochemistry & Society—was developed within a unique educational model called One Course At A Time, which has students participate in a single class for 18 consecutive days. The flexibility of our course design creates an exciting pedagogical opportunity to deeply explore and engage with scientific topics.

A large section of Biochemistry & Society class was dedicated to the intersection of genetics and society. Our genetics module opened with discussions on the clinical trial process, the evolution of medical ethics, and the biomedical research pipeline. These foundations in scientific practice were followed by a historical perspective on the field of genetics and the future promises and challenges presented by recently developed genetic technologies such as CRISPR/Cas9 editing. The genetics module culminated in a case study that asked students to use skills from prior sessions to make a decision about participating in a current genetics research study at a local R1 institution. The genetic research study we examined aims to identify the complex genetic traits of giftedness and the phenomenon of twice-exceptionality. We built an investigative ‘file’ containing the email study invitation, intake survey, and study consent form. Furthermore, students were directed to the research lab website, previous publications, and press releases on current and past projects. Students then completed a self-guided assessment of the study materials and made an initial decision about participation. The self-guided activity was followed by a class-wide discussion to highlight good study design, identify areas of concern, and points of clarification before consenting to participate. Students were also asked to consider possible research applications and implications by reviewing media about the historical and ethical considerations of intelligence research, as well as a new movement in behavioral genetics attempting to bridge genetics and social justice initiatives. After many rounds of individual and group feedback, students were asked to reflect on their decision and how their perception and understanding of genetic research changed as a result of engaging with a specific research study. Student feedback following this case study highlights the importance for practical applications of genetics concepts and for building more curricula training non-scientists to engage with genetic research.

1857F **Implementing Equitable Grading in Microbiology** Suparna Chatterjee New Mexico State University

Assessment is an important criteria for measuring student success and specifications grading implemented in a microbiology course to assess student success in an equitable system. It is a grading system based on the mastery of specific educational outcomes that determine the final grade a student can earn in a course. I have designed a specifications grading strategy for the undergraduate Microbiology for Health Sciences course, creating 16 individual learning outcomes (LOs). Most of the students in this course are Nursing majors for whom this course is mandatory. It implemented two design principles: (i) detailed feedback on completed work, what is done well, and what needs improvement through practice or review, and (ii) additional opportunities to practice skills that are challenging but can be achieved by resubmitting assignments. The grade

earned in the lecture depended on the number of LOs the students mastered. A student's final class grade depended on the number of LOs mastered combined with the grade earned in the final exam. Implementing this grading system it was found that students showed positive attitudes towards learning microbiology and the DFW (students receiving D, F, and withdrawal) rate dropped.

1858F **Integrating Research Ethics Instruction in a Genetics CURE** Joseph Ross[1], Sosse Kendoyan[2] [1]Biology, California State University, Fresno, [2]California State University, Fresno

Course-based Undergraduate Research Experiences (CUREs) provide an opportunity for students to conduct the entire scientific method, from background reading and hypothesis generation to experimental design, data collection and analysis, and dissemination of results. In addition to these common CURE components, there is significant value in training students to be ambassadors of the objectivity and trustworthiness of scientific research to their communities. Thus, education in the responsible and ethical conduct of research (RECR) should be integrated with CUREs, so that students learn about and apply the ethical norms of science in the context of conducting research. In the redesigned Genetics and Cell Biology Laboratory CURE, we introduced direct instruction on the concept of research ethics and on five core research ethics topics defined by the US Department of Health and Human Services: recordkeeping, misconduct and fraud, authorship, plagiarism, and human subjects research. We selected these topics because of their direct relevance to student research projects, because students maintain research notebooks, analyze and manipulate data, produce co-authored works that require citations, and are human subjects participants in the present research study on this CURE design. We conducted pre- and post-semester surveys and assessed the impact of the training on student understanding and implementation of ethical processes and decisions in their CURE projects. We find that most students have never experienced a CURE course or participated in mentored research with a faculty member, and most have poor understanding of the relevant ethical norms at the start of the course. By the end, student performance improved in understanding the norms (e.g. they are able to provide a definition of plagiarism and describe why avoiding plagiarism is important) and also in applying that knowledge. For example, when presented with a passage from a published peer-reviewed manuscript (with the citations removed), students improved in their ability to identify which sentences should contain citations and to explain their decisions. Here, we share these qualitative and quantitative data and describe the research ethics curriculum and how it was integrated into the course, with suggestions for others who also want to introduce RECR training in their CURE.

1859F **Incorporating information literacy into genetics undergraduate curriculum** Elizabeth J Wade Natural Science and Math, Curry College

Information Literacy is the ability to access, evaluate, and use information from a variety of sources, which can be difficult for undergraduate students today given the incredible amount of information and misinformation available. Here, I discuss how to incorporate information literacy into an undergraduate genetics course for science majors using class discussion, current events, research articles and specific assignments. This also increases student engagement, deepening their understanding of genetic concepts and fostering a meaningful learning experience by focusing on topics that are relevant to students' lives and prior understanding.

1860F **Building Sustainable Approaches to Ethical Inclusion of Indigenous Peoples in Genomic Research** Julie Beans[1], Jessica Blanchard[2] [1]Research Department, Southcentral Foundation, [2]University of Oklahoma

This presentation will provide an overview of three areas where our research team aims to advance the ethical inclusion of American Indian and Alaska Native (AIAN) peoples in genomic research through: 1) balancing Tribal community priorities with collective goals; 2) distributing power in ways that promote equitable partnerships; and 3) providing research and training experiences to support AIAN student interest in genomics. This work is conducted as part of the Center for the Ethics of Indigenous Genomic Research (CEIGR), a multidisciplinary consortium led by a mix of community-placed tribal partners, university researchers and community-based institutions working collaboratively to conduct research on ethical, legal, and social implications of genomics in AIAN communities in the United States. CEIGR aims to model meaningful community engagement in genomics research and move toward inclusive and equitable research practices – central to our efforts is a shared perspective that community engagement requires community building. An important goal of CEIGR is to increase the number of AIAN scientists in the field of genomics by creating meaningful experiences for AIAN undergraduate students and extend a network of support for AIAN student and scientists to collaboratively advance the field. The empiric and normative work we present provides examples of how to build sustainable approaches to ethical research with Indigenous communities.

1861S **Using *C. elegans* to study *dcaf-13* RNAi phenotypes to promote inquiry-based learning in an undergraduate Cell and Molecular Biology course** Jessica Sullivan-Brown, Jessica Sowa Biology, West Chester University

Inquiry-based undergraduate laboratories are designed to introduce students to the excitement of making novel scientific

discoveries and perform independent research. Our objectives were to provide undergraduates with opportunities to gain genuine experiences in contributing to fundamental scientific knowledge by characterizing novel RNAi phenotypes of relatively understudied genes in the worm *Caenorhabditis elegans*. In our efforts to create these experiences, we designed labs for an upper-level Cell and Molecular Biology course at a primarily undergraduate institution in which students characterized the RNAi phenotypes of the potential oncogene DCAF13 (DDB1 and CUL4 associated factor 13). We discovered that when *dcaf-13* is disrupted in *C. elegans*, the worms showed a significant effect to larval development as measured by determining overall length of worms at 48 hours of development. In addition, *dcaf-13*(RNAi) worms display either a failure or delay of reaching the L4 or adult stages. Our data also indicates that *dcaf-13*(RNAi) did not affect embryonic development in *C. elegans*; however, egg-laying was significantly decreased in *dcaf-13*(RNAi) worms suggesting a general role in fertility. We were able to publish this work in *microPublication Biology*, with student authors from the Cell and Molecular Biology course and continue to use this study as a platform for novel discoveries.

1862S **The Genomics Education Partnership: A Path to Classroom Research Experiences in Person or at a Distance** Alondra M Diaz-Lameiro[1], Martin G. Burg[2], Wilson Leung[3], Jennifer Kennell[4], Chinmay P. Rele[5], Katie M. Sandlin[5], Stephanie Toering Peters[6], Laura K. Reed[5] [1]Biology, University of Puerto Rico at Mayaguez, [2]Grand Valley State University, [3]Washington University in St. Louis, [4]Vassar College, [5]The University of Alabama, [6]Wartburg College

The Genomics Education Partnership (GEP) is a nationwide collaboration of 271 faculty from 215 institutions that has impacted more than 12k students since 2018. Our main goal is to increase accessibility to genomics and bioinformatics through the incorporation of Course-based Undergraduate Research Experiences (CUREs). Participating institutions range from Community Colleges, Primarily Undergraduate and Minority-Serving Institutions, to Research Universities. GEP provides a web-based platform (thegep.org) with curated curriculum and training materials that can easily be incorporated into existing courses, a robust network of nationwide virtual TAs, and ample professional development before, during, and after curriculum implementation for faculty. During the COVID-19 pandemic, GEP curriculum proved to be an outstanding tool to continue student research experiences, which produced novel data, in an online framework. Through the GEP curriculum, students learn to annotate genes in eukaryotic genomes and become familiar with various bioinformatics tools. In the process they learn to leverage evidence from reference genomes, experimental data, gene prediction algorithms, evolutionary conservation, and molecular biology rules to create a defendable gene model. All without the need of external funds, expensive reagents, or equipment, making the curriculum and the authentic research experience accessible for smaller institutions, newer faculty, and/or online students. The GEP research projects include investigations on venom evolution in parasitoid wasps, evolution of insulin pathway genes across 31 *Drosophila* genomes, the F Element in four *Drosophila* species, and genes associated with egg formation in the critically endangered Puerto Rican parrot, with a handful of new faculty-led projects currently in development. Student gene models are reconciled to generate large datasets for genomic evolution studies. In addition, GEP supports publication of gene models as microPublications, with students as lead authors. The GEP also engages in science education research. Our most recent study found that Community College (CC) student gains were comparable to non-CC students, with improvements in attitudes towards science and thriving in science, making our model widely applicable. In addition to accessing the curriculum materials and tools, GEP faculty benefit from the support of a national network of colleagues. The GEP is supported by NSF IUSE-1915544 and NIH IPERT-R25GM130517 to LKR.

1863S **A cohort-based research program for early-career undergraduates** Elyse Bolterstein[1], Samantha Brown-Xu[2], Ignatius Gomes[3], Jennifer Hasso[4], Scott Mayle[5], Shreya Patel[4] [1]Biology, Northeastern Illinois University, [2]Chemistry, Northeastern Illinois University, [3]Harold Washington College, [4]Northeastern Illinois University, [5]Physics, Northeastern Illinois University

It is well known that participating in undergraduate research prepares for their future careers. However many research internships are designed for upper-level students, which limits participation of students still deciding on their career tract. To help bring research opportunities to students earlier in their academic career, we developed STEM Academy, which is an 8-week collaborative research program designed for first and second-year students who are interested in STEM fields, but have little to no formal STEM experience. Our goal for this program is to serve as a bridge to mentored research programs, internships, and STEM careers.

The STEM Academy fulfills a goal of the Advancing Careers and Research Opportunities (ARCOS) program at NEIU, a title III HSI STEM grant funded by the Department of Education. ARCOS brings together our institute with a local 2-year college (Harold Washington College) to enhance career development, research opportunities, and transfer efficiency to NEIU. STEM Academy was developed and implemented by a team of faculty representing various STEM disciplines to serve the interests of our students. Our inaugural student cohort consisted of 23 NEIU and Harold Washington students, with interests in biology, chemistry, environmental science, computer science, and psychology.

STEM Academy introduced students to lab techniques and experimental design through 2 collaborative research projects. First,

students worked in teams to explore the impacts of environmental contaminants and nutrients on Drosophila development and activity - a project that combined principles in biology, chemistry, and data science. Students then self-selected into teams mentored by STEM academy faculty to investigate research questions in their discipline of interest. For example, groups of biology students investigated diversity and antimicrobial resistance of microbes collected from waterways around Chicago. Throughout the program, students also participated in tutorials on common lab techniques (e.g. creating solutions, statistical analysis) and wrote weekly reflections on their experiences, designed to guide them in preparing application materials for internships, jobs, and graduate school. Students presented both projects to our group and university community. Overtime, we will track the impact of STEM Academy on students' sense of community, ownership, self-efficacy, and success in entry into future research programs and careers.

1864S **Rediscovering Mendel`s Developmental Genetics to Dissolve the Trouble of Gene-Centrism** Hui Zhang, Yafei Guo, Jiaqi Zheng, Wenli Zhao, Ling Wang, Fuli Ma Northwest Normal University of China

There is an increasingly explicit critique of the belief of gene-centrism or genetic determinism in the community of genetics educators. Also, a similar tendency appears that taged Mendel as enemy of genetics No. 1, accusing his first holding oversimplified idea of "gene for green/yellow pea seed" with no consideration for environmental effect in organism development. In history, genetics discipline was founded by the later rediscoverers, what was to Mendel?

At the bicentennial of Mendel's birth, we reconstructed Mendel's narrative regarding the selfing reproduction of hybrid by using his own symbol system, $Aa \times Aa = (A + a)(A + a) = A/A + a/a + A/a + a/A = A + 2Aa + a \rightarrow 3A + a$. Remarkably, the three equal signs in the sequential expression were respectively lectured by Mendel himself as the principles of reproductive cells formation, of fertilization, and of seeds developments in 1865. The same pair of symbols, *A*, and *a*, contains three different senses, gametes, factors, and traits, whose numerical corresponding relationships between two entities of the three were often expressed, but no word like"*A*/*a* gene for *A*/*a* trait" founded in the context. According to preserved Mendel›s letter to Nageli In 1870, one factor carried by one gamete with capacity to transmit one trait to offspring was eventually exemplified in his controlled pollination experiment in *Mirabilis jalapa*.

In fact, as a physics teacher, Mendel in his mind proudly regarded his core discovery as the development law of two constant forms (*A*, *a*) and one hybrid form (*Aa*) and published it as the sole mathematical equation in the paper, $A/A + a/a + A/a + a/A = A + 2Aa + a$. The left four fractions named "vivifying unions" are equal to but quite different from the genotypes in modern genetics, *AA*, *Aa*, *aa*. The latter is simplified as only "material composition of elements" while Mendel`s involving "their arrangement in primordial cell" as well. The fraction illustrating the intracellular spatial position effect of gene arrangement also implicates Mendel`s temporal meaning, the above from male gamete while the below female one. Besides the spatiotemporal environmental effect that Holliday defined as epigenetic control of gene expression, the inter-allelic, and the polygenic non-allelic interactions in foundation cells, as well as living conditions of organism in wild habitat were all taken into account in his paper.

Here we also report that Bateson, et al., might be responsible for the common mistake of gene-centrism, because they fragmented and oversimplified Mendelism as only part of transmission genetics but missing his most favorite developmental part. Sure, it is time to rediscover Mendel`s Mendelism to construct a complete and harmonious genetics.

1865S **Bridging Research and Education with Model ORganisms (BREWMOR)** Dondra Bailey[1], Kelli Carroll[2], Wen Chen[3], Sean Coleman[4], Rebecca Delventhal[5], Renee Geck[6], Paul Goetsch[7], Jill Keeney[8], Michael Law[9], Te-Wen Lo[10], Kelsey Perry[11], April Rich[12], Josefa Steinhauer[13], Bryce Taylor[14], Cindy Voisine[15] [1]Coppin State University, [2]Wofford College, [3]California Institute of Technology, [4]Wartburg College, [5]Lake Forest College, [6]University of Washington, [7]Michigan Technological University, [8]Juniata College, [9]Stockton University, [10]Ithaca College, [11]University of Colorado-Colorado Springs, [12]University of Pittsburgh, [13]Yeshiva University, [14]Loras College, [15]Northeastern Illinois University

BREWMOR (Bridging Research and Education With Model ORganisms) is an organization of educators and scientists united around our shared goal of building a network dedicated to increasing experiential learning for biology students, primarily at the undergraduate level. BREWMOR disseminates and propagates best practices to engage and support students in rigorous model organism-based research excellence while creating and fostering strong, diverse and inclusive communities. We want to connect with more researchers and educators at TAGC to exchange resources, knowledge, and experience, and expand our community.

BREWMOR was founded following the 2020 TAGC meeting, helping to fulfill a need for educators around the globe in delivering hands-on, discovery-based undergraduate learning experiences during the height of the COVID-19 pandemic. The original work of BREWMOR was focused on high-impact teaching practices that would engage students in an online learning environment. As such, BREWMOR's outreach has focused on the most pressing needs for educators.

We do this through hosting community-focused virtual workshops and seminars on topics at the intersection of research and education. These workshops have been sponsored by GSA and have generally fallen into two categories; a winter half-day workshop, microBREW, and a two-day summer symposium, bigBREW, where one day is a symposium and another day is a workshop. Previous event topics have included: DEI Basics for Science Educators, CUREs, Grants for Education-Related Work and Research at PUIs, and Integrating Primary Literature into the Classroom.

We are actively working on ways to maintain engagement between workshops, including peer groups, and provide opportunities for community members to report back on their experiences in learning new pedagogy and implementing these new approaches in their classrooms. Come visit our poster to learn more about our community-building endeavors and future workshops.

1866S **Teaching the Genome Generation: Cultivating High School Genomics Through Teacher Education** Erica L Gerace, Alexa Wnorowski, Christina Vallianatos, Sarah Wojiski, Charlie Wray Genomic Education, The Jackson Laboratory

Teaching the Genome Generation™ (TtGG) provides pre-service and current high school teachers with the content knowledge, teaching strategies, and resources needed to enhance student learning in genetics and genomics, with an emphasis on math skills and data literacy. Our approach weaves three learning strands—molecular genetics, bioinformatics, and bioethics—together within the context of the Next Generation Science Standards (NGSS) and Common Core Math Standards. Classroom study findings indicate use of our curriculum leads to increased knowledge of, and confidence in, biotechnology laboratory procedures and increased student interest in genetics and genomics concepts. Newly designed modules emphasize quantitative skills in four genetics- and genomics-related content areas: cancer genetics, sequence comparison and identity, genotype-phenotype associations, and ancestry. Each module includes standards-aligned activities focused on problem-solving or inquiry through the exploration, analysis, and interpretation of genetic and genomic data. Modules also encourage exploration of ethics and social justice topics relevant to modern genetics and genomics, such as health disparities and access to genetic testing. Our new content is freely available on our website and includes teacher guides and multimedia tutorials for new tools and skills. Recently, our resources have expanded to include a suite of laboratory simulations and interactives, hosted on LabXchange and available to teachers around the world.

1867S **LacApp: A platform to help students master gene regulation** Alex de Lencastre, Paul Wolujewicz, Caitlin Hanlon Biology, Quinnipiac University

The lac operon is widely taught to biology students as a paradigm for how gene expression is regulated from bacteria to humans. However, students struggle to correctly apply their understanding of gene regulation when prompted with higher order questions (Stefanski et al, 2016). We hypothesized that repeated self-testing, known as “retrieval practice” (Karpicke and Blunt, 2011), would help students develop a deeper understanding of these important concepts compared to traditional approaches such as lecture and worksheets. Here, we describe the design and initial testing of LacApp with quantitative and qualitative data. LacApp enables students to self-test using a series of randomly generated combinations of regulatory proteins, DNA binding sites, and genes from the lac operon to predict how a given combination of those elements would affect expression of the operon genes. Feedback indicating if the student’s prediction was correct is immediately provided along with an explanation of the regulatory logic. To assess the feasibility of LacApp, two sections of an introductory genetics course were divided into a control and experimental cohort. The control cohort completed a worksheet while students in the experimental cohort worked with LacApp. All students then completed a short multiple-choice quiz in class. Students using LacApp ($n=23$) scored significantly higher on the quiz compared to students who used a conventional worksheet ($n=22$; $p<0.05$). Following the study period, all students were given access to LacApp. Students indicated that LacApp was the most helpful learning source for understanding gene regulation and that the most useful feature in the app was the immediate explanation of the correct answer. These data suggest that LacApp is a useful tool to support students when learning the concept of gene regulation. We are interested in expanding the use of LacApp, so educators who are interested in using this tool in their undergraduate genetics course are encouraged to stop by for further discussion.

1868S **Incorporating whole genome sequencing and analysis into a high school teaching lab** Maitreya Dunham University of Washington

Evolution can be difficult to learn and teach. We have developed a yeast experimental evolution and genomics lab (“yEvo”) for high school students to learn about evolution by doing it. Briefly, students passage yeast cultures in increasing dosages of a stressor. Strains with enhanced resistance are then whole genome sequenced by the university lab partner, and the resulting mutations can be analyzed both by the high school students as part of their class and by the university team as part of our research on genome evolution. One as yet unsolved aspect of yEvo has been involving the students in genome sequencing and analysis. I’ll present some strategies and tools we are exploring to improve this aspect of our curriculum, primarily addressing data visualization. Sequencing and analysis are as yet still taking place at the university lab. However, new web-based tools for

viewing sequencing read "pileups" have made it more practical for students to look directly at their data. We have developed a short module to lead students through using the web app version of the Integrative Genomics Viewer. By viewing their sequencing data at the read level, students learn more about how modern sequencing works and can directly compare their evolved and ancestral strains. As a second goal, we wanted to facilitate students comparing data to their classmates, as well as with other yEvo classrooms. We developed a Shiny app mutation browser that allows students to explore mutations and easily click through to resources at SGD to learn about the genes of interest: https://yevo.org/mutation-browser/ We are deploying these new tools in classrooms during the 2023-24 school year. Having students participate in the read mapping and variant calling steps of the bioinformatics pipeline remains a goal, on which we would welcome ideas.

1869S **ORFans and proto-genes: Engaging students in bioinformatics through the study of yeast genes of unknown function** Jill B Keeney Biology, Juniata College

The model yeast *Saccharomyces cerevisiae* is arguably the most-studied eukaryotic model organism, yet nearly 10% of the annotated genes are of unknown function. Additionally, the yeast genome contains thousands of unannotated genes, possible proto-genes with potential for evolutionary functional selection over time. We have developed *in silico* laboratory modules that are directed at investigating genes of unknown function, as well as proto-genes yet to be annotated. Through the modules, students are guided through application of cellular and molecular concepts, including the central dogma, protein structure and localization, and gene evolution. The modules direct students in interpretation of algorithm results, leading to student-generated hypotheses of gene function. The study of yeast genes can be used to reinforce basic biological concepts and provide data for generating hypotheses. Modules are appropriate for introductory courses and can be adapted for upper-level courses.

1870S **Full-Immersion Research Experience (FIRE): a hybrid CURE + Research Internship** Cheryl Van Buskirk Biology, California State University Northridge

Course-based Undergraduate Research Experiences (CUREs) help build a foundation for a scientific careers and have the capacity to involve many students in novel research. These course-based experiences often encourage students to seek out research internships within a faculty member's lab, which in turn cultivates personal connections with a community of scientists. To facilitate this transition, California State University Northridge (CSUN) Biology has begun to implement an undergraduate research experience called FIRE (Full Immersion Research Experience) that leverages the strengths of both course-based and internship models and provides a supportive transition to independent research. With the support of NSF-IUSE funding, we are implementing and assessing the impact of this model on student interest in research-related careers and on the capacity of the CSUN Biology department to involve undergraduates in research.

1871V **Genetics Beyond Laboratories: Using Drosophila as a learning tool for biology in Nepalese Schools** Suvechhya Bastola[1], Yogesh Joshi[2], Vibha Acharya[3], Prajjwal Rajbhandari[1], M. Alba Abad[4] [1]RIBB, [2]Anatomy and Cell Biology, Wayne State University, [3]University of Pittsburgh, [4]Engage Nepal with Science

Drosophila has an enormous potential beyond research for biology teaching. It is a powerful modern teaching tool not only for classical genetics but for many curriculum-relevant areas of biology, providing unique access to empowering and inspiring classroom experiments. Our project *Games of Flies and Genes* encourages science educators in Nepal to work collaboratively with fly researchers and takes *Drosophila* to the classrooms to make genetics lessons more interactive and dynamic. This project brings teachers and students under a common umbrella of nature and science by shifting the traditional classroom-based pedagogy to a new experiential learning process through workshops on genetics and fly research combined with the use of microscopes to explore real flies and gamification tools. *Game of Flies and Genes* is run by *Engage Nepal with Science* (ENwS) a collaboration between the University of Edinburgh (UK) and the Research Institute for Bioscience and Biotechnology (RIBB, Nepal) that aims to spread the culture of engaging with science to empower, inspire and build confidence in STEM. This project is believed to add yet another milestone to our goal of creating a culture of empowerment in research in communities in Nepal.

1872V **Using course-based undergraduate research experiences (CUREs) to develop approaches for DNA barcoding ramshorn snails** Jessica Shinn-Thomas, Shakhrizoda Khazratkulova, Gladys Leitch, Katherine Hawley, Thomas McCarthy Biology, Utica University

Using course-based undergraduate research experiences (CUREs), we aim to develop approaches for species-level identification of ramshorn snails purchased from Ward's Science and Carolina Biological Supply Company that are used in our undergraduate student-faculty research programs. Neither company provides species-level classification, information about from where the snails are collected, if they are consistently collected from the same geographical location, or if they

are aquarium-reared. Students in our 300-level, Genetics laboratory course for science majors contribute to developing DNA barcoding approaches for the COI and 16S rRNA genes for identifying the species of ramshorn snails used in our undergraduate research programs. Students develop and reinforce their skills in molecular genetics including tissue isolation, DNA extraction, polymerase chain reaction (PCR), gel electrophoresis, and primer analysis. Some students independently continue the research after the course concludes to sequence and analyze the barcodes using bioinformatics. Our preliminary phylogenetic analyses show the ramshorn snails sold by both companies to be either *Planorbarius corneus* or *Planorbella trivolvis* and further confirmatory approaches are underway. Upon confirming our approaches, we will analyze local wild-caught snails and additional batches of Ramshorn Snails from both companies to determine consistency in species among separate purchases and between companies.

1873T **Unraveling the Pathophysiology of Jordan's Syndrome: A Proteogenomic Approach** Harris J Bolus[1], Kali Smolen[2], Jasmine Carter[3], Julian Halmai[3], Chenchen Li[4], Viktoriya Solodushko[4], Chelsie Carpenter[4], Justin Roberts[5], Mark Swingle[4], Kyle Fink[3], Arminja Kettenbach[6], Richard Honkanen[4] [1]College of Medicine, Whiddon College of Medicine at the University of South Alabama, [2]Geisel School of Medicine at Dartmouth, [3]UC Davis Neurology and Institute for Regenerative Cures, [4]Department of Biochemistry and Molecular Biology, Whiddon College of Medicine at the University of South Alabama, [5]Department of Pharmacology, Whiddon College of Medicine at the University of South Alabama, [6]Department of Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth

Jordan's Syndrome (JS) is a rare developmental disorder caused by *de novo* heterozygous dominant missense variants of the PPP2R5D gene. It presents with symptoms ranging from developmental delays to seizures and sensory challenges. The biological role of PPP2R5D and pathophysiology of JS are largely unknown, and no treatment has yet been found. We aim to elucidate the consequences of PPP2R5D mutations using cell culture models of the syndrome.

Using CRISPR-Cas9, cell lines recapitulating the E198K mutation were generated, including HEK-293 cells, and patient-derived induced pluripotent stem cells (iPSCs) and neural stem cells (NSCs) in which isogenic controls were generated by fixing the patient's single-nucleotide polymorphism. We combined nanopore-based RNA sequencing, traditional RNA sequencing, and TMT-based quantitative phosphoproteomics. We analyzed the output using the Kyoto Encyclopedia of Genes and Genomes (KEGG) and Over-Representation Analysis (ORA). The significance threshold was $p < 0.05$ for RNAseq as well as HEK-293 phosphoproteomics. Due to greater sample size, an FDR threshold was calculated at $p < 0.0412$ and $0 < 0.016$ for iPSC and NSC phosphoproteomics, respectively, using the Benjamini-Hochberg procedure.

398 proteins were differentially expressed in all three proteomics datasets, including NAPRT (Nicotinate phosphoribosyltransferase), SLC3A2 (subunit of multiple large neutral amino acid transporters), and LDHA (L-lactate dehydrogenase A chain).

152 phosphopeptides were differentially phosphorylated in all three phosphoproteomics datasets, including KRT8, PPP1R12A (Protein phosphatase 1 regulatory subunit 12A), and AATF (Apoptosis antagonizing transcription factor, a possible HDAC1 inhibitor).

Overrepresentation analysis (ORA) of proteins, phosphorylation sites, and RNA transcripts with a significant change in abundance consistently revealed several KEGG pathways including spliceosome, RNA transport, regulation of actin cytoskeleton, proteoglycans in cancer, metabolic pathways, neurotrophin signaling, and insulin signaling.

Our findings suggest JS may involve the neuronal cytoskeleton, potentially affecting connectivity or morphogenesis. The prevalence of pathways and proteins associated with metabolism, cancer, and apoptosis hints at a broader metabolic disturbance. Additionally, the involvement of the spliceosome and RNA transport invite further research. Overall, our integrative proteogenomic approach provides insights into the multifaceted pathophysiology of JS and proposes novel candidate genes and proteins for future investigation.

1874T **Drosophila salivary gland transcription factors as novel targets for vector control** Bianca Palicha[1], Dorian Jackson[1], Deborah Andrew[1], Yuemei Dong[2] [1]Johns Hopkins University, [2]Molecular Microbiology & Immunology, Johns Hopkins University

The salivary gland (SG) secretions from mosquitoes and other vector species play essential roles in blood feeding, but also present a public health burden as the SGs serve as a gateway for transmission of a plethora of human pathogens. The genetic toolkit available for studying vector species is far less extensive than what is available in Drosophila melanogaster. More genetic reagents are necessary to gain further insights into vector biology. Interestingly, many of the key promoters currently utilized in vector research originated from Drosophila. As such, we are interested in leveraging our extensive understanding of SG development in flies to identify gene candidates with potential utility in vector-borne disease research. Sage is a basic helix-loop-helix (bHLH) transcription factor (TF) expressed exclusively in the SG of Drosophila melanogaster that regulates

expression of secreted cargo. During SG development, sage is activated at the onset of SG specification and persists for the duration of embryonic, larval, and adult life. Previous studies have also shown that sage is essential for cell viability during SG development, as null mutations resulted in SG apoptosis. Similar cell death is observed in silkworm moths in which genetic deletions of the sage ortholog resulted in the animals surviving with poorly developed silk glands. The Anopheles gambiae Sage ortholog AGAP013335 is also expressed in the SG at high levels across developmental stages. Additionally, a comparative analysis of Sage protein sequence and orthologs in other arthropods demonstrated a high degree of conservation in the bHLH binding domain across all primary mosquito vectors. Taken together, the tissue specificity coupled with its conserved developmental function across species make sage an ideal candidate for genetic studies in SG vector biology. Here, we describe our experimental approaches to characterize the function of AGAP013335 in mosquitoes as a potential target for vector control. Experiments are underway to test (1) whether Sage is functionally conserved in its capacity to bind DNA across insect species and (2) the effect of sage loss in A. gambiae mosquitoes.

1875T **Quantitative Analysis of Cytoplasmic Transfer between Human Retinal Organoids** McKaily Adams, Ying Liu, Mandeep Singh, Robert J Johnston Johns Hopkins

Degenerative photoreceptor diseases, such as age related macular degeneration and retinitis pigmentosa, are ever growing problems among older populations. As the retina lacks regenerative capacity, transplantation methods may restore functionality to degenerating photoreceptors. Stem cell-derived human retinal organoids have potential therapeutic applications for patients with degenerative diseases. When transplanted, organoid-derived donor photoreceptors transfer cytoplasm and mitochondria to host cells via tunneling nanotubes in a process called cytoplasmic transfer. Our goal is to use stable isotope labeling by amino acids in cell culture (SILAC) to quantitatively assess the transfer of proteins between donor and host cells. SILAC is a proteomics approach that allows 'heavy' isotopes of amino acids to be incorporated into proteins and identified by mass spectrometry. These studies will characterize the proteins that are transported during cytoplasmic transfer, suggesting how retinal organoid transplantation could transfer healthy material to degenerating host photoreceptors.

1876F **Nrf2/CncC and Hsf1 play a role in intestinal stem cell identity and gut homeostasis in *Drosophila*** Carlos L Quinones Sanchez[1], Heinrich Jasper[2], Jason Hackney[2], Airined Montes[3], Otto Morris[2], Alfredo Ghezzi[1], Imilce Rodriguez-Fernandez[1] [1]Biology, Universidad de Puerto Rico - Rio Piedras, [2]Genentech Inc, [3]Universidad de Puerto Rico - Rio Piedras

Adult somatic stem cells have a crucial role in maintaining the regenerative capacity of tissues throughout the lifespan of the organism. With age comes a reduction in tissue renewal and repair upon injury. Understanding the mechanisms that maintain stem cell function could potentially lead to the development of therapeutic strategies to mitigate age-related tissue degeneration and improve healthspan. Of particular interest is understanding how stem cells deal with different types of stressors such as oxidative stress and bacterial stress.

To study this, we use the fruit fly *Drosophila* intestinal stem cells as a model system. Intestinal stem cells have a crucial role in regenerating lost intestinal cells after bacterial infection, oxidative stress, or normal cell attrition. Thus, intestinal stem cells are always sensing the gut environment and respond to cues by activating or repressing proliferation.

By studying the function of two conserved stress-sensing transcription factors, namely Nrf2/CncC and HSF1 in intestinal stem cells (ISCs), we have uncovered an unprecedented role of these genes in stem cell identity. RNAseq experiments done in ISCs revealed that individually Nrf2/CncC and Hsf1 can repress a group of genes involved in proliferation. Unexpectedly, we found that both *Nrf2/CncC* and *Hsf1* repress the enteroendocrine (EE)-specification gene *asense*. Immunohistochemistry experiments show that when both *Nrf2/CncC* and *Hsf1* genes are knocked down in ISCs there is a significant accumulation of EE progenitors. This accumulation of EE progenitors led to an early onset of aging-like phenotypes such as microbial dysbiosis, leaky gut, and reduced survival. These findings could shed light on the mechanisms altered during aging that contribute to stem cell misdifferentiation and microbial dysbiosis.

1877F **Discovery of Drug Response-Associated Mutations in Mucinous Metastatic Appendiceal Cancer Using a Patient-Derived Tumor Organoid Platform** Daniel J. Gironda[1,2], Steven D. Forsythe[1,2,3,4], Cecilia R. Schaaf[1,2,4], Richard A. Erali[2,5], Ashok K. Pullikuth[1,2], Ming Leung[2,6], Shay Soker[2,4], Edward A. Levine[2,5,6], Konstantinos A. Votanopoulos[2,4,5,6], Lance D. Miller[1,2,6] [1]Department of Cancer Biology, Wake Forest School of Medicine, [2]Wake Forest Organoid Research Center, Wake Forest School of Medicine, [3]Endocrine Oncology Branch, National Cancer Institute, [4]Wake Forest Institute for Regenerative Medicine, Wake Forest School of Medicine, [5]Department of Surgery, Wake Forest School of Medicine, [6]The Atrium Health Wake Forest Baptist Comprehensive Cancer Center, Wake Forest School of Medicine

Metastatic appendiceal cancer (mAC) is an aggressive orphan disease that affects ~1/100,000 patients in the U.S. every year. Clinically, mAC presents as multiple tumor lesions colonizing spatially distinct sites throughout the peritoneal cavity, with no group yet to assess the molecular heterogeneity between distinct metastases in regard to drug responsiveness. With

IRB approval, we created patient-derived tumor organoids (PTOs) from 17 mAC patients treated at our institution to model the role of intra-patient tumor heterogeneity on drug responsiveness. We performed PTO drug screening with standard chemotherapies (FOLFOX, FOLFIRI) to enrich for chemo-sensitive or -resistant tumor cell subclones. PTOs derived from anatomically distinct locations within the same patient and treated with equimolar doses of FOLFOX or FOLFIRI showed, in some instances, differential drug responses as measured by ATP release. We selected 17 tumors from 6 patients that demonstrated robust chemo-sensitivity or -resistance between treatments for downstream whole exome sequencing (WES). PTO DNA was extracted from 51 total treated PTO groups (vehicle, FOLFOX, FOLFIRI) and 6 corresponding saliva samples (healthy controls), analyzed for integrity and quantity, then analyzed by WES using the Illumina NextSeq 6000 platform. Resulting data were processed and analyzed for mutation calls using GATK and DRAGEN pipelines. The variant allele frequency (VAF) was quantified and compared between vehicle-treated and FOLFOX or FOLFIRI-treated PTOs- an increase in VAF post-treatment represented possible chemo-resistance, with decrease in VAF representative of possible chemo-sensitivity. Recurrent mutations solely associated with chemo-resistant PTOs and present in ≥67% (n=4/6) of our mAC patients were associated with impaired G-coupled protein receptor function, dysregulated Wnt signaling, inhibition of DNA damage repair, and inhibition of intrinsic apoptosis. Alterations exclusive to chemo-sensitive PTOs and present in ≥50% (n=3/6) of mAC patients include negative regulators of fatty acid metabolism, inducers of epithelial to mesenchymal transition (EMT), and repressors of t-cell invasion. These preliminary data suggest that the underlying biology of chemo-sensitivity or -resistance in mAC may be predicted through the PTO-modeled identification of recurrent mutations across inter- and intra-patient lesions. Follow up analyses on a larger cohort of mAC PTOs will be needed to validate these findings.

1878S **Topoisomerase 3b enhances stability of maternal mRNAs that are essential for neurodevelopment of progeny** Seung Kyu Lee, Amy Qiang, Aaron Park, Dimitrios Tsitsipatis, Yutong Xue, Tianyi Zhang, Showkat Dar, Weiping Shen, Jennifer Martindale, Myriam Gorospe, Emmanouil Maragkakis, Weidong Wang National Institute on Aging/NIH

Topoisomerase 3 beta (TOP3B) is the only dual-activity topoisomerase in eukaryotes that can change topology for both DNA and RNA. Current evidence suggests that TOP3B can facilitate transcription on DNA, in addition to translation and turnover of mRNAs. Top3b forms a complex with Tudor domain containing 3 (TDRD3), which interacts with the Fragile X Mental Retardation Protein (FMRP) to regulate mRNA translation in neurons. In humans, the *Top3b* mutation has been linked to schizophrenia, autism, and cognitive impairment, whereas TOP3B inactivation in mice results in reduced lifespan and abnormal neurodevelopment. However, the detailed mechanism of how Top3b contributes to mental health and which genes are regulated by TOP3B at DNA and RNA levels remain unclear.

During the quiescent period of ovarian development, the oocyte remains transcriptionally inactive, yet there is a decline in mRNA translation. In *Drosophila*, a fully matured oocyte can be maintained in a quiescent state by restricting nutrition and mating, which provides an ideal environment for studying mRNA stability and translation in the absence of transcription. Here, we employed the quiescent oocyte model to investigate whether and how TOP3B-TDRD3 complex facilitates translation or degradation of maternal RNAs in oocytes. Furthermore, we explored the intergenerational effect of Top3b on maternal RNA maintenance by assessing progeny development.

Our results demonstrate that *Drosophila* embryos derived from the $Top3b^{-/-}$ or $Tdrd3^{-/-}$ oocytes under normal nutrition conditions develop normally. Conversely, embryos derived from oocytes with extended quiescent period exhibit infertility and abnormal neurodevelopment, characterized by severe defects in the ventral nerve cord (CNS) formation. These phenotypes resemble those observed in the embryos from $fmr1^{RNAi}$ flies, suggesting that the TOP3B-TDRD3 complex functions similarly to FMRP in promoting zygotic neurodevelopment. Our RNA-seq analysis revealed that a subset of mRNAs undergoes increased degradation in quiescent $Top3b^{-/-}$ oocytes, suggesting that these mRNAs rely on TOP3B for their stability. Furthermore, the TOP3B-regulated mRNAs overlap with those regulated by FMRP, implying a coordinated role for TOP3B and FMRP in mRNA degradation. Notably, the poly(A) tail length of the RNAs from the quiescent $Top3b^{-/-}$ oocytes exhibited a significant reduction compared to WT or $Top3b^{-/-}$ under normal condition, suggesting that Top3b promotes RNA stability by maintaining the poly(A) tail length. Together, our findings support a model that the TOP3B-TDRD3 complex works with FMRP to regulate maternal mRNA degradation in oocytes, and this function is critical for normal neurodevelopment in embryos.

1879S **A germline organoid model of *Taeniopygia guttata* (zebra finch) Primordial Germ Cell (PGC) migration *in vitro*** Bianca Brown, Ajuni Takkar, Naomi Greengold, Chennai Kaminski, Mary Collins, Michael Sanchez, Taraji Ellington, John Bracht American University

Primordial germ cells (PGCs) comprise an undifferentiated stem cell population that give rise to gametes. Set side during embryonic development, PGCs must migrate through the developing embryo to their destination, the gonads. The process has been studied in mammals and fish, but not in birds due to the shelled embryo. We developed an *in vitro* culture system for the growth of *Taeniopygia guttata* (zebra finch) organoids and observation of PGC migration into these structures. Our ultimate

objective is to study the function of the germline-restricted chromosomes (GRCs), an accessory chromosome only found in the germ line.

1880T **Tissue-Specific DAF-2 Degradation extends the lifespan and healthspan of *C. elegans* males** Rose S Al-Saadi, Hannah B Lewack, Patrick C Phillips Biology, University of Oregon

Aging is a universal phenomenon experienced by nearly all multicellular organisms, representing the primary risk factor for multimorbidity, as well as many chronic and neurodegenerative diseases. However, our understanding of the molecular mechanisms contributing to healthy aging remains limited. The nematode *Caenorhabditis elegans* has emerged as a pivotal model organism for uncovering genes and genetic pathways that regulate aging. This includes the identification of the remarkably long-lived *daf-2* mutants. The male mating behavior of *C. elegans* serves as an excellent model for the study of healthspan, given its robust and neurologically complex nature. Notably, in males, *daf-2* mutants not only exhibit exceptional longevity but also an extension of their reproductive healthspan, as measured by their mating success. However, due to the ubiquitous expression of *daf-2*, pinpointing the specific tissues where it regulates lifespan and reproductive healthspan has proven challenging. Recently, usage of the auxin-induced degron (AID) system has enabled researchers to determine that the targeted degradation of DAF-2 in the intestine plays a significant role in extending lifespan without influencing development or reproduction in hermaphrodites. Additionally, degradation of DAF-2 in other tissues, such as neurons, germline, and hypodermis, showed a slight but significant extension of hermaphrodite lifespan. However, the potential sex-specific effects of this tissue-specific degradation on lifespan and reproductive healthspan have remained unexplored. To address this gap, we used DAF-2 AID strains targeting specific tissues to investigate the effects of tissue-specific DAF-2 degradation on lifespan and reproductive healthspan in males. Our findings indicate that the degradation of DAF-2 in all somatic tissues, but not a specific tissue type, extends reproductive healthspan. This somatic degradation, akin to what occurs in hermaphrodites, also significantly extends male lifespan. This project contributes to a deeper understanding of how genetic sex influences the aging process and age-related decline.

1881T **Sex-specific larval viability effects of mutations in *Drosophila melanogaster*** Rob H Melde[1], JoHanna Abraham[2], Maryn R Ugolini[2], Madison P Castle[2], Molly M Fjalstad[2], Daneila M Blumstein[2], Nathaniel Sharp[2] [1]Integrative Biology, University of Wisconsin Madison, [2]Genetics, University of Wisconsin Madison

Mutations persist in all populations. Every generation some new mutations will be introduced, and other existing mutations will be removed (selection). Since new mutations tend to be deleterious, the fitness of a population is always lower than theoretically expected (mutation load). Selection acting on traits that directly impact reproductive success (sexual selection) is thought to reduce the mutation load experienced by females. Sex-specific selection (selection acting differently on males and females) often overlaps with cases of sexual selection, however since not every life history trait is directly involved in reproductive success there may exist examples of sex-specific selection that fall outside of the scope of sexual selection. One such life history trait that may be larval viability since during early development many genes have sex-biased expression. Here, in an effort to better understand the evolution and maintenance of sex, we investigate sex-specific viability selection. To do this, we test whether specific mutations or mutations more generally show evidence for a sex-bias in their fitness effects on larval viability. To test whether specific mutations experience sex-specific viability selection we measured relative viability of eight phenotypically dominant marker mutations in *Drosophila melanogaster*. We find that 2/8 mutations show sex-biased larval viability effects, where females experience greater reductions in viability than males. We also find that averaged across sexes, 5/8 mutations significantly decrease viability, and one significantly increases viability. We also find that a recessive allele shows a sex-biased viability effect, with a significant decrease in males and no change in females. To test whether mutations more generally show sex-specific viability effects, we utilized mutagenesis to measure sex-specific viability of 33 genotypes containing many randomly induced mutations, relative to an unmutagenized strain. We find that mutations, on average, show sexually concordant viability effects, where they tend to decrease viability similarly in both males and females. Our results indicate that while viability selection on average is sexually concordant, certain specific mutations show sex-biased viability effects (in both directions). Here we provide novel evidence that sex-specific selection can act prior to adulthood by providing evidence of sex-biased fitness effects in multiple commonly used *Drosophila melanogaster* marker mutations. Future studies of sex differences in selection should not ignore the possibility of sex-specific selection prior to adulthood.

1882T **Tdrd5l promotes male identity in germline stem cells** Caitlin Pozmanter, Mark Van Doren Biology, Johns Hopkins University

Germline sex determination is regulated by a combination of signals from the somatic gonad, and germline autonomous sexual identity regulated by the RNA-binding protein Sex lethal (Sxl). Previously our lab identified *Tudor domain containing protein5-like (Tdrd5l)* as being important for male identity in the germline. Tudor-domain containing proteins are conserved across the animal kingdom for their necessary functions in germline development including post-transcriptional gene regulation. Tdrd5l is

expressed in the developing germ cells and GSCs in males but is repressed in female GSCs at least in part due to regulation by Sxl. Currently we are working to understand how Tdrd5l promotes male germline identity.

Tdrd5l mutant adult testes exhibit dramatic germline loss which is often seen in mutants for sex determination factors where the sex of the germline does not match the sex of the surrounding soma. One important regulator of germline sex determination is the JAK/STAT pathway, which promotes male germline identity but is repressed in female germ cells downstream of *Sxl*. Interestingly, *Tdrd5l* is also important for regulating germline JAK/STAT activity. In *Tdrd5l* mutants, male GSCs showed a reduction of Stat staining indicating a loss of JAK/STAT signaling. Another important signaling pathway active in the GSC niche is the BMP pathway. Our work shows that BMP signaling (pMAD) in GSCs is sexually dimorphic and is substantially higher in female GSCs compared to male GSCs. Loss of *Tdrd5l* in the male germline results in increased pMAD expression in male GSCs suggesting possible feminization of these cells. Further, expression of Tdrd5l in the female germline led to a decrease in GSC pMAD levels comparable to male GSC pMAD levels. Thus, these data support a model where *Sxl* and *Tdrd5l* act autonomously in the germline to regulate key signals from the somatic gonad acting through both the JAK/STAT and BMP pathways to control germline sexual identity. Tdrd5l localizes to a perinuclear body similar to, but distinct from, the nuage. Current work focuses on understanding the composition and function of the "Tdrd5l body" and how it influences signaling from the somatic gonad to the germline.

1883T **Female specific increased Insulin/insulin-like growth factor signaling pathway promotes increased body fat in *Drosophila* females than males** Puja Biswas, Colin Miller, Elizabeth Rideout Cellular and Physiological Sciences, University of British Columbia

Female flies store more body fat than males. While growing evidence suggests catabolic factors contribute to the sex difference in body fat by restricting male fat storage, less is known about the metabolic pathways that promote fat storage in females. Given its known role as a positive regulator of fat storage, we performed a detailed investigation of the insulin/insulin-like growth factor signaling pathway (IIS) in male and female adult flies. We found that mRNA levels of *Drosophila insulin-like peptides* (*dilps*) were higher in females, and that females had higher peripheral insulin sensitivity. IIS activity in the abdominal fat body was also higher in females than in males. To test whether increased IIS activity contributes to increased fat storage in female flies, we genetically ablated the insulin-producing cells (IPCs) in adult flies and measured body fat. IPC ablation significantly reduced body fat in females but not in males. In line with previous findings, females with ablated IPCs had decreased offspring production. Together, our data suggest that IIS activity is higher in females, and that this elevated activity contributes to the sex difference in body fat by promoting fat accumulation in females. This reveals previously unrecognized sex differences in IIS regulation, and identifies IIS as an additional metabolic pathway that contributes to the sex difference in body fat.

1884T **Y chromosome toxicity does not contribute to sex-specific differences in longevity** Renald Delanoue, Charlene Clot, Chloe Leray, Thomas Pihl, Bruno Hudry Institut de Biologie Valrose, Université Côte d›Azur, CNRS, Inserm

Men and women are phenotypically different. Height, weight, disease prevalence or life expectancy are sex-biased, but the origin of these differences is still not well understood. Some studies suggest that differences in longevity are due to the intrinsic presence of the sex chromosomes, and in particular due to the Y chromosome structure. A correlation between Y chromosome number and longevity was observed, since life expectancy is reduced in individuals with supernumerary Y chromosomes. In the animal kingdom, heterogametic sexes (the males in mammals or some insects, the females in birds or reptiles) have shorter lifespan, and this led to the hypothesis of a "toxic effect" of the Y (or W) chromosome. These chromosomes, mostly composed of simple repeated sequences and transposable elements, are transcriptionally silenced in large heterochromatic domains. In *Drosophila*, we measured that the Y chromosome represents 13% of the male genome and these large heterochromatin structures are absent in females. During aging, heterochromatin marks are lost, transposons become derepressed and transpose, potentially generating deleterious mutations and faster aging. It suggests that the Y chromosome-associated toxicity might impact the male physiology according to its size. This led us to test whether Y chromosome size has any consequences on sex-biased phenotypes and longevity. To this aim, we developed an innovative CRISPR/Cas9 strategy in *Drosophila* using gRNAs to target specific repeated sequences of the Y chromosome. With this method, we generated a library of Y chromosomes with different sizes or complete loss. Using this library in combination with a reporter gene, we demonstrated that the size of the Y chromosome can affect heterochromatin maintenance in the whole genome. However, we measured how Y chromosome presence or size modifies *Drosophila* lifespan and to our surprise, we revealed that the amount of Y chromosome heterochromatin does not change fly lifespan. The hypothesis of the Y chromosome-associated toxicity cannot explain sex differences in lifespan. Instead, we could show that sex-biased life expectancy is essentially controlled by the sex determination pathway itself, through the female-sex determinant, *transformer*.

1885T **Investigating the molecular basis of sex-biased brain aging in *Drosophila melanogaster*** Nathan Nigrin, Gunjan Singh, Kaitlyn Cortez, Kate O'Connor-Giles, Erica Larschan Brown University

Sex-biased aging differences, despite being widely observed in diverse species, are not well understood. Even further, there is a growing desire to understand the basis of the significantly sex-biased progression of aging and neurodegeneration in humans. To address this problem, we are investigating dosage compensation, the process in which X chromosome-linked genes are upregulated in XY males to equalize their expression to XX females, for a potential role in the aging brain. We have previously shown that dosage compensation is highly dysregulated in the aging male Drosophila brain and are thus interested in examining whether this process is linked to sex differences in aging phenotypes.

Methodologically, we investigate how the downregulation of MSL2, MLE, and CLAMP, required components of the dosage compensation complex (DCC) in Drosophila, may decrease lifespan in males, where the complex is normally active. We use a modified UAS-Gal4 system known as the geneswitch system to temporally control RNAi-mediated DCC component knockdown in adults, thus inhibiting dosage compensation. We then study these populations through survivorship assays, molecular techniques such as qPCR and western blots, and computational methods, including RNA-seq and ATAC-seq to assess sex-specific differences in aging brains. In a parallel approach, we are using the CRY2-blue light system to temporally inhibit MLE function, followed by assessment of differences in transcription, translation, and chromatin accessibility. Early results have indeed shown shortened lifespan in MLE-inhibited individuals; an exciting result as we move forward with our more mechanistic experiments.

Separately, we are measuring the role of histone modifications to Drosophila chromatin, which have been used to approximate age as an epigenetic "clock." H4K16ac chromatin marks are deposited by the DCC to modulate chromatin accessibility of X chromosome genes, and thus are an effective way of studying dosage compensation's impact on aging flies. We use both bulk histone proteomic methods and the genomic technique of CUT & RUN to measure the presence and localization of these histone acetylation marks on chromatin to elucidate any differences between male and female brains throughout normal aging. Overall, these experiments will bring us closer to an understanding of sex-based differences in aging, specifically in the brain.

1886T **GA binding transcription factor CLAMP regulates the dynamics of splicing condensates in *Drosophila*** Smriti Vaidyanathan, Mukulika Ray, Erica Larschan Department of Molecular Biology, Cell Biology, and Biochemistry, Brown University

Many RNA binding proteins (RBPs), part of the spliceosome complex, form nuclear condensates through phase separation. However, how spliceosome condensates are regulated and their impact on splicing function remains unclear. Furthermore, while extensive sex-specific splicing is reported in all organisms, the influence of the dynamics of spliceosome condensates on it remains unexplored. In this present study, we investigated the dynamics of Hrp38 (homologous to the human HnRNPA2B1 family protein), a splicing component involved in many human neurodegenerative disorders, in *Drosophila* larval tissues. Additionally, for the first time, we explored the dynamics of another conserved component of the spliceosome complex, RNA helicase A (MLE), and compared the dynamics of MLE and Hrp38 in sex-specific cells. An earlier study identified CLAMP (chromatin-linked adaptor for male-specific lethal proteins) as a transcription factor integral to *Drosophila* sex-specific splicing. CLAMP regulates splicing function via interactions with RBPs in spliceosomes, and our computational analysis revealed that CLAMP shares binding sites with many splicing-involved RBPs. CLAMP also undergoes phase seperation due to the presence of a PRLD domain. Therefore, we hypothesize that CLAMP sex-specifically regulates the function, behavior, and dynamics of RBP nuclear condensates. To investigate the role of CLAMP in the dynamics of MLE and Hrp38, we utilized *Drosophila* CLAMP mutant and CLAMP RNAi backgrounds and live-cell imaging techniques. We employed the software package TrackIt and developed a robust pipeline for image processing, particle detection, tracking, and data analysis to perform a quantitative analysis of the behavior of MLE and Hrp38 in nuclear condensates under different conditions. Our preliminary results suggest distinct differences in the dynamics of MLE and Hrp38 in nuclear condensates between female and male CLAMP mutant and wild-type samples. In conclusion, by combining live-cell imaging and computational analysis, we gain a deeper understanding of the dynamics of RBPs and their significance in gene regulation, offering potential avenues for future research in splicing mechanisms. Sex-based differentiation remains an area of ongoing research with significant implications for healthcare. Enhancing our insight into the regulation of sex-based differences in brain function and disease susceptibility has the potential to revolutionize healthcare across diverse populations.

1887T **Germline novelty through recurrent copy-number, protein, and regulatory evolution of the synaptonemal complex** Kevin Wei University of British Columbia

The synaptonemal complex (SC) is a protein-rich structure necessary to tether homologous chromosomes for meiotic recombination and faithful segregation. Despite being found in most major eukaryotic taxa implying a deep evolutionary origin, components of the complex can exhibit unusually high rates of sequence evolution, particularly in *Drosophila* where orthologs of several components could not be identified outside of the genus. To understand the cause of this paradoxical lack of conservation, we examine the evolutionary history of the SC in Drosophila, taking a comparative phylogenomic approach with

high species density to circumvent obscured homology due to rapid sequence evolution. We find that in addition to elevated rates of coding evolution due to recurrent and widespread positive selection, components of the SC, in particular the central element *cona* and transverse filament *c*(*3*)*G* have diversified through tandem and retro-duplications, repeatedly generating paralogs with novel germline functions. Strikingly, independent *c*(*3*)*G* duplicates under positive selection in separate lineages both evolved to have high testes expression and similar structural changes to the proteins, suggesting molecular convergence of novel function. In other instances of germline novelty, two *cona* derived paralogs were independently incorporated into testes- expressed lncRNA. Surprisingly, the expression of SC genes in the germline is exceedingly prone to change suggesting recurrent regulatory evolution which, in many species, resulted in high testes expression even though *Drosophila* males are achiasmic. Overall, our comprehensive study recapitulates the adaptive sequence evolution of several components of the SC, and further uncovers that the lack of conservation not only extends to other modalities including copy number, genomic locale, and germline regulation, it may also underlie repeated germline novelties especially in the testes. Given the unexpected and frequently elevated testes expression in a large number of species and the ancestor, we speculate that the function of SC genes in the male germline, while still poorly understood, may be a prime target of constant evolutionary pressures driving repeated adaptations and innovations.

1888T **The role of X chromosome dosage compensation during development** Océane Tournière[1], Seth Cheetham[2], Andrea Brand[3], Irene Miguel-Aliaga[4], Bruno Hudry[1] [1]Institut de biologie Valrose, Université Côte d'Azur, [2]Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, [3]Gurdon Institute, University of Cambridge, [4]The Francis Crick Institute

Sex chromosomes control sex determination in most organisms. For example, in mammals and Drosophila, females with two X chromosomes have twice the number of X-linked genes compared to males, who only have one dose. In flies, the activation of a dosage compensation complex in males ensures that the level of most of these genes' products is the same in both sexes. This process is critical for male survival because a lack of any protein of this complex results in male-specific lethality. Despite extensive characterisation of the molecular mechanisms driving dosage compensation, its physiological contexts and the reasons behind lethality remain unclear. The exact biological functions of dosage compensation, the developmental processes and X-linked genes sensitive to abnormal X dosage have not been isolated so far.

To identify the developmental stages and organs that require dosage compensation, we conducted tissue-specific experiments. Our screening process, involving 250 cell-specific lines, revealed that dosage compensation is necessary for male survival in one specific tissue - the tracheal cells at pupal stage. Using RNA-DamID, we mapped and compared the binding profiles of the dosage compensation complex in tracheal cells with those in organs where the complex is dispensable. This approach identified of a small set of X-linked genes compensated only in tracheal cells. We are currently restoring the dose of these candidates, one by one, to rescue tracheal-specific dosage compensation silencing and identify developmental processes behind dosage compensation lethality.

We identified the genes and cells and are studying the processes causing male lethality due to X chromosome imbalance. Our results provide insights into the causative mechanisms responsible for dosage compensation of the sex chromosomes.

1889T **Investigating the Origin of Prostate Macrophages through Genetic Lineage Tracing** Peri Wivell, Andrew Pletcher, Maho Shibata The George Washington University

Prostate tissues contain heterogeneous populations of immune cells. Published single-cell RNA sequencing data from mouse and human prostates show that macrophages constitute a large portion of immune cells in the prostate. Under disease conditions, different subsets of macrophages can either promote or resolve inflammation, causing tissue damage or aiding in tissue repair. Previously, it was believed that tissue-resident macrophages were maintained and repopulated by blood-circulating monocytes derived from progenitors in adult bone marrow (BM). More recent studies have revealed that several tissue-resident macrophage populations arise from embryonic precursors in the yolk sac (YS) or fetal liver (FL) prior to birth and continue to maintain themselves throughout adulthood independent from BM-derived precursors. We hypothesized that distinct populations of macrophages in the mouse prostate arise from embryonic origins and contribute to the heterogeneity of macrophages in the prostate. To identify embryonic origin macrophages in the mouse prostate, we genetically labeled macrophages using a yellow fluorescent protein (YFP) reporter mice. Prostate tissues containing lineage-labeled cells were then collected and characterized during different stages of postnatal organogenesis: prior to, during, and after puberty. Through immunohistochemical and immunofluorescence staining for YFP, macrophage marker F4/80 and proliferation marker Ki-67, we show that macrophages of embryonic origin exist in the prostate. Further, these cells proliferate locally within the prostate and remain in the tissue after puberty. Our findings suggest that tissue-specific macrophages of embryonic origin may function to regulate prostate organogenesis. Understanding the function of tissue-resident macrophages during normal prostate organogenesis and applying this knowledge to prostatic diseases such as benign prostatic hyperplasia will further

expand our understanding of immune cell dysregulation.

1890T **Why is there a *maleless* homologue in one of the homomorphic sex chromosomes of the *Aedes aegypti* mosquito?** Christen Hughes[1,2], Chujia Chen[3,4], Mark Potters[1,4], Zhijian Tu[3,4] [1]Biochemistry, Virginia Tech, [2]Fralin Life Sciences Institute, [3]Genetics Bioinformatics and Computational Biology Program, Virginia Tech, [4]Fralin Life Sciences Institute, Virginia Tech

The *Aedes aegypti* mosquito is a major vector for dengue, chikungunya, and Zika viruses. In contrast to *Drosophila melanogaster,*which has well-differentiated heteromorphic X and Y chromosomes, only small regions differ between the homomorphic sex-determining chromosomes in *A. aegypti,* and these regions are known as the M and m loci. There has been a concerted effort investigating the M locus which contains two genes *Nix* and *myo-sex*. *Nix* is the male determining factor and shown to masculinize females, and *myo-sex* is required for flight in males. Conversely, the m locus has not been extensively studied and the current m-locus assembly has 44 gaps within this 1.2Mb region. Our lab has generated a more continuous haplotype-resolved assembly. Within the newly assembled m locus, we identified a sequence that has a 65% amino acid identity to an autosomal orthologue of the *maleless* gene in *D. melanogaster* which encodes for an RNA helicase that is involved in dosage compensation. While dosage compensation is not expected in *A. aegypti*, the presence of an m locus *maleless* homologue (mMH) is of high interest. However, it is not clear whether mMH is a functional paralog of *maleless* or a pseudogene. We have preliminary evidence that mMH is present only on the m chromosome and it is transcribed in *A. aegypti* early embryos. We are determining the transcriptional profile of mMH and surveying its distribution in various strains of *A. aegypti*. We will investigate the function of mMH by knocking out mMH. This research will inform on sex determination within *A. aegypti*, which can be applied to sex ratio distortion efforts that decrease the ratio of biting females.

1891T **Identifying the sex determination gene *doublesex* in *Stiphra sp*. by degenerate PCR** Bailey Baratka[1], Stephen Madigosky[2], Alexis Nagengast[1] [1]Biochemistry, Widener University, [2]Biology, Widener University

Sex determination (SD) is the process that results in differences between males and females of a species initiated by chromosomal differences. Sex determination (SD) varies between species, but the similarities between the pathways can be examined using an evolutionary perspective. Extreme differences between male and females is known as sexual dimorphism and often found in insects. One of the best characterized SD pathways is in the fruit fly *Drosophila* and several gene products have been identified, such as *doublesex (dsx)*. The gene *dsx* has been found in multiple species of insects that are more distant in the evolutionary tree from fruit flies, such as beetles (Coleoptera). This is consistent with the hypothesis that the SD pathway evolved from the end of the pathway to the beginning. Jumping sticks (*Stiphra*) are more distant from fruit flies in the phylogenetic tree of insects than beetles. Therefore, we hypothesize that *dsx* will have sex-specific expression that results in the sexual dimorphism of jumping sticks. Previous work amplified genomic sequence with *Cyclommatus metallifer finae* (stag beetle) degenerate PCR primers and was concluded to not be *doublesex* sequence and showed that the DNA sample was contaminated. Therefore, new DNA was isolated from a female jumping stick and work is ongoing with newly designed primers to clone PCR products into *E. coli* before sequencing. This should allow for the isolation of dsx in an attempt to identify the SD pathway in jumping sticks.

1892F **Histone methyltransferases differentially regulate transcription and chromosome structure in oogenesis and spermatogenesis** Carolyn Remsburg[1], Lacole Fung[1], Lauren Salvitti[2], Aimee Jaramillo-Lambert[1] [1]Biological Sciences, University of Delaware, [2]Charles River Laboratory

Meiosis is the specialized cell division that results in the formation of haploid gametes from a diploid cell. During this process, duplicated chromosomes must undergo significant condensation and compaction before segregating into daughter cells. As defects in this process can result in aneuploidy, a leading cause of infertility and miscarriages, meiosis must be tightly regulated. Condensation and compaction are regulated by condensins, cohesins, and specific post-translational histone modifications, and there are sex-specific differences in this process. In *C. elegans,* bivalents at diakinesis (the last stage of prophase I) are significantly longer in oocytes than in sperm. Our lab identified two histone methyltransferases that differentially impact bivalent length in the male versus female germline. MET-2 catalyzes the dimethylation, and SET-25 catalyzes the trimethylation of histone H3 lysine 9 (H3K9me2 and H3K9me3). In *met-2* null worms, bivalent length during spermatogenesis is significantly shorter than in wild-type (WT); while in *met-2; set-25* worms bivalent length during spermatogenesis is significantly longer than in WT. Bivalent length during oogenesis in *met-2* worms is not significantly different than in WT worms. *met-2* and *met-2; set-25* worms have reduced brood sizes and embryonic viability compared to

WT, indicating that chromosome compaction contributes to gamete formation and quality. We also measured bivalent length in *him-17* mutant worms, as they have reduced H3K9me2 in both hermaphrodite and male gonads. Similar to *met-2*, bivalent length is shorter during spermatogenesis than in WT worms. However, shorter bivalents are also observed in oogenesis in *him-17* compared to WT. Immunolabeling showed that MET-2 localizes to germline nuclei through diplotene in hermaphrodites but remains localized through diakinesis in males. This suggests that MET-2 may function later during spermatogenesis than oogenesis. As H3K9 methylation is associated with transcriptional repression, we used immunolabeling for active RNA polymerase II (RNA pol II) to assay for global transcription. Results indicate germline nuclei in *met -2* males have more active RNA pol II during diplotene compared to WT indicating that changes in transcription may contribute to the reduction in brood size and embryonic viability. By dissecting the sex-specific regulation of chromosome structure and transcription during meiosis, we will elucidate key mechanisms of this essential process.

1893F **The impact of inter-organ communication on ovulation following traumatic injury in *Drosophila*** Cameron Dixon, Ethan Anderson, Kim McCall Biology, Boston University

Traumatic injuries (TIs) from intimate partner violence, vehicular collisions, high-impact sports, and even mundane activities can be fatal. However, survivors of TIs can have residual pathophysiological disturbances post-injury that lead to life altering conditions, including neurodegenerative diseases, mental illness, and metabolic disorders. Reproductive issues are a known consequence of TI especially in women, however this has remained poorly understood. These issues with reproduction are seen through menstrual cycle dysregulation, lower libido, decreased fertility, and increased rates of miscarriages. These consequences are not only localized at the time of the injury but can persist through the remainder of the individual's life. *Drosophila melanogaster* have recently emerged as a stellar model of TI due to relatively short lifespans, conservation of molecular/cellular cascades following injury response, and avoid many of the ethical dilemmas of using mammalian models. Reproductive consequences had not previously been tested using the *Drosophila* model and we have found that reproductive consequences are conserved. These reproductive consequences come in the form of decreased egg laying behavior and the retention of mature egg chambers, mimicking issues in ovulation. Investigation into the genetic and cellular mechanisms of these reproductive responses is underway. We hypothesize that hormonal disruption following TI leads to this change in egg laying and retention. Our recent data suggest that insulin may be the culprit for these reproductive issues. Insulin signaling and function is highly conserved in *Drosophila* and it has been shown that altered insulin production affects ovary health. Interestingly, patients who have undergone TI have higher rates of hyperglycemia and diabetes, implicating insulin disruption in humans following TI. These observations suggest that insulin is a prime candidate to be investigated further for its role in reproductive consequences following TI. Experiments are currently underway to tease apart which tissues are important for insulin expression for reproductive health and also how TI affects the expression profiles of other hormonal signaling pathways.

1894F **Using long-read sequencing data to analyze sex-based differences in alternative splicing in different species of *Drosophila*** Kinfe Bankole[1], Adalena V Nanni[2], Netanya Keil[1], Olga Barmina[3], Alison Morse[1], Ana Conesa[4], Lauren M McIntyre[1] [1]Molecular Genetics and Microbiology, University of Florida, [2]UPMC Genome Center, [3]University of California, Davis, [4]Institute for Integrative Systems Biology, Spanish National Research Council

Alternative splicing is a fundamental regulatory process. Alternative splicing results in structural differences between transcripts including: alternate donor/acceptor sites, alternate exon cassettes, intron retention, alterative transcription start sites and alternative polyadenylation sites. These different transcripts isoforms are now directly measurable due to advancements in long read sequencing technology. However, the variation in the observed transcripts from this technology poses a challenge in thinking about how best to quantify isoform expression from long reads. For protein coding genes, the structural differences between transcripts can be organized by the potential target protein. We develop an analytical approach that begins with raw long read data, then maps these reads to a reference annotation. Any transcripts with the same junctions are identified. We identify a set of possible similar proteins based on grouping transcripts that contain overlapping exons. We then determine whether the long-read transcripts are likely to make a protein in order to quantify isoform expression. Using this approach, we quantify gene and isoform expression in male and female head tissue for three species of *Drosophila*: *melanogaster*, *simulans*, and *serrata*, and identify conserved and divergent sex-specific isoforms.

1895F **Understanding the role of exosomes in competitive male reproductive success** Yoko A Takashima, Nora Brown, Alexandra Hoff, Ben R Hopkins, Andrew G Clark, Mariana F Wolfner Molecular Biology and Genetics, Cornell University

Male x female interactions at the behavioral, physiological, and molecular levels can profoundly influence the outcomes of mating encounters. In *Drosophila*, males transfer seminal fluid proteins (Sfps) and other factors to females, inducing physiological and behavioral changes known as the post-mating response (PMR). Disruption of Sfp production by the male impacts the female PMR in a way that reduces male reproductive success. Most factors responsible for the PMR are produced in the male accessory gland, a secretory epithelial tissue composed of two morphological cell types - main and secondary

cells. While only comprising 4% of the secretory cell tissue, secondary cells are essential for a male's reproductive success. In addition to synthesizing specific Sfps, these cells secrete exosomes, minute lipid-bound vesicles that encapsulate and transfer proteins and RNAs to the female and to sperm. We hypothesize that variation in exosome transfer among different genetic lines will impact sperm competition outcomes. We are exploring the natural variation of exosome production by immunofluorescent staining and confocal microscopy to quantify exosome abundances within wild-derived lines of flies such as the *Drosophila* Genetics Reference Panel (DGRP). With these techniques, we will utilize a genome-wide association (GWAS) approach to identify previously unknown genetic variants that impact exosome biology, with a particular focus on sperm competition outcomes. To extend this, we are developing a protocol to purify, quantify, and characterize exosomes and their cargo to dissect how exosome contents impact sperm competition outcomes.

1896F **The Role of Octopamine in *Drosophila* Exercise Response** Annie Backlund, Laura K Reed Biological Sciences, University of Alabama

Thirty four percent of people in the United States have metabolic syndrome: a cluster of symptoms such as obesity, high blood pressure, and insulin resistance. Metabolic syndrome greatly increases the chance of developing type-2 diabetes and heart disease, which are leading causes of death in the United States. Treatments for metabolic syndrome often include lifestyle changes such as increasing exercise; however, little is known about why males often exhibit greater adaptations to exercise than females in both humans and *Drosophila*. The Power Tower is a device that exercises flies by taking advantage of their negative geotaxis, which is a directional movement against gravity. Previous *Drosophila* studies have found octopamine to be essential for flies' adaptational response to chronic exercise training. Octopamine is a catecholamine found in invertebrates that is structurally and functionally similar to norepinephrine in humans. Norepinephrine acts as a hormone and neurotransmitter in the sympathetic "fight or flight" response to stress such as exercise. In humans, the nervous system releases epinephrine and norepinephrine in order to mobilize fuel substrates, increase blood pressure, and increase heart rate in order to meet the physiological demands of exercise. Several weeks of exercise training also increases an individual's capacity to secrete epinephrine/norepinephrine to more robustly respond to a stressful event. Previous studies have found that male flies exhibit a greater response to exercise than females due to differential expression of octopaminergic neurons. However, little work has been done that compares the sexes using multiple genetic lines. We will evaluate how males and females of several wild-derived genetic lines of *Drosophila* adapt to exercise and elucidate the role of octopamine in these responses. We will train several DGRP lines on the Power Tower and compare male and female climbing performance and time to fatigue before and after a two week long training program. Also, we will feed unexercised flies octopamine to better understand how this compound contributes to sex differences in response to exercise. We hypothesize that octopamine-fed flies will exhibit exercise adaptations even though they did not undergo the training program, and octopamine feeding will rescue females' exercise intolerance.

1897F **Quantifying the impact of biological sex and genetic background on the response to nickel toxicity using *Drosophila melanogaster*** Allie Hutchings, Jesse Petahtegoose, Alexis Okengwu, Claudia Taylor, Thomas Merritt Laurentian University

Females and males are biologically different. However, the sexual dimorphic effects we find in one genetic background, or genotype, may contrast in another. Taken together, both biological sex and genetic background work to provide broad scale conclusions of biological processes. In this study, we use the *Drosophila melanogaster* model system to compare both sexes of isogenic, genetically identical flies and wild caught, genetically diverse populations of flies to study the effects of nickel (Ni) toxicity on an organism-wide level. We use multiple isogenic lines to control for different genetic backgrounds and to compare sex differences. In contrast, we use wild-derived lines of flies to obtain generalized sex specific responses to stress that is more indicative of a natural population. We look at broad scale responses through mortality assays for both Ni toxicity and starvation, as well as more specific responses through enzyme activity, total lipid, and feeding assays post Ni exposure. In whole, we find that isogenic lines are more sensitive to stress than wild lines. Across the isogenic lines, our results clearly show that genetic background effects are significant but are more substantial across females than males. Furthermore, the sexual dimorphic effects are not consistent across genetic backgrounds. In fact, we find that in two isogenic backgrounds there are virtually no sex differences, whereas another line has an ~60% difference between males and females. Wild lines show less differences across lines but consistently found an ~55% difference between the sexes. Future work will utilize multiple metal contaminants to broaden our understanding of the metal interaction network. Overall, our results show that the magnitude of stress differs across both sex and genetic background, highlighting the importance of considering both in experimental design.

1898F **An Odorant-Binding Protein involved in courtship behaviour of *Drosophila melanogaster*** Enisa Aruçi[1], Stéphane Fraichard[2], Isabelle Chauvel[2], Lucie Moitrier[3], Jean-François Ferveur[2], Loïc Briand[3] [1]Cornell University, [2]University of Burgundy, [3]INRAe

Odorant binding proteins (OBPs) constitute a family of soluble carrier proteins mostly found in the sensillar lymph of

chemosensory hairs. They are not only involved in the chemoreception but also in several other function (Rihani *et al.*, 2021). In our project, we used *Drosophila melanogaster* as a model organism, to find a link between the presence of bacteria, the expression of OBPs and behavioural performance of flies. More particularly, we investigated the expression of OBP56d, present in the adult chemosensory system and in the gut, and we measured the influence on reproductive-related behaviours. We used both *in vitro* and *in vivo* approaches to characterize several aspects pertaining to OBP expression in adult gustatory appendages, gut and reproductive organs.

To carry out this project, we analysed by quantitative reverse transcription-polymerase chain reaction (RTq-PCR) the expression profiles of this OBP in different body parts (thorax, head, and intestine) in males and females. These flies were exposed to fasting periods of various durations. Beside its expression in distinct regions of the gut, and in the proboscis, it was also detected in male reproductive organs suggesting that it could be involved both in nutrition and reproduction. The effect of OBP56d was studied on female and male courtship behaviours by using OBP56d mutant and control drosophila w^{118}. Our data showed a decrease of mating by 33% between mutant drosophila (55%) and w^{118} (88%). We observed mating between mutant female/male and w^{118} female/male. The decrease of mating between mutant female and w^{118} male was by 47%. On the other hand, mutant male and w^{118} female had nearly the same percentage of mating like the controls one (85%). Also, we used competitive fluorescence binding assay to determine its binding properties to a broad panel of potential ligands.

Based on this data, we can conclude that the absence of OBP56d has an impact on female behaviour during mating. As we know, the recognition between members or cells of the opposite sex is an important ingredient in the success of mating and our findings indicate that OBP56d may be implicated in perception of chemical signal during mating.

1899F **Investigating how germline sexual identity controls sex-specific gene expression** Harrison Curnutte, Mark Van Doren Biology, Johns Hopkins University

In nature, animal species often exhibit sexual dimorphism, or differences in morphology and behavior between sexes. An important difference between the sexes are the gonads, the testis and ovary, which produce the sperm and egg necessary for sexual reproduction. In order to develop proper gametes, both the germ cells and the somatic cells of the gonad must decide their sexual identity. The RNA binding protein Sex lethal (Sxl) has been shown to be a master regulator of somatic sex determination and is expressed based on the presence of two X chromosomes in the female as opposed to one in the male. Sxl is also important in the germline, where it is both necessary and sufficient for female germline identity. However, autonomous sex determination downstream of Sxl is not well characterized in the germline. Interestingly, germline sex determination has also been shown to be regulated in a non-autonomous manner via somatic signals. How sex determination in the germline is regulated by a combination of autonomous cues, downstream of *Sxl*, and non-autonomous cues, based on somatic cell signaling, is unknown and of great interest to the field.

A key aspect of sex determination is the control of sex-specific gene expression, about which little is known in the germline. We will use expression of *Tdrd5l* (Tudor domain-containing protein 5-like) as a model for understanding sex-specific gene expression. Tdrd5l is expressed in a male-specific manner in the early germline and is important for male germline sexual identity. *Tdrd5l* RNA and protein are initially expressed in the embryonic germline of both sexes, but subsequently become male-specific by an unknown mechanism. At the third larval instar (L3) stage, Tdrd5l protein and RNA are both absent from female germ cells while they remain highly expressed in males, suggesting possible transcriptional regulation. Surprisingly, we have found that sex-specific expression of *Tdrd5l* RNA in developing germ cells is independent of *Sxl*. Additionally, we have found that a male soma is sufficient to drive expression of *Tdrd5l* RNA in female germ cells. However, *Tdrd5l* is regulated independently of JAK/STAT signaling, which is a key male-specific signal regulating germline gene expression. Altogether, our study of *Tdrd5l* regulation indicates that a previously unidentified signal from the somatic gonad to the germline regulates sex-specific germline gene expression and we are currently studying the nature of this signal.

1900F **A fitness analysis of *OdsH* in *Drosophila* using selection with two alleles of X-linkage** Sha Sun[1,2], Chau-Ti Ting[2,3], Chung-I Wu[2,4] [1]Univ California, Irvine, [2]University of Chicago, [3]National Taiwan University, [4]Sun Yat-sen University

In organisms with the XY sex-determination system, there is an imbalance in the inheritance and transmission of the X chromosome between males and females. Unlike an autosomal gene, an X-linked recessive gene in a female will have phenotypic effects on its male counterpart. Thus, genes located on the X chromosome are of particular interest to researchers in molecular evolution and genetics. Here we present a model for selection with two alleles of X-linkage to understand evolutionary forces acting on genes on the X chromosome. This model was applied to the fitness analysis of an X-linked gene, OdsH, in the fruit fly *Drosophila melanogaster*. We introduced a site-specific sequence modification into the *OdsH* locus that was easily identified by an eye color marker gene. In a laboratory population setting, after twenty generations of fitness competition, two genetically modified *OdsH* variants displayed a 40% difference in allele frequencies. Using maximum likelihood estimation (MLE), we determined the fitness components of the *OdsH* alleles separately in males and females,

including viability and fertility effects. Results of the analysis indicate that the two *OdsH* gene variants show a fitness difference, and that sex-specific fertility and viability effects are both contributing factors to selection on an X-linked gene.

1901F **Transcriptomics analysis of allergen-induced inflammatory gene expression in the Four-Core Genotype mouse model** Carolyn Damilola Ekpruke[1], Rachel Alford[1], Dustin Rousselle[1], Maksat Babayev[1], Shikha Sharma[1], Sarah Commodore[1], Aaron Buechlein[2], Douglas Brandt Rusch[2], Patricia Silveyra[1] [1]Environmental and Occupational Health, Indiana University Bloomington, [2]Indiana University Bloomington

Sex differences in allergic inflammation have been reported, but the mechanisms underlying these differences remain unknown. Contributions of both sex hormones and sex-related genes to these mechanisms have been previously suggested in clinical and animal studies. Here, Four Core Genotypes (FCG) mouse model was used to study the inflammatory response to house dust mite (HDM) challenge and identify differentially expressed genes (DEGs) and regulatory pathways in lung tissue. Briefly, adult mice (8-10 weeks old) of the FCG (XXM, XXF, XYM, XYF) were challenged intranasally with 25µg of HDM or vehicle (PBS-control group) 5 days/week for 5 weeks (n=3/10group). At 72 hours after the last exposure, we analyzed the eosinophils and neutrophils in the bronchoalveolar lavage (BAL) of FCG mice. We extracted lung tissue and determined DEGs using Templated Oligo-Sequencing (TempO-Seq). DEGs analysis was performed using the DESeq2 package and gene enrichment analysis was done using Ingenuity Pathway Analysis. A total of 2,863 DEGs were identified in the FCG. Results revealed increased eosinophilia and neutrophilia in the HDM-treated group with the most significantly expressed genes in XYF phenotype and a predominant effect of female hormones vs. chromosomes. Regardless of the sex hormones, mice with female chromosomes had more downregulated genes in the HDM group but this was reversed in the control group. Interestingly, genes associated with inflammatory responses were overrepresented in the XXM and XYF genotypes treated with HDM. Sex hormones and chromosomes contribute to inflammatory responses to HDM challenge, with female hormones exerting a predominant effect mediated by inflammatory DEGs.

1902F **Loss of a postmeiotically expressed X to autosome retrogene, *Phf8l*, results in male subfertility** Ivan F Mier, Martin F Arlt, Jacob L Mueller Human Genetics, University of Michigan

X to autosomal retrogene copies are primarily thought to compensate for meiotic sex chromosome inactivation (MSCI), the silencing of X- and Y-linked genes. Here we report a copy of the X-linked gene *Phf8,* that retrotransposed to an autosome in *Muridae* (*Phf8l)* and acquired postmeiotic-specific expression. In *Peromyscus*, *Phf8l* transposed to the Y Chromosome (*Phf8y)*, massively amplified (~140 copies), and retained postmeiotic-specific expression. The specific expression of *Phf8l,* and *Phf8y* in postmeiotic haploid sperm cells suggests these lineage-specific genes have a role in male fertility. Using CRISPR/Cas9 we generated *Phf8l* $^{-/-}$ mice, and used existing *Phf8* $^{-/Y}$ mice, to study the roles of *Phf8l* and *Phf8* in male fertility. *Phf8l* $^{-/-}$ mice have reduced fecundity. In *Phf8l* $^{-/-}$ *Phf8* $^{-/Y}$ mice, 5S rRNA gene expression is highly upregulated in the testis, indicating PHF8 and PHF8L potentially repress postmeiotic 5S rRNA transcription. We find PHF8L directly interacts with FAM178b and ZFP318, which may facilitate target 5S rRNA repression. Our studies of *Phf8l* and *Phf8* highlight the importance of studying autosomal retrogenes with postmeiotic gene expression in addition to those that compensate for MSCI.

1903F **The Integration Institute: Sex, Aging, Genomics, and Evolution (IISAGE)** Ellie Duan[1], Peggy R Biga[2], Anne Bronikowski[3], Tony Gamble[4], Erica Larschan[5], Richard Meisel[6], Ritambhara Singh[5], James Walters[7], Ashley Webb[8], Gerald Wilkinson[9], Nicole Riddle[2] [1]Cornell University, [2]The University of Alabama at Birmingham, [3]Michigan State University, [4]Marquette University, [5]Brown University, [6]University of Houston, [7]The University of Kansas, [8]buck institute, [9]University of Maryland

In many animals, aging shows sex-specific patterns, often with one sex aging faster or having a shorter lifespan. What causes the diverse patterns of sex-specific aging across the animal kingdom is unknown. The IISAGE Biology Integration Institute will determine how diverse biological processes contribute to sex differences in aging and uncover their evolutionary history. IISAGE will bring together expertise from across biology to identify the molecular mechanisms and generalizable rules that govern differences in aging between females and males. We will test hypotheses focused on differences between females and males in genome architecture, organismal biology, and phenotypic plasticity to understand differences in aging. IISAGE will define how processes at the molecular, organismal, and population level interact to generate sex differences in aging. IISAGE will produce novel analysis tools and hundreds of matched datasets profiling gene expression and chromatin in dozens of species, including several Drosophila species, houseflies, and lepidoptera. By integrating across disciplines, approaches, and levels of biological organization, IISAGE will develop predictive models for how genome architecture, organismal biology, and phenotypic plasticity can interact and lead to differences in aging. Integrated with its scientific mission, IISAGE's training, education, and outreach program will increase diversity in STEM and prepare trainees to work in diverse careers and in multidisciplinary teams. The IISAGE summer program will engage > 50 undergraduates from groups underrepresented in STEM. A citizen science project will engage pet owners and K-12 students to collect data for IISAGE scientific goals.

1904F **Exploring the hippocampal transcriptome following perturbations of locally synthesized estrogen in the zebra finch (Taeniopygia guttata)** Rebecca Andrade[1], Yvette M Nau[2], Zoe Joy[1], Elaina Bashaw[1], John Bracht[2] [1]Neuroscience, American University, [2]Biology, American University

The conversion of testosterone, which circulates at high levels in males, into estradiol (E2), which circulates at high levels in the female, via aromatization occurs in many tissues including the brain in several vertebrates. In songbirds, the hippocampus (HP) a telencephalic structure critical for learning and memory, is a major site of E2 synthesis where aromatase is readily detectable in both sexes. In the HP, aromatase is abundant at synaptic loci and is surprisingly sparse in other neuronal compartments. Decreases in local E2 synthesis via the aromatase inhibitor 1,4,6-Androstatriene-3,17-dione (ATD) in the zebra finch (*Taeniopygia guttata*) HP impairs spatial memory performance such as seen in HP-lesioned birds, Aromatase inhibition with concomitant E2 replacement restores memory function back to control levels, suggesting that local synaptic aromatization may be a crucial modulator of memory function in songbirds. The genomic mechanisms underlying these observations, however, are unknown. This project seeks to understand the transcriptional changes that contribute to the poor spatial memory performance in male and female zebra finches lacking E2 in the HP by studying three hippocampal treatment groups: positive control, ATD, and ATD with E2 replacement. Using weighted gene correlation network analysis (WGCNA), the project centers around identifying gene clusters within RNAseq data (Illumina) across the treatment groups outlined above, revealing genes that systematically change under variations in the endocrine environment through the presence or absence of E2.

This research was supported by NSF grant IOS 2050260

1905S **Early-life exercise in Drosophila alleviates the sex-specific divergence of aging-associated gene expression in thorax muscle tissue** Eric C Randolph[1,2], Peggy R Biga[1], Nicole C Riddle[1] [1]Biology, University of Alabama at Birmingham, [2]University of Alabama at Birmingham

Transcriptional differences associated with aging are common in muscle tissue. Muscles also alter transcription in response to exercise irrespective of age. Exercise therefore has the potential to affect transcriptional differences associated with aging in muscle tissue. The optimal intensity, duration, frequency, and age at which exercise has the greatest effect on aging-related transcriptional differences are currently unknown. Available data suggest that there might be sex-specific responses to exercise. *Drosophila melanogaster* is an ideal model to investigate exercise effects as Drosophila are sexually dimorphic, have a short lifespan, are commonly used to study molecular mechanisms of aging, and share many physiological responses to exercise with humans. This study investigates sex-specific differences in transcriptional responses to early-life exercise in Drosophila muscle tissue. We will determine whether these gene expression responses persist to later ages or influence transcriptional differences associated with aging in adult flies.

We collected transcriptome data from wild-type male and female Drosophila that were either non-exercised or exercised for 2 hours/day for 5 days early in life. Flies were sampled at two time points, young (8 days) and old (54 days). Transcriptome analysis focused on the thorax to define gene expression differences in muscle tissue between sexes in both age and exercise. A principal component analysis indicated a clear separation of gene expression profiles between sexes along the PC1 axis, indicating sex as the largest determinant in gene expression differences. Thorax tissue from non-exercised flies showed 244 differentially expressed genes (DEGs) associated with aging in females, 189 DEGs in males, and 52 shared DEGs indicating the presence of sex-specific transcriptional differences associated with aging. Directly after early-life exercise, thorax muscle tissue showed 116 DEGs associated with exercise in females, 39 DEGs in males, and 5 shared DEGs indicating sex-specific responses to exercise. DEGs associated with aging were reduced more than half in thorax tissue from exercised files with females showing 84 DEGs, 87 DEGs in males, and 10 shared DEGs. Thus, early life exercise in Drosophila appears to reduce sex-specific transcriptional differences associated with aging in thorax tissue. Studying gene regulation differences between sexes during aging provides insights into genetic influences on sex-specific aging.

1906S **Genetic control of mating plug ejection timing in *Drosophila melanogaster*** Rachel M J Craig, Bianca M Villanueva, Jolie Carlisle, Adriana Andrus, Mikaela Matera-Vatnick, Dawn S Chen, David Cabello, Andrew G Clark, Mariana F Wolfner Cornell University

Although it would seem that males and females both benefit by cooperating to maximize offspring number, competition between male and female reproductive strategies can lead to sexual conflict, which in turn can drive rapid diversification of genes mediating reproductive processes. In *Drosophila*, female flies can manipulate the parental contributions of males by controlling the number of sperm stored from a mating. The “mating plug” (MP), which forms in the uterus of the female via coagulation of ejaculated seminal fluid proteins (Sfps) and four female proteins, is a contributor to this process. Rapid ejection of the MP prevents sperm retention, while delayed ejection of the MP increases the number of sperm that can be stored. However, nothing is known about the molecules (male or female) that modulate MP ejection (MPE) rates, and how those

molecules may interact to control that modulation. Using the *Drosophila* Genetic Reference Panel, we measured the mean times of MPE across many female genetic backgrounds. We then performed a genome wide association study to identify candidate genes that may influence MPE, which revealed a large number of neuronal genes and genes involved in oogenesis. We are beginning to test the neuronal candidate genes by using RNAi KD to determine their role in mating plug ejection. Additionally, we determined using neural network predictions that several of the neuronal candidates may be in a network with each other. Using daughters of Tudor flies, which lack a germline, compared to genetically matched flies with a germline, we were able to determine that oogenesis influences MPE timing as well, and we have begun to investigate this connection further using other known oogenesis mutants. Finally, we have begun to genetically examine the roles of MP Sfps on MPE timing.

1907S **Geographic origin and sleep patterns predict disease outcomes in *Drosophila melanogaster*** Mintong Nan[1], Jonathan Wang[2], Raymond St. Leger[1] [1]Entomology, University of Maryland, [2]Sarepta Therapeutics

Given the diversity in disease outcomes, even among closely related individuals, there is an urgent need to examine how defense is linked with other aspects of host physiology. The overall goal of this study was to employ *Metarhizium anisopliae* 549-*Drosophila* as a model system to examine how environmental and genetic factors influence fly survival across different biomes, as well as interactions between fungal infection, sleep, and host defense. We showed that resistance to Ma549 varies by sex and place of origin, with males and African lines usually being more resistant, and correlated with sleep parameters. Both the mean climate and climate extremes at collection sites, particularly tropical sites, were associated with disease resistance in the laboratory. Using representative fly lines, we found that daytime sickness sleep increased within the first two days post infection with Ma549, particularly in males of a line that were very resistant. Host defenses are linked to circadian rhythms in living organisms. Disrupted circadian rhythm can thus influence disease outcomes. Here, we employed a well-characterized sleep-deprived *Drosophila Shaker* mutant with intact circadian rhythms to confirm that sickness sleep contributes to enhanced survival. We also used two mutants with disrupted circadian clock-controlled genes to examine the role of the clock in activity and sickness sleep after Ma549 infection. Our data demonstrate that *period* and *Shaker* genes protect against disease, whereas active *ClkJrk* reduces survival in infected *Drosophila*.

1908S **Male Meiotic X Chromosome Inactivation in X-A Translocations and its Implications for Sperm Viability in *Drosophila*** Camila C Avelino[1,2], Timothy L Karr[1], Maria D Vibranovski[2,3] [1]Biodesign Institute, Arizona State University, [2]Department of Genetics and Evolutionary Biology, University of Sao Paulo, [3]School of Mathematical and Natural Sciences, New College of Interdisciplinary Arts and Sciences, ASU, Arizona State University

Chromosomal translocations between the X chromosome and autosomes frequently underlie male infertility in various species, including *Drosophila.* This phenomenon is closely linked to the regulatory process known as Meiotic Sex Chromosome Inactivation (MSCI). Our recent research has revealed that the loss of RNA polymerase II activity during the final stages of meiosis I on the X results in their inactivation. However, it remains uncertain whether this inactivation is chromosomally associated or if it is tied to a specific nuclear territory where these chromosomes are recruited to. In an effort to investigate those hypotheses and understand the causes of male infertility in *Drosophila*, this study employed *Drosophila melanogaster*'s lineages bearing X-autosomal 2nd chromosome translocations, both fertile and infertile, to examine the transcriptional activity of translocated chromosomes at different spermatogenic stages and to analyze their impact on sperm structures. Utilizing multi-color fluorescent in situ hybridization (FISH) probes in *Drosophila* brain cells, our investigation revealed that sterile males exhibited reciprocal translocations involving the euchromatic regions of the X and 2nd chromosomes. Conversely, within the fertile lineage, we observed non-reciprocal translocation, with the euchromatic region of the 2nd chromosome relocating to the X chromosome, leaving the latter chromosome intact. In male meiotic cells of sterile lineages, the translocated portion of the X chromosome was found within the autosomal territory, indicating that male infertility is a consequence of regulatory changes deriving from the X chromosome›s relocation to a different chromosomal territory. In contrast, the other relocation involving the autosomal 2nd chromosome did not produce the same effect, as confirmed through double immunofluorescence-FISH analysis. We also found in the late spermatogenic stages the fertile strain had multiple compacted spermatid bundles and individualization complexes whereas in the infertile strains, there were scattered spermatid nuclei and a few Individualization complexes, besides no mature sperms in the seminal vesicle. This study elucidates that X chromosome inactivation is subject to territorial-level regulation, and the recruitment of the X chromosome into an autosomal territory significantly impacts male fertility.

1909S **Mass spectrometry revealed sexual dimorphism in response to cancer** Anindita Barua[1], Fei Cong[1], Yang Tang[2], Xiaowen Liu[2], Wu-Min Deng[1] [1]Biochemistry and Molecular Biology, Tulane University, Louisiana Cancer Research Center, [2]Biomedical Informatics and Genomics, Tulane University, New Orleans Bioinnovation Center

Sex disparities in cancer incidences and mortality is an ongoing quest. Genetic mutation leading to cancer, responses to

carcinogens, cancer prognosis or diagnosis, response, or resistance to chemotherapy, all controlled in a sex-specific manner. It necessitates exploring the key factors and signaling pathways fueling the sexual dimorphism in cancer. Our study uses the *Drosophila* tumor model to investigate the sex-specific response to cancer and how it contributes to changing signaling pathways, thus enhancing tumor growth. Previously, our lab induced primary tumors in the larval salivary gland transition zone (TZ) by constitutively expressing the Notch intracellular domain (NICD) under the retn-gal4 driver. In the current study, we injected the primary tumor in the w^{1118} fly abdomen, where the tumor proliferates and develops into a first-generation tumor mass. *Drosophila* lifespan depends on many factors, and tumor injection causes aging and a significant lifespan reduction. Generally, a control female without a tumor lives ~ 49 days, and a control male lives ~ 43 days. However, with tumors, both sexes live ~32 days, a comparable mortality age. It indicates a disproportionately increased aging in female tumor hosts compared to male, showing sex-specific differences in cancer/tumor response. To investigate the differences at the proteomic level, we performed mass spectrometry (MS) on the whole fly tissue collected after ten days of tumor injection. We removed the tumor from the host abdomen prior to MS. MS identified 834 differentially expressed proteins (DEPs) between the tumor injected and control female, but only 539 DEPs for males. The data further reveals only 166 upregulated and 71 downregulated DEPs shared between males and females, thus indicating a distinct sex-specific response to tumors in the *Drosophila* model. The Gene ontology (GO) reveals DEPs to be associated with metabolic and innate immune pathways, pointing to a possible area to focus on for elucidating the differential responses to cancer based on sex.

1910S **Characterizing the Role of Doublesex in Creating Sexual Dimorphism in the Somatic Gonad** Natalie A Murphy, Samantha C Goetting, Jose Pac Cordero, Mark Van Doren Biology, Johns Hopkins University

Doublesex (Dsx) and Mab-3 Related Transcription factors (DMRTs) are paramount for sex determination across the animal kingdom. In flies, Dsx, like mammalian Dmrt1, is first expressed in the somatic gonad during embryogenesis, and is required for male vs. female gonad development. There are two Dsx isoforms – Dsx^F in females and Dsx^M in males – which have the same DNA binding domain but regulate their targets differently to yield sexual dimorphism. Bioinformatic analyses were used to predict Dsx targets; many of the top hits were transcription factors containing BTB (Broad-complex, Tramtrack, and Bric-a-brac) domain(s), which promote homo- and hetero-dimerization of BTB proteins. BTB domain transcription factors are important for gonad development in both the male and female, including *bab1/2*, *chinmo*, *fru*, and *mamo*. An *RNAi* screen of BTB domain transcription factors recapitulated these results and revealed another factor worth further characterization: *lola* (*longitudinals lacking*).

lola has a multitude of differentially spliced isoforms and has many putative Dsx binding sites along the entire length of the gene. Previous studies have shown isoform-specific roles in proper somatic gonadal precursor (SGP) coalescence during embryonic gonad formation as well as roles in adult somatic niche cells (terminal filaments/cap cells and cyst stem cells, in the females and males, respectively). We are curious if there are additional sex-specific roles and/or expression of certain *lola* isoforms. In the larval ovary, *lola* knock-down via the somatic driver c587 caused disorganization of the intermingled cells and the terminal filaments – interestingly, this phenotype appears to be a combination of both *bab* and *mamo* phenotypes. In the larval testis, *lola* knock-down produced an expanded “DAPI bright” zone of less differentiated germ cells. However, there appeared to be a decrease in the number of less differentiated (i.e., zfh1-positive) cyst cells/cyst stem cells.

Given these data, we hypothesize that *lola* is regulated by Dsx and plays an important role in both male and female somatic cell fate. It may be interacting with other BTB domain proteins (*mamo* and *bab1/2* in the female; *chinmo* in the male) to create the sexual dimorphism of the ovary and testis. Ultimately, we aim to expand the current knowledge on how DMRTs control sexual dimorphism and elucidate genetic interactions critical for sexual identity in both flies and mammals.

1911S **Investigating the spreading mechanism of the MSL Dosage Compensation Complex on the X chromosome.** Arthur Langford[1], Mitzi I Kuroda[2,3], Janel Cabrera[1] [1]Biology, Emmanuel College, [2]Medicine, Brigham and Women’s Hospital, [3]Genetics, Harvard Medical School

While previous research has made progress in characterizing the specific proteins that participate in gene activating complexes, the overall mechanism of how they interact with chromatin targets to induce gene activation is not well understood. Therefore, to further investigate their behavior, we utilized the Dosage Compensation Complex (DCC) as a model for studying interactions between gene activating complexes and their gene targets. The DCC is responsible for upregulating transcription of X-linked genes in male Drosophila by two-fold during dosage compensation to compensate for the dosage differences of such genes between males and females. There are two main theories proposed for how the DCC carries out dosage compensation: a sequence-dependent or sequence-independent manner. To determine the course of action taken by the DCC during dosage compensation, we developed Drosophila mutants lacking copies of the endogenous MSL2 gene, which encodes for the MSL2 DCC protein component, and delivered MSL2 back to such flies at gradual time points during early

development using a heat shock/FLP-FRT recombinase system. In this fly system, the spread of the DCC on chromatin can now be analyzed using immunostainings and in situ hybridizations. We hypothesize that the DCC carries out dosage compensation and spreads across the X chromosome in a sequence-independent manner. This model can be used to investigate the potential method of action taken by regulatory protein complexes in order to activate genes and offer insight on how they may become compromised in human diseases.

1912S **Knockout of highly conserved SFP ablates male fertility** Dominic Hockenbury[1], Yasir Hashim Ahmed-Braimah[2] [1]Center for Reproductive Evolution, Syracuse University, [2]Center for Reproductive Evolution, Biology, Syracuse University

In *Drosophila,* seminal fluid proteins (SFPs) are key components of the male ejaculate and are essential determiners of reproductive fitness. SFPs are required for fertility as well as inducing a range of post mating physiological responses in females. To date nearly 300 SFPs have been identified, however the vast majority of these remain uncharacterized and their role in reproduction and/or postcopulatory sexual selection is not clear. SFPs are functionally diverse and contain proteins from a variety of biochemical processes, most notably proteases and protease inhibitors that are thought to be critically important in biochemical interactions with female proteins. Another class of proteins that is enriched among SFPs are carbohydrate bonding proteins, presumably involved in glycolytic reactions within the accessory glands and in mated females. However, the molecular mechanisms and fertility roles of these ejaculate glycolysis modulators have yet to be explored. One of these uncharacterized glycolysis SFPs is the highly conserved *beta*-glucoronidase (*CG15117*), which catalyzes the breakdown of complex carbohydrates. *CG15117* is (1) predominately expressed in the male accessory gland—but maintains low level expression in other tissues, (2) is transferred to the female during mating, and (3) is one of the most conserved SFPs in *Drosophila.* To identify CG15117's role in reproduction, we created a CRISPR/Cas-9 knockout mutant by ablating 5 bp from the coding sequence and introducing a premature stop codon. We found that CG15117 is required for male fertility: females that are mated to knockout males do not produce progeny, fail to store sperm and will readily remate, suggesting that an ensemble of key postcopulatory processes is disrupted. To further examine the molecular basis of this male sterility we performed label-free quantitative proteomic analysis and bulk RNA sequencing on mutant males as well as females mated to mutant and control males and find systematic abnormal abundance of several proteins—including some SFPs— in the accessory glands and in the transferred male ejaculate. Our results show that the often-ignored carbohydrate metabolism proteins that are part of the seminal plasma are essential for fertility in *Drosophila*.

1913S **Temporal transcriptomics identifies sexually dimorphic trajectories during mouse adrenal gland postnatal development** Ben Maggard, Yuan Kang, Hui Wang, Chen-Che Jeff Huang Auburn University

The primary aim of this research is to elucidate the genetic expression patterns throughout the postnatal development of the mouse (Mus musculus) adrenal gland at a genome-wide level. Employing RNA sequencing (RNA-seq) coupled with bioinformatics analysis, we aim to identify potential genes and pathways steering the maturation of this pivotal endocrine organ. RNAs from whole adrenal glands in wild-type mice were extracted at postnatal days (P) 0, 7, 15, 21, 28, 35, and 49, with a minimum of three data points analyzed at each developmental stage. Each data point comprises the adrenal glands of 3-4 mice, and the extracted RNAs underwent paired-end RNA-seq analysis through a commercial service provider. Results revealed a notable increase in the expression of most differentially expressed genes (DEGs) from P0 to P7. The construction of a heatmap encompassing all DEGs unveiled gene clusters contributing to the sexual dimorphism observed in the adrenal gland transcriptome during early postnatal development. Notably, genes within these clusters exhibited an age-dependent sexual dimorphism commencing from P28. Gene ontology analysis indicated that, at P0, DEGs between males and females were associated with gene expression regulation, particularly histone demethylation. Conversely, DEGs at subsequent developmental stages were linked to the specific functions of the adrenal gland. Notably, many of these gene ontology terms were related to lipid metabolism, encompassing processes such as steroid biosynthesis, fatty acid metabolism, and monocarboxylic acid catabolism. This suggests the presence of a sexually dimorphic lipid metabolism in the mouse adrenal gland.

1914S **Consequences of variable escape from X inactivation in humans** Carrie Zhu, Jared Cole, Arbel Harpak The University of Texas at Austin

In humans, X chromosome inactivation substantially reduces gene expression from the "inactive" X (Xi). While inactivation is usually thought of as absolute—with escape from inactivation being a rare exception—recent work exposed surprising variation in Xi expression levels across genes, tissues and individuals. We investigated the consequences of variation in Xi expression for sex differences and within-sex variation.

First, we show that in non-recombining regions, and across 13 tissues examined, Xi expression levels estimated from a single individual linearly predict sex differences in gene expression remarkably well. We conclude that continuous variation in Xi

expression is the major driver of sex differences in expression in the non-recombining X, with only a minor role for variation in Xi expression among individuals and compensatory regulatory mechanisms. In contrast, in the pseudoautosomal region, Xi expression and sex differences were entirely uncorrelated.

Second, we show that variation in Xi expression across genes has a surprisingly small effect on variation in gene expression within females. We develop theoretical predictions for the contribution of X-linked regulatory genetic variation to heritability differences between males and females, and fit it to eQTL and GWAS data in genes of variable Xi expression. With few exceptions, the strong fit to the data further supports a small role of other compensatory mechanisms.

Overall, our results demonstrate that the continuous variation in Xi expression is a key factor underlying sex differences in humans.

1915S **Understanding Sex Determination in African Clawed Frogs (*Xenopus)*** Sarah Porter[1], Lindsey Kukoly[2], Caroline Cauret[2], Danielle Jordan[3], Benjamin Evans[2], Richard Behringer[4], Marko Horb[1] [1]Eugene Bell Center for Regenerative Biology and Tissue Engineering, Marine Biological Laboratory, [2]Biology, McMaster University, [3]School of Biological Sciences, University of Aberdeen, [4]Genetics, University of Texas MD Anderson Cancer Center

In amphibians there is great diversity among species in the genetic mechanisms by which sex determination is achieved. For example, considerable variation exists in whether males or females are heterogametic (and thus whether there are XY/XX or ZW/ZZ sex chromosomes). In African clawed frogs (*Xenopus*), all known species have female heterogamy, however the location of the sex chromosomes varies significantly. *Xenopus* species lack diverged sex chromosomes and instead possess sex determining loci located on different autosomes. Most *Xenopus* species display a ZZ/ZW system, where the female is the heterogametic sex. Within the *Xenopus* genus, we focused on two species: *X. laevis* and *X. tropicalis*. *X. laevis* are tetraploids, which possess L and S allo-alleles. The sex determining locus for this species has been identified as W chromosome and is located on chromosome 2L. Located within this region, the gene *dm-w*, determines female sex by inhibiting the expression of dmrt1(which is responsible for male sex determination). Comparatively, *X. tropicalis* is a diploid organism, where chromosome 7 is believed to possess the sex determining loci. X*. tropicalis* lacks *dm-w* altogether and it is unknown if there is a single sex determining gene responsible for the female sex in this species. I will present our efforts of using CRISPR-Cas9 techniques to study the mechanistic aspects of how genetic sex determination functions and evolves in *Xenopus*. Moreover, several other *Xenopus* mutants have been generated (*amh, foxl2, dmrt1, ccdc69w, scanw, dmw & ar)* to assess their involvement in sex determination. We aim to use knockout mutants and gene expression techniques to develop a comparative framework in which to better understand how the genetic basis of sex determination systems have evolved and function within the model species, *Xenopus*.

1916S **Sexually dimorphic Atf4 expression and activity control adipose tissue physiology** Lydia Grmai[1], Melissa Mychalczuk[2], Aditya Arkalgud[1], Deepika Vasudevan[1] [1]Cell Biology, University of Pittsburgh, [2]Biochemistry, Molecular, and Cell Biology, Cornell University

Metabolic differences between males and females have been well documented across many species. However, the molecular basis of these differences and how they impact tolerance to nutrient deprivation is still under investigation. In this work, we use *Drosophila melanogaster* to demonstrate that sex-specific differences in fat tissue metabolism are driven, in part, by dimorphic expression of the Integrated Stress Response (ISR) transcription factor, Atf4. We found that female fat tissues have higher Atf4 activity than their male counter parts under homeostatic conditions. This dimorphism was partly due to a female bias in *Atf4* transcript abundance in fat tissues and driven by canonical sex determinants: masculinization of female fat tissues via depletion of the sex determinant *transformer* alters the relative abundance of *Atf4* splice isoforms. These differences persist under stress conditions, where female fat tissues show substantially higher Atf4 induction than males in a genetic model of nutrient deprivation, indicating that higher Atf4 activity confers higher tolerance to nutrient deprivation in females. Finally, we demonstrate that dimorphic ISR activity in fat tissues confers a metabolic advantage that increases stress tolerance into adulthood: genetic induction of nutrient deprivation caused developmental lethality specifically in males. We are currently testing the dependence of this sex-specific viability defect on ISR pathway activation. Together, our data describe a previously unknown facet of ISR signaling wherein sexual identity of adipose tissue confers differential stress tolerance in males and females. Future work will investigate functional differences between Atf4 isoforms and how they inform sex differences in fat tissues. Since Atf4 promotes cellular function and survival under homeostasis and stress, our studies will shed light on how sexual identity influences metabolism in both homeostasis and disease.

1917V **The between-sex multivariate genetic architecture acts as a constraint to the evolution of sex-difference in contemporary humans** Anasuya Chakrabarty[1], Saikat Chakraborty[2], Diptarup Nandi[3], Analabha Basu[1] [1]National Institute of Biomedical Genomics, [2]GSK India, [3]Azim Premji University

Sex-difference (SD) is ubiquitous in humans despite a shared genetic architecture between the sexes. In human genetics, SD is usually studied by estimating the between-sex genetic correlation (r_{mf}) of traits (e.g., correlation between height in males and females). But inspecting SD in single traits does not provide a complete biological overview, because traits are not independent and are genetically coupled. One way to circumvent this is to investigate the multivariate genetic architecture of the sexes by estimating the multivariate counterpart of r_{mf}, the **B** matrix which contains the between-sex genetic covariances in the diagonal and the between-sex-between-trait genetic covariances (e.g., covariance between height in males and weight in females) in the off-diagonals. **B** is indirectly shaped by sex-specific selection and is decisive in the evolution of SD as it can constrain or facilitate the independent divergence of the sexes. Though investigating **B** is common in other animals, there has been a dearth of such studies in humans. Using such a multivariate approach, we investigated SD in the genetic architecture of 12 anthropometric, fat depositional, and sex-hormonal phenotypes in humans from publicly available GWAS summary statistics of the UK Biobank under a LD score regression framework. We found that the sexes not only have a different genetic architecture, but intriguingly the directions of most of the between-sex-between-trait covariances were opposite, most prominently between testosterone and the anthropometric traits. Testosterone is closely associated with fitness in males, and BMI (anthropometric) is an indicator of obesity which has ramifications in many complex disorders. We estimated an overwhelming number of negative genetic correlations, 28 out of 66 pairs in between-sex-between-trait, which indicates sexual antagonism in humans. We found **B** to be asymmetric which indicates difference in the underlying genetic architecture between the sexes. Furthermore, **B** did not act as a genetic constraint to the predicted divergence between the sexes in response to simulated concordant random selection gradients. In contrast, **B** substantially reduced the predicted divergence between males and females when randomised selection vectors were antagonistic. Though we found sexual antagonism in our study, the evolution of SD under sexually antagonistic selection in contemporary humans would be constrained by the multivariate between-sex genetic architecture.

1918V **Genetic and behavioural correlates of a male-specific aging phenotype in Drosophila hypocausta** Lauren Kovacik[1], Kevin Wei[2] [1]University of British Columbia, [2]University of Bristish Columbia

Drosophila has long been a model system for understanding the genetic and evolutionary mechanisms underlying sexual dimorphism in color patterns. We identified a unique sexual dimorphic phenotype in Drosophila hypocausta, in which the males dramatically darken as they age, while females remain pale. This species offers a unique system to understand the interaction between sexual dimorphism, sex-specific aging, and sexual selection. To uncover the genetic architecture of age- and sex-dependent coloration differences, we collected RNA-seq data from males and females of increasing age (3, 10, and >25 days old); male-specific gene expression either increased or decreased over time. Using various statistical and graphical techniques, 3 genes were identified that are significantly differentially expressed between the sexes and ages, including the body coloration gene yellow which shows a staggering 128-fold decrease in expression between young and old males. These genes are strong candidates that require further exploration, starting with a knockout of yellow using CRISPR-Cas9. To understand the purpose of this darkening phenotype, we hypothesize that it acts as a signal for sexual maturity thus conferring selective advantage in aged males through increased mating success. Supporting this possibility, we find that older and darker males consistently have higher mating success in female mate-choice assays. Additional behavioural assays are currently underway to differentiate between female preference versus male sexual maturity and elucidate other age-dependent behaviours.

1919T **Antifungal killer toxins from yeasts - discovery and their application in craft breweries.** Victor Zhong[1], Nicholas Ketchum[2], Ximena Garcia[1], Paul A Rowley[3] [1]University of Idaho, [2]Rhinegeist Brewery, [3]Biological Sciences, University of Idaho

Secondary fermentation of beer by diastatic strains of *Saccharomyces cerevisiae* can result in undesirable consequences, such as off-flavors, increased alcohol content, hyperattenuation, gushing, and the spontaneous explosion of packaging. Many strains of *Saccharomyces* yeasts can naturally produce proteinaceous “killer” toxins that inhibit the growth of competing yeasts. We recently completed a comprehensive study of killer toxin production by 1,270 *S. cerevisiae* strains and found that 50% produce killer toxins. This large collection of 638 diverse killer yeasts has enabled the discovery of killer toxins that can prevent the growth of diastatic yeasts. Specifically, 90% and 71% of diastatic strains are susceptible to the K1 and K2 killer toxins, respectively. This screening approach also identified a novel polymorphic K2 toxin that effectively inhibited K1-resistant diastatic yeasts. Adding killer yeasts to a simulated industrial-scale contamination event by diastatic yeasts successfully prevented hyperattenuation. Craft breweries can only safeguard against diastatic yeast contamination by using selective culturing methods or PCR to detect diastatic yeasts, followed by the destruction of contaminated products. Using killer yeasts in brewing offers a novel approach to safeguard against product loss and to remediate contaminated craft beers due to diastatic yeast contamination.

1920T **The Effect of Long Non-coding RNA Expression on Vitamin E Concentration in Maize Grain** Morgan A Apolonio[1], Sam Herr[2], Michael A Gore[2] [1]University of California, Berkeley, [2]Cornell University

Tocochromanols are a group of antioxidants synthesized in plant tissues and have varying levels of vitamin E activity, but tocochromanols with the highest vitamin E activity tend to occur at low levels in maize grain. In efforts to increase tocochromanol abundance in maize grain, Transcriptome-Wide Association Studies (TWAS) have been used to resolve quantitative trait loci (QTL) associated with grain tocochromanol concentrations to the gene level. While the causal loci underlying most of the large-effect QTL have been identified, relatively smaller effect QTL remain unresolved. Our past efforts have not explored the potential role of long non-coding RNAs (lncRNA), which are transcripts longer than 200 bp that do not encode a protein, in the genetic control of natural variation for tocochromanols in maize grain. Therefore, we hypothesize that lncRNAs could account for a portion of the unexplained genetic variation. We tested this hypothesis by conducting a new TWAS analysis in a maize association panel scored for lncRNA expression and grain tocochromanol levels. Nearly 20% of the identified lncRNAs were expressed in more than 10% of the individuals in the panel and were retained for the TWAS analysis. Of these, we found thirteen putative lncRNAs to be significantly associated with tocochromanols and of which four coincided with unresolved grain tocochromanol QTL identified in the maize nested association mapping panel. Our results highlight that including lncRNAs may be useful in resolving vitamin E-associated QTL in maize grain.

1921T **Breeding of high iron and zinc and grain yield under abiotic stress conditions, supporting enhanced maize biofortification** Tesfaye TW Mekonnen, Maryke MT Labuschagne, Angeline AV van Biljon Plant Sciences, University of the Free State

Breeding of high iron and zinc and grain yield under abiotic stress conditions, supporting enhanced maize biofortification

Abstract

Maize is a crucial staple food crop in Sub-Saharan Africa, particularly for low-income households. However, the combined threats of heat and drought stress have significantly reduced the yield potential of biofortified maize, resulting in macro and micronutrient deficiencies among the population relying on maize-based diets. To address this issue, the study aimed to investigate the correlation between biofortified inbred lines and hybrid performance in terms of nutritional attributes, such as iron (Fe), zinc (Zn), and protein, under combined heat and drought stress conditions. The experiment was conducted at CIMMYT in Zimbabwe, using an α-lattice design with three replications. A total of 77 crosses and seven parents, chosen for their zinc, iron, and provitamin A traits, were evaluated under abiotic stress conditions. The findings revealed that the hybrid effect significantly impacted various nutritional attributes, including zein fractions, Zn, Fe, phytic acid, and grain yield. Under combined heat and drought stress conditions, the hybrids' Fe, Zn, and grain yield concentrations significantly decreased. However, zein fractions and phytic acid content in the grains increased under stress conditions. There was a strong positive correlation between grain yield and the concentrations of Zn and Fe, particularly under combined stress conditions. This investigation confirmed that developing high-yielding maize varieties with enhanced micronutrient content is possible under combined heat and drought stress conditions. This finding is significant as it provides a potential solution to reduce micronutrient deficiencies in Sub-Saharan Africa. The study concluded that developing high-yielding maize varieties with increased micronutrient content is possible under combined heat and drought stress conditions. Furthermore, the positive correlation between grain yield and the concentrations of Fe and Zn suggests that hybrids.

Keywords: Drought, Fe, Heat, Maize, Protein, Zein fractions, Zn

1922F **Adaptation to hatchery conditions in the threatened westslope cutthroat trout (*Oncorhynchus clarkii lewisi*)** Ylenia Chiari[1], Leif Howard[2], Scott Relyea[3], James Dunnigan[3], Matthew C Boyer[4], Gordon Luikart[2] [1]Biology, George Mason University, [2]Flathead Lake Biological Station, Montana Conservation Genomics Laboratory, Division of Biological Science, University of Montana, [3]Sekokini Springs Hatchery, Montana Fish Wildlife and Parks, [4]Montana Fish Wildlife and Parks

Hatcheries play a crucial role as a substantial resource investment, offering a valuable tool to enhance angling opportunities and support the conservation of native fish. In addressing the imperative to conserve native fish, it becomes crucial to understand the degree to which the artificial production process affects survival and fitness of hatchery fish that are released into the wild. Hatchery may differ from natural environments in terms of crowding, light, temperature, diet, and competition, as well as exposure to pathogens and predators. Fish born and raised in hatchery until they reach a size suitable for release into the wild may adapt to the hatchery's specific conditions and potentially be maladapted to the natural environment where they are released. In this work, we have tested for adaptation to hatchery conditions in westslope cutthroat trout

(*Oncorhynchus clarkii lewisi*) and assessed if this adaptation persists once fish from the hatchery are re-introduced into the wild. To this purpose, we have genotyped through RAD-capture and obtained RNASeq from fish sampled from wild populations, fry generated from fish from these populations that were reared and spawned at Sekokini Springs hatchery, and from fish from the wild populations where the fry from the hatchery was released. We then tested for genetic (variation in allele frequencies obtained using more than 1000 SNPs) and epigenetic (differences in DNA methylation) adaptation affecting gene expression between natural, hatchery, and released fry. Our results will not only be useful for guiding conservation aquaculture practices at Sekokini Springs hatchery to enhance native trout restoration efforts, but will also further our understanding of rapid adaptation to captivity conditions.

1923F **Early-life fecal transplantation from high muscle yield rainbow trout to low muscle yield recipients accelerates somatic growth through respiratory and mitochondrial efficiency modulation.** Guglielmo Raymo University of Maryland

Previous studies conducted in our lab revealed microbial assemblages to vary significantly between high (ARS-FY-H) and low-fillet-yield (ARS-FY-L) genetic lines in adult rainbow trout. We hypothesized that a high ARS-FY-H donor microbiome can accelerate somatic growth in microbiome-depleted rainbow trout larvae of the ARS-FY-L line. Germ-depleted larvae of low ARS-FY-L line trout reared in sterile environments were exposed to high or low-fillet yield-derived microbiomes starting at first feeding for 27 weeks. Despite weight-normalized diets, somatic mass was significantly increased in larvae receiving high fillet yield microbiome cocktails at 27 weeks post-hatch. RNA-seq from fish tails reveals enrichment in NADH dehydrogenase activity, oxygen carrier, hemoglobin complex, gas transport, and respiratory pathways in high fillet-yield recolonized larvae. Transcriptome interrogation suggests a relationship between electron transport chain inputs and body weight assimilation, mediated by the gut microbiome. These findings suggest that microbiome payload originating from high fillet yield adult donors primarily accelerates juvenile somatic mass assimilation through respiratory and mitochondrial input modulation. Further microbiome studies are warranted to assess how increasing beneficial microbial taxa could be a basis for formulating appropriate pre-, pro-, or post-biotics in the form of feed additives and lead to fecal transplantation protocols for accelerated feed conversion and fillet yield in aquaculture.

1924F **Cross-species Regulatory Network Analysis Identifies FOXO1 and the Circadian Clock as Drivers of Ovarian Follicular Recruitment** Ashley Kramer[1], Alberto Berral González[2], Kathryn Ellwood[3], Shanshan Ding[3], Javier De Las Rivas[2,2], Aditya Dutta[3] [1]Animal and Food Science, University of Delaware, [2]University of Salamanca, [3]University of Delaware

The laying hen ovary undergoes a complex process of follicular development, comprising primordial, primary, pre-recruitment, and pre-ovulatory stages. Transition to the pre-ovulatory stage is vital for successful ovulation. Although several differentially expressed genes (DEGs) have been identified in these stages, understanding the master regulators orchestrating gene expression changes remains incomplete. Here, we employ master regulator analysis (MRA) to identify key transcription factors controlling DEGs in pre-recruitment and pre-ovulatory follicles. Samples for RNA-seq were obtained from these stages and DEGs were determined. Subsequently, an ARACNe network analysis integrating human ovarian TCGA data with hen ovarian DEGs was performed, which was consequently used in the MRA to identify key transcription factors (TFs) using VIPER. Notably, FOXO1, known for its role in apoptosis and cell cycle regulation, emerged as a critical TF affecting the WNT/beta-catenin pathway. BHLHE40 and CLOCK were identified as regulators of the circadian rhythm, critical for the egg-laying cycle. RT-qPCR validation confirmed the upregulation of BHLHE40 and CLOCK, implicating their roles in regulating the pre-ovulatory stage. The downregulation of FOXO1, FST, and other TFs in the pre-ovulatory stage indicated their involvement in follicular development and hormone regulation. This study provides key insights into the regulatory mechanisms of follicular development in laying hens, offering a comprehensive understanding of the pivotal role of FOXO1 in mediating apoptosis and the regulatory roles of BHLHE40 and CLOCK in circadian rhythms. Understanding these master regulators will be crucial for unraveling the complex molecular processes governing ovulation and reproductive success in laying hens.

1925F **Identification of genetic and environmental factors influencing aerial root traits that support biological nitrogen fixation in sorghum** Wilfred Vermerris[1,2], Emily S.A. Wolf[3], Saddie Vela[3], Jennifer Wilker[4], Alyssa Davis[1], Madalen Robert[5], Rafael Venado[4], Catalin Voiniciuc[5], Jean-Michel Ané[4,6] [1]Microbiology & Cell Science, University of Florida, [2]UF Genetics Institute, University of Florida, [3]Plant Molecular & Cellular Biology, University of Florida, [4]Bacteriology, University of Wisconsin, [5]Horticultural Sciences, University of Florida, [6]Agronomy, University of Wisconsin

Biological nitrogen fixation (BNF) refers to the process by which symbiotic microorganisms reduce nitrogen from the air to ammonium that they make available to their host plants. Crop plants able to obtain a portion of their nitrogen needs via BNF require less nitrogen fertilizer, which contributes to more sustainable agricultural practice. Select accessions of the cereal crop sorghum (*Sorghum bicolor* (L.) Moench) form mucilage-producing aerial roots that harbor nitrogen-fixing bacteria. We performed a genome-wide association study (GWAS) of the sorghum minicore, a collection of 242 landraces, and 30 accessions from the sorghum association panel (SAP) in two locations (Florida and Wisconsin), under a standard or

reduced level of fertilizer, with the goal of identifying loci associated with the number of nodes with aerial roots and aerial root diameter. Sequence variation near genes encoding transcription factors that control phytohormone signaling and root system architecture showed significant associations with these traits. In addition, the location had a significant effect on the phenotypes. Concurrently, we developed an F2 population from crosses between bioenergy sorghums and a landrace that produced extensive aerial roots to evaluate the mode of inheritance of the loci identified by the GWAS. Furthermore, the mucilage collected from aerial roots contained polysaccharides rich in galactose, arabinose, and fucose, whose composition displayed minimal variation among 10 genotypes and the two fertilizer treatments. These combined results illustrate the benefit of allele mining, support the development of sorghums with the ability to acquire a substantial portion of their nitrogen needs via BNF, and provide insights in the mechanisms of BNF in other grasses.

1926S **Bacillus amyloliquefaciens modulate sugar metabolism to mitigate arsenic toxicity in Oryza sativa L. var Saryu-52** Harshita Joshi, Shashank Kumar Mishra Microbial Technologies, CSIR-NBRI

In the current study, plant growth-promoting rhizobacterium Bacillus amyloliquefaciens SN13 (SN13) was evaluated for arsenic (As) toxicity amelioration potential under arsenate (AsV) and arsenite (AsIII) stress exposed to rice (Oryza sativa var Saryu-52) plants for 15 days. The PGPR-mediated alleviation of As toxicity was demonstrated by modulated measures such as proline, total soluble sugar, malondialdehyde content, enzymatic status, relative water content, and electrolytic leakage in treated rice seedlings under arsenic-stressed conditions as compared to the respective control. SN13 inoculation not only improved the agronomic traits but also modulated the micronutrient concentrations (Fe, Mo, Zn, Cu, and Co). The desirable results were obtained due to a significant decrease in the AsIII and AsV accumulation in the shoot (47 and 10 mg kg−1 dw), and the root (62 and 26 mg kg−1 dw) in B. amyloliquefaciens inoculated seedlings as compared to their uninoculated root (98 and 43 mg kg−1 dw) and shoot (57 and 12 mg kg−1 dw), respectively. Further, metabolome (GC-MS) analysis was performed to decipher the underlying PGPR-induced mechanisms under arsenic stress. A total of 67 distinct metabolites were identified, which influence the metabolic and physiological factors to modulate the As stress. The expression analysis of metabolism- and stress-responsive genes further proclaimed the involvement of SN13 through modulating the carbohydrate metabolism in rice seedlings, to enable improved growth and As stress tolerance.

1927S **De novo transcriptome assembly of 7 California native plant species** Savanah M. Senn[1], Gerald Presley[2], Steven Carrell[3], Meika Best[1], Les Vion[1], Matthew Kostoglou[1], John Hsieh[1], Adrianna L. Bowerman[1], Karu D. Smith[1], Daila Melendez[1,4] [1]Agriculture, LA Pierce College, [2]Wood Science & Engineering, Oregon State University, [3]Center for Quantitative Life Sciences, Oregon State University, [4]Horticulture, Oregon State University

How do plants in semi-arid environments respond to biotic and abiotic stress? In this study, we created transcriptomic resources for *Quercus agrifolia, Eriodictyon crassifolium, Trichostema lanatum, Dendromecon rigida, Artemisia californica, Arctostaphylos glauc*a, and *Ribes malvaceum* from the Angeles National Forest to facilitate inquiry.

During May 2022, snap frozen plant tissue samples for RNA sequencing were collected. Library prep was performed by BGI Americas and samples were sequenced on the DNBSeq platform. QC was performed with SOAPnuke. The trancriptomes were assembled in Trinity and assessed with BUSCO. Transcripts were quantified with salmon, and Trinotate was used for annotation. DE analysis was carried out in R DESeq2 for replicated *Quercus agrifolia* samples in different fire history areas of the Gold Creek Preserve.

The most complete assemblies were *Quercus agrifolia* (96.18% complete), *Dendromecon rigida* (95.44% complete), and *Eriodictyon californicum* (94.88% complete).

In oak tree leaves, there were elevated transcripts for myrcene synthase on the Red Trail and elevated geraniol-8 hydroxylase activity on the Green Trail. Elevated amounts of secondary metabolites could be influenced by light, temperature, herbivores, pathogens, or abiotic stress.

In the contrast between oak gene expression on the Green Trail vs. the Blue Trail, there was elevated myrcene synthase and isoprenoid biosynthetic activity on the Blue Trail, and elevated elevated triterpenoid synthesis activity on the Green Trail. It would be expected from the literature that the elevated isoprenoid biosynthetic process would occur in the most sun-exposed area of the Green Trail, however the transcripts related to the biosynthetic process were elevated on the Blue Trail.

Regarding antioxidants, in the contrast of the Red Trail vs. the Green Trail, Shikhimate/ Quinate dehydrogenase was higher on the Green Trail. In the contrast between the Green and Blue Trail, transcripts for Phylloquinone biosynthetic process were higher on the Green Trail. In the contrast between the Red Trail and Blue Trail, hydroquinone biosynthetic process transcripts

were higher on the Blue Trail, whereas Shikhimate/ quinate dehydratase and 3-dehydroxyquinate dehydratase/ shikhimate dehydrogenase transcripts were abundant on the Red Trail.

In the contrast between oak gene expression on the Red Trail vs. Green Trail, Malectin-like domain transcripts were higher on the Green Trail. Adenylate cyclase/ putative disease resistance protein was higher in oak transcripts from the Red Trail. Phosphatidylinositol phospholipase C /response to bacterium was higher on the Red Trail.

Our findings indicated that in *Quercus agrifolia,* there was differential expression of genes related to plant defense, antioxidants, and terpene synthesis. Elevation and the presence of potential pathogens are expected to be contributing factors.

1928S **Genetic characterization of a wild emmer by hard winter wheat backcross population** John Hill Price[1], Mary J Guttieri[1], Eduard Akhunov[2], Moses Nyine[2] [1]HWWGRU, USDA-ARS, [2]Dept. of Plant Pathology, Kansas State University

Wild emmer (*Triticum turgidum* subsp. dicoccoides), the tetraploid progenitor of hexaploid bread wheat (*Triticum aestivum*), is an important source of biotic and abiotic stress resistance in wheat breeding. However, a lack of domestication traits or regional adaptation to major bread wheat growing regions has hindered the use of this species in breeding for agronomic or end-use quality traits. To help address this gap, as well as to accelerate efforts to incorporate stress tolerance and disease resistance into elite wheat germplasm, we have developed a backcross introgression population, consisting of a diverse set of 25 wild emmer accessions crossed to a set of six elite hard winter wheat lines adapted to the US Central Great Plains. Here, we present an assessment of the length and distribution of introgression segments in this population, frequency of recombination events across the genome, and the frequency of aneuploid events in this interspecific cross, characterized using whole genome skim-sequencing. Additionally, we discuss early measurements of phenotypic diversity in this population, and identify several traits for which this population will contribute useful diversity into US wheat germplasm.

1929S **Optimizing expected cross value for genetic introgression- smart crossing design with whole-genome functional genomic knowledge** Pouya Ahadi[1], Balabhaskar Balasundaram[2], Juan Borrero[2], Charles Chen[3] [1]H. Milton Stewart School of Industrial and Systems Engineering, Georgia Institute of Technology, [2]School of Industrial Engineering and Management, Oklahoma State University, [3]Biochemistry and Molecular Biology, Oklahoma State University

In plant and animal breeding, the pursuit of superior phenotypes is essential to meet the breeding objectives of enhanced productivity, increased financial returns, improved welfare, and reduced environmental impact. Traditionally, these breeding goals are achieved by identifying the individuals with desirable traits and crossing them to create the segregation of phenotypes in a new generation that allows further selection for advancement.

In this study, we address the mate selection problem in the hybridization stage of a breeding pipeline, which constitutes the multi-objective breeding goal key to the performance of a variety development program. The solution framework we formulate here seeks to ensure that individuals with the most desirable genomic characteristics are selected to cross, allowing for maximizing the likelihood of the inheritance of desirable genetic materials to the progeny. Unlike approaches that use phenotypic values for parental selection and evaluate individuals separately, or a few genetic markers, we use a criterion that employs the genetic architecture of target traits, considering the segregation and combination of the genomic information of the pair of individuals.

We, here, introduce the expected cross value (ECV) criterion, which quantifies the expected number of desirable alleles for a gamete produced by two selected individuals of the base population, providing a comprehensive assessment of all genetic potential. We have developed an integer linear programming formulation for this parental selection problem using the ECV criterion. The formulation is capable of controlling the inbreeding level between selected parents. Furthermore, we extend the application in two directions: (i) simultaneous improvement of multiple target traits, and (ii) finding multi-parental solutions for designing crossing blocks. We evaluate and discuss the performance of the ECV criterion compared other selection approaches. Finally, we explore how the ECV criterion and the proposed integer linear programming techniques can be effectively applied to improve the efficiency of genetic introgression while maintaining genetic diversity within breeding programs.

1930V **Exploiting admixture in livestock to inform the genetic architecture of important traits** Pamela Wiener[1], Juliane Friedrich[1], Richard Bailey[2], Andrea Talenti[3], Mazdak Salavati[4], Félix Meutchieye[5], Keith Ballingall[6], Guillaume Salle[7], Olivier Hanotte[8,9], Emily Clark[1], James Prendergast[1] [1]Roslin Institute, [2]University of Łódź, [3]Oxford Nanopore Technologies, [4]Scotland's Rural College, [5]University of Dschang, [6]Moredun Research Institute, [7]INRA, [8]University of Nottingham, [9]International Livestock Research Institute

Admixture, in which gene flow between genetically separated populations leads to the production of individuals with complex ancestry, is an important process across the biological spectrum. Human-mediated admixture (hybridization, cross-breeding) has played an influential role in the history of domesticated animals, leading to the development of new breeds, local populations and commercial lines. Modern approaches in genotyping allow the genetic dissection of the impact of admixture on individual genomes, which can be exploited to address important issues in genetics and agriculture. This work, encompassing two studies, involves the application of population genetics techniques to admixed livestock populations in order to characterise ancestry across the genome and to identify loci of specific ancestry or with steep genomic clines (gradients in allele frequency across the overall range of admixture levels), providing evidence of association with restricted cross-breeding.

In one study, we used SNP array data to confirm previous results that some Caribbean sheep have West African and European origins, presumably due to introduction of sheep from both geographic regions. We then identified genomic regions with an excess of West African ancestry, which contain genes that are candidates for adaptation to tropical environments. In a separate study, we analyzed genotypes generated by whole-genome sequencing to characterize genomic clines in a number of African cattle populations, which vary in the level of admixture between taurine (Near Eastern origin) and indicine (South Asian origin) lineages. This analysis identified many genomic regions with steep clines, indicating restricted introgression, which may be related to genomic incompatibilities and reproductive isolation between taurine and indicine backgrounds. These studies provide insights into the genetic basis of environmental adaptation and hybrid incompatibility. In addition, they may contribute to breeding and management strategies in livestock, e.g. related to improved heat tolerance.

1931T **Genomic Evidence of Selection on Gall Size among Goldenrod Gall Fly *Eurosta solidaginis*** Zhenzhu Xiao[1], Arthur Weis[2], Linyi Zhang[1] [1]Department of Biological Sciences, George Washington University, [2]University of Toronto

Predicting the evolution of traits in response to natural selection is a fundamental pursuit in evolutionary biology. Achieving this goal necessitates a holistic approach, connecting genotype, phenotype, and fitness. However, such investigations are often limited, either due to the complexity of pinpointing the trait under selection or the scarcity of genomic resources for trait elucidation. In this study, we aim to bridge this knowledge gap by identifying the genomic signatures of natural selection acting on a pivotal phenotype: gall size in goldenrod gall flies—a classic model for studying multitrophic interactions in trait evolution. Previous research has established key insights: 1) gall size exhibits heritability among these insects, 2) small galls face elevated predation risk by parasitoid *Eurytoma gigantea*, and 3) large galls are more susceptible to avian predation. This ecological interplay generates stabilizing selection on gall sizes within populations. Our study's objective is to detect genomic evidence of selection acting on gall sizes. To achieve this, we collected gall samples from three distinct sites, encompassing the time points before any natural enemies' attacks, after parasitism events, and subsequent to bird predation. We conducted a genome-wide association study involving 736 individuals to uncover the genetic architecture underlying gall size variation. Furthermore, we employed pool sequencing across these three time points to track allele frequency changes and corresponding phenotypic scores in gall sizes over time. Our investigation seeks to discern whether allele frequency changes occur among loci responsible for gall size, shedding light on the genomic underpinnings of this key ecological trait's evolution in response to natural selection.

1932T **Repeatability of evolution varies across timescales in the introduced African Fig Fly, *Zaprionus indianus*** Jerry He[1], Alyssa Bangerter[2], Logan Rakes[1], Ansleigh Gunter[1], Alan Bergland[2], Priscilla Erickson[1] [1]University of Richmond, [2]University of Virginia

Invasive species are immensely successful in new environments, but the biological mechanisms that enable their spread remain elusive. Some invasive species show rapid adaptation to new habitats, but few studies have captured post-invasion adaptation in real time. The African Fig Fly, *Zaprionus indianus*, arrived in North America two decades ago and rapidly spread northwards along the East Coast. We have tracked *Z. indianus* populations over six years in two temperate Virginia orchards where they are locally extirpated each winter and re-colonize each spring from an unknown source. With a generation time of three weeks, these introduced populations potentially adapt for 5-6 generation in new environments. We hypothesized that populations undergo predictable post-colonization evolution across multiple locations and years, resulting in repeated changes in allele frequencies across time and space. Using a new chromosome-level genome assembly for *Z. indianus,* we have sequenced over 200 individual flies and 34 pooled samples to estimate allele frequencies over time in Virginia and across a 20° latitudinal transect in the eastern United States. While North American populations show little genome-wide population structure, we identified a haplotype on the X chromosome that is highly geographically differentiated across multiple years of sampling. Analysis of pooled samples recapitulates this finding and identifies a second latitudinally differentiated autosomal locus. In contrast to our expectations, we find unpredictable post-colonization evolution across replicate orchards and years. In one large Virginia orchard, we detect a modest signal of parallel post-colonization allele frequency changes across six years of sampling. However, the variants that change predictably in this orchard tend to change frequency in the opposite

direction in a second orchard approximately 100 km away. Founder effects result in early colonizing populations with different genetic compositions each year, but throughout the course of the growing season, the populations become similar to one another. In contrast, we find parallel long-term changes in allele frequencies in Virginia and Florida over several years of sampling, suggesting that North American populations are undergoing similar changes over longer time periods. Our ongoing studies show that rapid evolution in highly polymorphic invasive species may be common, but the repeatability varies across timescales and populations.

1933T **Characterizing seasonal changes in the microbiome of Apis mellifera** Bronwyn M Boyd, Clare Scott Chialvo Biology, Appalachian State University

Pollinators play a critical role in maintaining balanced ecosystems, and the service provided by these species is essential to both wild flowering and crop species. Despite their ecological importance, pollinator populations are declining worldwide due to anthropogenic change. One such pollinator, the western honey bee (*Apis mellifera*), is one of the primary species responsible for the pollination of food crops. Since 2006, scientists have been monitoring the health of honey bee populations due to significant losses resulting from a combination of various emergent and pre-existing environmental threats, such as varroa mites, climate change, and beekeeping practices such as queen trade. Given their importance to agriculture, there is a need to develop new mechanisms for assessing and improving hive health. In this study, we seek to quantify how the gut microbiome of worker bees changes over the course of a season and identify whether these changes correlate with phenotypic markers of hive health. We used Oxford Nanopore sequencing to characterize the microbiome of pooled worker bee samples collected from 20 hives located in Watauga County, NC at four time points. The results of our study will help to expand our understanding of how temporal factors influence changes in the microbiome and their association with the hive health.

1934T **CRISPR/Cas9-based homing gene drive for population control of the crop pest, *Drosophila suzukii*** Amarish K Yadav[1], Cole Butler[2], Akihiko Yamamoto[3], Alun L Lloyd[2], Maxwell J Scott[3] [1]Entomology and Plant pathology, NC State University, [2]Biomathematics Graduate Program and Department of Mathematics, NC State University, [3]Entomology and Plant Pathology, NC State University

CRISPR/Cas9-based homing gene drives for biased inheritance of genetic elements are currently being explored for the genetic suppression of human disease-vectors and agriculture pests. Genes required for female development, such as *doublesex* (*dsx*), have been identified as a potential target of gene-drives for pest population suppression. *doublesex* transcripts undergo sex-specific alternative-splicing to produce male and female Dsx isoforms required for proper sexual and somatic tissue differentiation. Here, we have established split homing drives which target the *dsx* gene in *Drosophila suzukii*, an invasive crop pest. The gene drive element, containing *dsx* single guide RNA and DsRed genes, was introduced into the coding region (CDS) of female-specific exon of *dsx*, which is essential for function in females but not males. However, in most strains, hemizygous females showed dominant sterility due to male *dsx* transcript production. A modified homing drive that included an optimal splice acceptor site to prevent the male splice site rescued the dominant sterility in females. Super-Mendelian inheritance of the gene-drive cassette (94-99%) were noted with a line that expressed Cas9 with two nuclear localization sequences (NLS) under the *D. suzukii nanos* promoter. Interestingly, mathematical modeling suggests that these strains could be used for suppression of lab cage populations of *D. suzukii* with repeated releases at relatively low release ratios (1:4). We are currently evaluating the potential of these homing strains for genetic suppression of lab cage populations of *D. suzukii*. In addition, with the aim of reducing the potential for resistance to develop, we have made new drive strains that express two or more gRNAs targeting *dsx*.

1935T **Tempo-spacial distribution of Drosophila** Chau-Ti Ting, Shun-Chern Tsaur National Taiwan University

Taiwan has a particular terrain, with altitudes ranging from lowland to mountains of 4,000 meters above sea level. The climate varies from subtropical, tropical, and temperate to frigid zones, coupled with abundant rainfall breeding a rich insect fauna. This study takes advantage of the unique condition to investigate Central Taiwan's altitudinal distribution and species abundance of drosophilid flies. We spent one week each in February 2020 and August 2023 on the Central Cross-Island Highway to conduct surveys from the lowland to 2,600 meters. Five traps were set up, each with a 400-meter altitude separation, supplemented by sweeping actions along the road and into the forest areas. In total, 4,466 and 380 fruit flies were collected, totaling 21 genera and 110 fruit flies. Preliminary analysis of fruit fly species in the mid-altitude (alt. around 1,000 meters) are more abundant in species diversity. This diversity provides a general basis for studying the species and genetic diversity.

1936T **Character evolution in the *Impatiens* genus (Balsaminaceae): a statistical approach** Sudhindra R Gadagkar, Nicholas J Beck Midwestern University

The plant family Balsaminaceae (Order Ericales) comprises only two genera, Impatiens and *Hydrocera*, which are very

dissimilar. While *Hydrocera* is monotypic with *H. triflora* as its only species, Impatiens ranks among the largest angiosperm genera, containing more than 1000 species that are diverse and taxonomically complex. For these reasons, this exploratory study used the Impatiens genus to study character evolution. Nucleotide sequences for three intragenic DNA spacers (ITS, atpB-rbcL, and trnL-F) of 150 species of *Impatiens* and three outgroup species were obtained from Yu et al. (2015) to infer the phylogeny using maximum likelihood. Forty-six morphological and morphometric traits, also obtained from the study were superimposed onto the tree to study their evolution. Instances of parallel and de novo evolution were found. Traits were correlated using the statistic Cramer's V after eliminating those that exhibited significant phylogenetic signal, determined using Pagel's λ. Categorical principal components analysis was used to reduce the dimensionality of the 46 traits to a few underlying meta traits. The results of this study are presented here.

1937F **Characterization of Triclocarban (TCC) activity in the *Drosophila melanogaster in vivo* model** Adriana Muñoz Hernández, David García Mendoza, Patricia Ramos Morales Biología Celular - Genética y Toxicología Ambiental-Banco de Moscas, Universidad Nacional Autónoma de México, Facultad de Ciencias

Triclocarban (3,4,4-trichlorocarbanilide, TTC) is a common ingredient in personal care products often used in combination with Triclosan (TCS). Since the COVID-19 pandemic, the use of multiple disinfection and cleaning products containing TCC has increased. Although it has been used for fifty years, it has recently been of concern since it has been pointed out that it could act as an endocrine disruptor that implied a significant hazard to ecosystems, both due to its extensive use in multiple cleaning and disinfection products, as well as its persistence and environmental distribution. TTC is among the top 10 Contaminants of Emerging Concern (CEC). Once products containing TCC are applied to the skin (or breathing) it enters the body where is metabolized by cytochrome P450 enzymes, and their metabolites constitute a potential risk to human health. In this work, the activity of TCC was evaluated in two wild type strains of *Drosophila melanogaster*: CS (regular metabolism) and ORR (modified metabolism) to determine its toxicity and the extent of the consequences of a unique exposure across several generations. Third instar larvae were fed for 48 h with TTC [1.78E-06 – 26.4 mM]. For each concentration, the number of treated flies (t, F0) recovered (Survival, S) and the Sex Ratio (PSx) were recorded. To evaluate the reprotoxic effect over generational time, each generation 15 pairs of flies, 1♀ t x 1♂ t from each concentration or from their respective negative control were put independently into vials with *Drosophila* food free of TCC. Once the adults (F1 to F3) were recovered, the number of females and males were register and morphological review was made using a SMZ-445 stereo zoom. The fertility, average of progeny per family (PPF) and sex proportion from treated flies (F0) or those from F1 to F3 flies was compared to that of their respective control flies. TCC clearly affected the CS flies, being lethal from 2.5 mM and, although it affected the average of progeny per family of the CS and ORR flies, adults were recovered for the later strain at the highest concentrations. The use of different biomarkers favors the analysis of the response obtained. To evaluate the effects over time of compounds of concern is of priority to know the real hazard that implied for life and the environment. Acknowledgement: PAPIIT (IN226923), DGAPA-UNAM. Keywords: Triclocarban, emerging contaminants, *Drosophila*, endocrine disruptor, reprotoxic. Topic: Ecological Genetics and Genomics: Impact of environmental damage on biodiversity.

1938F **Wolbachia Improved Fitness Traits of *Drosophila* Fed Rotten Fruit Diet** Oluwatobi E Fijabi[1,1], laura k Reed[2], Alex Wheelock[3], Maria Rico Lopez[4] [1]University of Alabama, [2]Biological Sciences, University of Alabama, [3]Bates College, Lewiston, [4]Saint Xavier University, Illinois

Host-microbe interaction is essential in the face of temperature shifts due to global climate change. *Wolbachia*'s influence on *Drosophila's* fitness traits is variable and contextual. Evidence of *Wolbachia*'s transition from parasitism to mutualism is known based on evidence of its provisioning of nutrients to its host. However, this evidence is limited to assessing its influence on lab diets different from *Drosophila's* encountered natural diet. We hypothesize that *Wolbachia* status will influence the fitness traits of *Drosophila* fed strawberries under acute stress. We expect a positive impact on fitness components driven by provisioning between *Wolbachia* and the host. We approached this question uniquely using three DGRP lines naturally infected with *Wolbachia* and their *Wolbachia*-cured counterparts. We eliminated maternal bacteria, then larvae emerged on rotten strawberries until they were sexed. They were exposed to cold stress (4° without food, 15min recovery at 25˚C), heat stress (38˚C for 45min without food, 3.5hrs recovery at 25˚C), or control condition (4hr 15min at 25°C without food). All flies further recovered on food for at least 12 following treatments before phenotyping. We measured fecundity, weight, longevity, climbing performance, emergence survival, and starvation resistance as a proxy for fitness. Our result revealed sexual dimorphism across phenotypes. *Wolbachia* status did not influence emergence survival. Male flies are better climbers. Wolbachia infection status interacted with sex, genotype, and thermal stress conditions to impact the phenotypes of starvation, climbing performance, fecundity, longevity, and weight of strawberry-fed flies at emergence. In sum, our results showed a positive impact of *Wolbachia* in combating environmental stress. This impact, however, is genotype, sex, and stressor dependent. This study is essential for understanding the ecological and seasonal adaptations of holobionts

1939F **Quantifying compositional variability in microbial communities** Maike L Morrison[1], Katherine S Xue[2], Noah A

Rosenberg[2] [1]Biology, Stanford University, [2]Stanford University

Microbial communities present new challenges for the development of statistics for diversity measurement. To understand the composition of microbial communities and the differences among communities across spatial locations, time points, or experimental replicates, we present a new normalized measure for characterizing variability across multiple microbiome samples. The statistic relies on the diversity partitioning framework employed by Fst, with samples playing the role of "populations" and taxa playing the role of "alleles" [1]. Its convenient mathematical properties--such as its commensurability across different numbers of taxonomic categories and different numbers of communities considered--allow users to compare its values between disparate data sets. Extensions incorporate phylogenetic similarity among taxa and spatial or temporal distances between communities. In a longitudinal analysis of gut microbiomes of healthy adults taking an antibiotic, we are able to both quantify the increase in temporal variability of microbiomes following the antibiotic course and to measure the duration of the antibiotic's influence on microbial variability.

[1] Morrison, M. L., Alcala, N., & Rosenberg, N. A. (2022). FSTruct: An FST-based tool for measuring ancestry variation in inference of population structure. Molecular Ecology Resources, doi.org/10.1111/1755-0998.13647.

1940F **CRISPR-Cas9 on Red Palm Weevils Yellow-e gene** Adilla Razali[1], Ligia Cota Vieira[2], Ling Li[3], Girlie Agbayani[3], Khaled Amiri[3], Claude Desplan[2] [1]CGSB, New York University Abu Dhabi, [2]New York University Abu Dhabi, [3]UAE University

The red palm weevil, *Rhynchophorus ferrugineus* (Olivier) originating from tropical Asia is a harmful pest of more than 30 palm species, including economically relevant crops, such as date palms, coconut palms and oil palms. In the Middle East, date palms particularly are crucial, as they are the main cash crop in this region. The most harmful stage of this pest is the larval stage, where they destroy the trunk of the palm from inside and eventually killing it. Pesticides are the most common method used to control this pest, which elicits negative impacts on the environment. We are trying to develop a more sustainable and eco-friendly strategy to control the red palm weevil population by using genetic control- CRISPR/Cas9. CRISPR/Cas9 is a recognized gene editing method, that has been vastly used on a variety of species, but it has never been used on the red palm weevil. Our analyses show that we have successfully edited the *yellow-e* gene in the red palm weevil using this method. Our data also showed that the loss of this gene causes the changes in coloration, impacts pupa to adult transition and increased mortality due to dehydration.

1941F ***Steinernema* nematodes as an emerging genetic model to study microbial symbiosis** Mengyi Cao Carnegie Institution for Science

Nematodes are among the most abundant and diverse groups in the soil fauna and they play a significant role in soil ecology. The associations between the soil-dwelling entomopathogenic (EPN, insect-parasitic) nematodes of *Steinernema spp.* and their naturally occurring mutualistic bacteria in the genus *Xenorhabdus* have been established as experimental models and have great potential for agriculture due to their antagonistic effects on agricultural pests. The transmission stage of the *Steinernema* nematode is a developmentally arrested infective juvenile (IJ) that carries symbiotic bacteria in an intestinal pocket. The IJ invades an insect via a repertoire of host-seeking behaviors, releases the symbiont, and reproduces within the insect cadaver. The next-generation IJ progeny leaves the insect cadaver to seek for a new insect host. In this talk, I will present our recent success in the development of both forward and reverse genetics tools in the nematode host to increase the power of *Steinernema-Xenorhabdus* as a model system to study microbial symbiosis. I will also discuss the ongoing projects exploring the application of this symbiotic system in various directions.

1942F **Genome-wide analysis of mutation in cadmium exposure in adapted and non-adapted *Daphnia pulex* genotypes** Nathan Keith[1], Craig E Jackson[2], Stephen P Glaholt[1], Kim Young[3], Joseph R Shaw[3] [1]O'Neill School of Public and Environmental Affairs, Indiana University, [2]O'Neill School of Publican and Environmental Affairs, Indiana University, [3]Indiana University

Exposure to chemical pollutants can alter the rate, and genome-wide distribution of germline mutations. However, studies measuring the effect of chemical exposure on mutation rate and spectra have not considered the eco-evolutionary background of studied genotypes, which could potentially influence the rates and patterns of germline mutations upon chemical exposure. Utilizing *D. pulex*, we conducted a comprehensive experiment to test our overarching hypothesis that adaptation to chemical pollution also protects the germline from mutagenesis. We, 1) identified *Daphnia pulex* populations that have adapted to live in mining-devastated regions by increasing their tolerance to cadmium. 2) We completed a large-scale MA experiment with an adapted genotype to measure the rate of germline mutation in both control conditions and an environmentally relevant concentration of cadmium. 3) We compared these MA experiment results to a previously reported and identically designed MA experiment with a non-adapted genotype. We report that patterns of cadmium-induced mutagenesis in the adapted

genotype were reversed compared to our previous observations in a non-adapted genotype. Cadmium exposure altered the single nucleotide mutation (SNM) rate in the same genome regions in adapted and non-adapted genotypes, but the rates were changed in opposite directions. Cadmium also altered specific SNM classes (e.g., A:T > G:C) in these genotypes in opposite directions. Cadmium mutagenesis in the non-adapted genotype was linked to oxidative DNA damage and interference with DNA repair mechanisms via cadmium replacing zinc in zinc-containing protein domains. The reversal of germline mutational trends in the adapted genotype suggests protection against cadmium toxicity, and we demonstrate that adapted populations have elevated copy-number, and expression levels of metallothionein, the protein that protects against cadmium toxicity by binding to cadmium irreversibly.

1943F **Chloroplast Phylogenomics of the Genus *Morus L.* (Moraceae)** Bibek Adhikari[1], Sanam Parajuli[1,2], Madhav P Nepal[1] [1]Biology & Microbiology, South Dakota State University, [2]Biology and Microbiology, South Dakota State University

There are approximately 13 species of mulberries (Genus *Morus*; Family Moraceae) distributed across temperate to subtropical regions of the world. *Morus rubra* – Red mulberry, native to North America – is an endangered species found in riparian areas of eastern North America. The species integrity of *M. rubra* is threatened by introgressive hybridization with its invasive exotic congener *M. alba* (white mulberry) challenging the species identification. To address this challenge, and threats posed by hybridization to the species integrity of *M. rubra*, we analyzed chloroplast genomes of 45 specimens including *M. rubra*, *M. alba*, and hybrid individuals. The average *M. rubra* chloroplast genome size is 159,415 bp with 128 genes coding for 83 proteins, 8 rRNAs, and 37 tRNAs. The chloroplast genome of *M. rubra* is larger than that of *M. alba* by 122 bp. The DNA sequence polymorphism analysis segregated the 45 samples into 13 haplotypes – 12 belonging to *M.* rubra and a single *M. alba* type. The coding sequences were found to be conserved within and in between the species and the variation was observed mostly in the non-coding and intergenic spacer regions. The phylogenomic analysis of the chloroplast genomes of 11 species supported previously published *Morus* phylogeny with well-resolved Asian and North American clades. Nine hypervariable sites were identified across the *Morus* genomes, which are yet to be tested for their effectiveness as species-specific markers. The results from this study not only provide insight into the *M. rubra* chloroplast genomes structure but also provide a foundational data for addressing complex taxonomic issues, genus biogeography, and understanding population genetics and hybrid swamp due to introgressive hybridization.

1944S **Cracking the *Drosophila* Eggshell: Identifying Genes Essential for UVB Sensitivity** Lillian Pennington, Llewellyn Green, Erin S Kelleher The University of Houston

Throughout development, organisms are continuously exposed to environmental mutagens, such as ultraviolet (UV) light emitted from the sun. UV radiation poses a significant threat to terrestrial organisms, including Drosophila melanogaster. During embryogenesis, a pivotal stage in the Drosophila life cycle marked by rapid mitotic divisions, it is imperative to minimize DNA damage caused by UVB radiation for proper development. It's important to recognize that in Drosophila and other oviparous organisms, embryogenesis occurs in the external environment, leaving the embryo unprotected from UVB radiation. In response to UV-induced DNA damage, Drosophila express genes encoding specialized DNA repair enzymes called photolyases. While several DNA repair genes have been recognized for their role in protecting Drosophila from UVB irradiation, the requirement for specific eggshell components in UVB tolerance has not been investigated. As the outermost membrane of Drosophila eggs, the eggshell guards the developing embryo from external threats, including UVB radiation. Therefore, we anticipate that specific proteins within the eggshell play a vital role in protecting the developing egg against UVB radiation. To identify eggshell genes essential for UVB protection in Drosophila, we are analyzing the UV sensitivity of a panel of eggshell mutants. The lethality of the eggshell mutants will be compared with that of DNA repair mutants to assess the importance of various eggshell genes in UVB protection. Several mutants have shown similar mortality to DNA repair mutants when exposed to UV radiation, revealing the role of certain eggshell proteins in UV irradiation sensitivity. Identifying UV-tolerant eggshell genes in Drosophila is significant because it can enhance our understanding of how oviparous organisms protect themselves from UVB rays.

1945S **Conservation of the Regulatory Region and the Genes they Regulate within a Network** Chinmay P. Rele, Laura Katie Reed Biological Sciences, The University of Alabama

Understanding how protein-coding genes are regulated paints a clearer picture of how the proteome and genome interact with the environment and each other. Regulatory regions are important for the temporal expression patterns of genes. The sequences of regulatory regions of genes are highly variable, both across species and within species. We are studying the evolution of protein-coding sequences and the regulatory regions of genes within the Insulin-signaling pathway (INS/Tor) and how their evolution correlates with other characteristics of the genes within the context of a network. Insulin-signaling genes are interesting within Drosophila because they include duplications within the genus and variation in the number of genetic and physical interactions. In this study, we use computationally-generated predictions from the RefSeq pipeline to annotate the genome, with special interest on the 63 genes assigned to the INS/Tor pathway in 32 Drosophila species.

These same genes and species are also being used by the Genomics Education Partnership to establish high-quality hand-curated gene annotations that will later be used to improve the predictions of the analysis represented here. The conserved elements identified within regulatory regions upstream of genes are likely cis-regulatory elements of those genes. We predict that conservation in these upstream regions are correlated with metrics of the gene such as dN/dS, intron size, indel abundance, number of interactions with other genes and proteins, and metrics describing network topology. We predict that the conservation of the regulatory regions and the CDS are positively correlated. We also predict that the conservation of the regulatory regions/genes are correlated with centrality measures such as eigenvector centrality, and also with their "hubness" – highly connected genes connected to other highly connected genes are more conserved. Regulatory regions of genes with shortest average path length to all the other genes in the network are also predicted to be the most conserved. We believed this would imply that the conservation of a gene is affected by its direct interactors, but the conservation of its regulatory regions is more affected by how much its associated gene connects to all other genes in the network. Understanding the interplay between network topology and conservation of the regulatory region and CDS will improve our understanding of how the genome and interactome evolve over time.

1946S **Diapause experience has lasting effects on post-diapause adult brain gene expression in monarch butterflies** Samuel M Stratton[1], Delbert A Green[2] [1]EEB, University of Michigan, [2]University of Michigan

Diapause is an induced state that enables organisms to halt development, becoming longer-lived and more stress-tolerant, in order to withstand environmentally harsh conditions. Then after a biologically determined amount of time and environmental conditions become favorable, development is resumed. While the dynamics of diapause, from entry to exit, are becoming well understood at the genetic and molecular level, it is less clear what are the lasting consequences of the diapause process once development is resumed. The monarch butterfly provides a captivating system to address this question as monarchs enter reproductive diapause in the fall which coincides with their migration from northern USA and southern Canada to central Mexico. This occurs in order to ensure sufficient resource allocation for migratory success. Here, two groups of monarch butterflies were reared under different pre-adult conditions, either natural fall (diapause inducing) or laboratory summer (direct development). Then these groups were raised in identical natural fall conditions as adults. After outdoor entrainment, individuals were then brought indoors to a fall-like incubator to further standardize experience before sequencing. We find that that fall conditions during pre-adult development were necessary to induce diapause. Further, among the group with pre-adult fall rearing, because the fall-like incubator was slightly above diapause-breaking temperatures, there was heterogeneity in individual reproductive maturation. RNA-seq analyses on the brains of these individuals uncovered that post-diapause, reproductively mature individuals retained signatures of diapause such as upregulation of genes related to DNA repair, DNA maintenance, maintaining tissue integrity, along with downregulation of genes related to cell division. Ultimately, these results showcase the lasting effects of diapause and encourage further questioning on the ecological and evolutionary consequences of this phenomena.

1947S **Investigating the non-homologous end joining (NHEJ) and single-strand annealing (SSA) pathways of DNA double-strand break (DSB) repair with single-allele resolution after CRISPR/Cas9 treatment in embryos of the Major Dengue Vector, *Aedes aegypti*** Joseph S Romanowski[1,2], Hitoshi Tsujimoto[1], Kevin M Myles[1], Zachary N Adelman[1] [1]Entomology, Texas A&M University, [2]Graduate Program in Genetics and Genomics, Texas A&M University

The *Aedes aegypti* mosquito is a major human disease vector estimated to be responsible for over 400 million dengue virus infections each year and is the focus of genetic control approaches. Tools such as CRISPR/Cas9 induce DNA double-strand breaks (DSB) which can achieve desirable, DNA repair-mediated edits for these control strategies. The repair mechanisms that drive these sequence changes, however, are not well understood. Here, we report an *Aedes aegypti* embryo assay capable of studying the non-homologous end joining (NHEJ) and single-strand annealing (SSA) pathways of DSB repair with genomic DNA ready for sequencing in as little as 24-hours post-CRISPR/Cas9 micro-injection. Paired with polymerase chain reaction (PCR) and Oxford Nanopore sequencing technologies, this assay allows for both single and pooled embryo data with single-allele resolution of DNA repair events, providing information about how factors such as DSB site can influence the NHEJ and SSA repair pathways to inform self-eliminating gene drive control approaches.

1948S **Using DNA metabarcoding to evaluate the diet of sea lamprey (*Petromyzon marinus*) in the Great Lakes** Conor O›Kane[1], John Robinson[2], Kim Scribner[2], Weiming Li[2], Jeannette Kanefsky[2], Nicholas Johnson[3], Tyler Bruning[3] [1]Fisheries & Wildlife, Michigan State University, [2]Michigan State University, [3]United States Geological Survey, Hammond Bay Biological Station

The invasive sea lamprey (*Petromyzon marinus*) is a harmful hematophagous ectoparasite of Great Lakes fishes that requires international control. Current annual assessments of sea lamprey control program success include the observation of wounds on native lake trout (*Salvelinus namaycush*) to estimate sea lamprey damage and extrapolate mortality rates. However, due

to the difficulty of obtaining a representative sample of Great Lakes fishes and challenges involved with the assessment of blood diets, comprehensive dietary analyses for sea lamprey are lacking. Previous studies using stable isotope and fatty acid analyses indicate sea lamprey diet composition varies within and across the Great Lakes, but these methods cannot reliably identify individual species in sea lamprey diets. With the advent of high-throughput sequencing technologies and improved accuracy of species-level identification, DNA metabarcoding may allow for a more extensive examination of sea lamprey diets given the presence of DNA in fish blood cells. The purpose of this research is to use molecular investigations of dietary composition to address three objectives: 1) identify an effective blocking primer to suppress sea lamprey DNA amplification 2) characterize retention times of observable DNA under experimental conditions within sea lamprey digestive tracts at different temperatures and fasting periods, 3) compare the detectability and composition of host DNA after consecutive feedings on multiple species. We developed and tested eight blocking primers with varying base pair length, end modifications (C3 spacer and inverted dT), and purification methods via gel visualization, quantitative PCR, and DNA metabarcoding. Between samples the average Ct value difference with and without blocking primers was 13.72 (sd = 0.95), indicating a 13,520x average suppression of sea lamprey DNA amplification. We then evaluated retention times of dietary DNA in sea lamprey across five fasting periods (0, 5, 10, 20, 30 days), following a seven-day feeding period at three temperatures (0, 5, 10 °C). Following metabarcoding and subsequent bioinformatic analyses, sequence read counts were compared to investigate a relationship between fasting period length and temperature on dietary DNA detectability. Additionally, similar relationships were explored from sea lamprey allowed consecutive feedings on two different species to assess detectability of both hosts

1949S **Environmental DNA metabarcoding reveals community-wide patterns of aquatic invertebrate gene flow and genetic drift in Grand Canyon.** Jared Freedman[1], Theodore A Kennedy[2], Molly K Burke[1], David A Lytle[1] [1]Integrative Biology, Oregon State University, [2]Grand Canyon Monitoring and Research Center, USGS

The spatial distribution of genetic diversity in river networks reflects complex influences of landscape characteristics on the evolutionary and demographic histories of aquatic organisms. Aquatic invertebrates with complex life histories face unique barriers to gene flow, such as stream network configuration, inhospitable terrestrial landscapes, and anthropogenic habitat alterations, that influence community-wide patterns of genetic connectivity. However, widespread collection of genetic samples from multiple species of interest is often prohibitively difficult. To detect community-wide genetic patterns, we used environmental DNA (eDNA) metabarcoding to simultaneously capture community and population genetic data for aquatic invertebrates in the Grand Canyon reach of the Colorado River. Trace DNA was obtained from water samples at 36 sites in the Colorado River and its perennial tributaries, which was then sequenced using a degenerate primer set that targets a fragment of the aquatic invertebrate COI gene. We utilized synthetic spike-in PCR standards of known copy number to obtain normalized between-sample quantification of each species, as well as strict denoising and filtering parameters to extract haplotype level information for many aquatic invertebrate species. Pairwise measures of genetic distance and river network distance were compared to assess the regional influence of gene flow and genetic drift across the Grand Canyon ecosystem. In total, we identified 1,201 haplotypes across 448 species, with 80 species containing sufficient genetic variability to perform population genetic analyses. 55 of these species exhibited low regional gene flow, 11 exhibited moderate regional gene flow, and 8 exhibited high regional gene flow. Further work is ongoing to incorporate more complex analyses that take into account multiple modes of ecological distances, including least-cost terrestrial distance and non-geographic environmental distance. These result suggests a widespread limitation to aquatic invertebrate gene flow between aquatic habitats in the Grand Canyon, particularly between geographically isolated tributaries. The ability of eDNA metabarcoding data to detect ecologically-relevant patterns of genetic variability presents a promising step forward for ecological genetics, as it allows for investigations of the impact landscape features and environmental gradients across entire communities.

1950S **Comparative genomics identifies adaptive immune genes experiencing differential selection in Hawaiian honeycreepers with potential applications for conservation.** John H. Neddermeyer[1], Michael G. Campana[2], Marc Tollis[3], Robert C. Fleischer[2], Jeffrey T. Foster[1] [1]Biology, Northern Arizona University, [2]Center for Conservation Genomics, Smithsonian National Zoo and Conservation Biology Institute, [3]Engineering, Informatics, and Applied Sciences, Northern Arizona University

Infectious disease has been one of the most constant selective pressures in the evolution of birds and mammals. Host genetics are frequently identified as a major component of infection outcomes in both humans and wildlife. Wildlife around the globe are imperiled by the introduction of novel infectious diseases, with devastating consequences for biodiversity, and the introduction of avian malaria to the Hawaiian Islands is a preeminent example. Avian malaria has been identified as a main driver of honeycreeper extinctions. The severe mortality observed in Hawaiian honeycreepers is likely due to an evolutionary history devoid of malaria causing parasites. The severe impact of the parasite on native bird species makes avian malaria in Hawai'i a unique model system for understanding selective pressures of disease. Using whole genome sequencing data from 17 extant and one recently declared extinct honeycreeper species we sought to use comparative genomic methods to identify genes contributing to disease susceptibility in Hawaiian honeycreepers. We assembled honeycreeper genomes from Illumina sequences using two approaches, de novo with 10X Genomics linked-reads and reference-guided using one of

the honeycreeper de novo assembled genomes as reference. Post assembly we assessed genome continuity and annotation completeness. A total of 41 genomes were included in analyses, 18 honeycreepers and 23 non-honeycreeper genomes downloaded from NCBI. Given that avian malaria is ubiquitous throughout the world and does not cause severe population declines a key assumption of our work is that honeycreepers are uniquely susceptible to avian malarial disease. Using highly conserved genes identified by BUSCO we constructed a species tree based on 7,592 gene trees to serve as input into Progressive Cactus. From our multispecies alignment, using the chicken genome as a reference, we identified adaptive immune genes for selection analyses. We determined if genes were under selection in honeycreepers, using branch-site methods implemented in HyPhy, and using PhyloP in PHAST. We found several adaptive immune genes experiencing differential selection in honeycreepers. Specifically, genes involved in MHC Class I and II signaling. Further, using codon-site selection tests we identified codons in pathogen recognizing motifs under differential selection in honeycreeper species. These analyses offer information at the scale of a single genome per species, but evolution often occurs at the population level. Genes involved in the adaptive immune response identified as experiencing differential selection in honeycreepers offer targets for population level studies, where allelic associations between honeycreeper infection and disease survival can be made.

1951S **Gene copy number promotes the rapid evolution of pests across Diptera** Dylan Padilla, Michael Angilletta School of Life Sciences, Arizona State University

Diptera is one of the most species-rich and ecologically innovative groups of organisms, making up 10-15% of all animal species. Historically, they have constituted a major group of pests that inflict serious damages to plants and animals, both directly by ingesting phloem/blood and indirectly as vectors of numerous diseases. Deciphering the evolutionary mechanisms responsible for the rapid evolution of pests and invasive species could enable us to apply control measures, preventing major ecological and even economic impacts. Here, we investigate the evolution of the *foraging* gene (*for*) across diptera; a gene known to alter the foraging behavior of certain species of flies. Through a gene-tree species-tree reconciliation analysis, we found multiple events of gene duplication, and gene loss throughout the history of dipterans. Interestingly, the number of *for* paralogs among species seems to be associated with the rapid evolution of pests. Our results show evidence of a potential mechanism underlying the rapid evolution of pests across dipterans, enabling us to mitigate relevant ecological and economic impacts of human concern.

1952T **Comparative Single-Cell Transcriptomic Analysis in C. elegans and C. briggsae Embryos** Rupa Khanal[1], Christopher R. Large[1], LaDeana Hillier[2], Chau Huynh[2], Priya Sivaramakrishnan[1], Felicia Peng[1], Qin Zhu[3], Erik Nordgren[1], Jean Rosario[1], Junhyong Kim[1], Robert H Waterston[2], John I. Murray[1] [1]University of Pennsylvania, [2]University of Washington, [3]University of California, San Francisco

Understanding the intricate mechanisms of gene regulation during the development of multicellular organisms is pivotal in evolutionary biology. C. elegans has a fully mapped invariant lineage, and it is nearly perfectly conserved in related species such as C. briggsae. This offers a unique opportunity to identify homologous cell states across the organism and therefore, compare transcriptomic dynamics between species at single-cell resolution.

We analyzed single-cell RNA-seq datasets comprising over 193,020 cells from C. briggsae embryos and 255,027 cells from C. elegans embryos. Through joint annotation and quantitative comparisons, we show that most well-expressed orthologous genes have a high conservation of their expression profiles between the two species. We classified genes based on expression breadth and conservation, and identified constraints including that broadly expressed genes are more likely than specifically expressed genes to have conserved expression. Genes annotated with certain functional categories such as transcription factors tend to have high conservation, while others such as genes annotated with neuronal function show more differences between species in embryonic expression.

By measuring transcriptome conservation of terminal and progenitor cell types across species, we uncovered several patterns. Both species exhibited a higher proportion of species-specific marker genes in early progenitor cells compared to later stages. In terminal cells, germline, muscle and intestine have more similar transcriptomes across species than most neurons and glia. Most hypodermal cell types have strong conservation of 1:1 ortholog expression, but also express more genes that have more complex orthology relationships. Examining transcriptome similarity across time showed that while on average lineages have a maximum similarity at the 200-350 cell stages, individual trajectories can deviate from this pattern.

In conclusion, our comparative analysis highlights the interplay of conservation and divergence in gene expression during embryonic development.This contribution deepens our insights into developmental biology and evolution on a broader scale.

1953T **Investigating the evolution of new body parts in the rapidly evolution genitalia of *Drosophila*** Gavin Rice[1], Tatiana Gaitan[2], Kenechukwu Charles-Obi[1], Julia Zeitlinger[2], Mark Rebeiz[1] [1]Department of Biology, University of Pittsburgh, [2]Stowers Institute for Medical Research

Recently evolved traits i.e., novelties, often represent key features that allow animals to exploit new ecological niches (e.g. feathers in birds) and can even help them find a mate (e.g. bioluminescence in fireflies). Yet few, if any, morphological traits we term as novel are entirely independent of other traits found throughout the body plan. Many novel traits have been hypothesized to be formed through genetic network co-option, where a genetic network becomes activated in a new part of the body plan. Yet even though this theory has been implicated countless times, few cases establish the sufficiency of network co-option to induce a novel morphology. Once a genetic network is deployed, how these networks become rewired to produce the trait's unique characteristics remains unclear.

The rapidly evolving genitalia of Drosophila provide a powerful system to study the developmental basis of morphological novelty. We investigated how the phallus of *Drosophila eugracilis* gained over 150 novel projections. Developmental tracking of cellular morphology uncovered evidence that these projections are unicellular. Larval trichomes, which have a well-characterized genetic network, are also formed as unicellular projections but are much smaller and differ in shape. Our analysis shows that the main transcription factor for the larval trichome network, Shavenbaby, and 14 of its known downstream targets have gained expression in the *Drosophila eugracilis* phallus. This suggests that the co-option of this network underlies this dramatic phenotype. In fact, activation of the larval trichome genetic network in the phallus of *Drosophila melanogaster*, which naturally lacks these unicellular projections, induces a partial phenocopy of the novel unicellular projection found in *Drosophila eugracilis*. This indicates that genetic network co-option is sufficient to induce novelties. Additionally, we find a portion of the *shavenbaby* genetic network differs when it is activated ectopically in *Drosophila melanogaster* with respect to the native projections of *Drosophila eugracilis*, highlighting nodes in the network that were likely added after these projections first evolved.

1954T **Understanding cellular and molecular developmental mechanisms of ovariole number determination across Hawaiian *Drosophila*** Cassandra Extavour[1,2,3], Adriana Aguilar-Maldonado[3] [1]Organismic & Evolutionary Biology, Harvard University, [2]Howard Hughes Medical Institute, [3]Molecular & Cellular Biology, Harvard University

Female reproductive fitness in *Drosophila* is highly heritable and determined by the egg-producing subunits of the ovary, the ovarioles. Previous work in our lab has characterized genetic, molecular, and cellular mechanisms underlying ovariole number variation in some *Drosophila* species, including *Drosophila melanogaster* and *D. sechellia*. However, we do not yet have a good understanding of which developmental mechanisms could be targets of evolutionary change for ovariole number determination. We have chosen two unique study systems to investigate the developmental and molecular mechanisms regulating ovariole number; the drosophilids of the *virilis* subgroup and those endemic of the Hawaiian Islands. These groups contain closely related flies that have diverged over relatively short time scales but that have evolved very different ovariole numbers as well as distinct ecological niches. I will discuss my progress in characterizing ovariole development and determining the cell biological basis of ovariole number determination in Hawaiian *Drosophila*, (2) investigate whether key genetic regulators within the mTOR, JAK/STAT, EGFR, or Hippo signaling pathways have been the targets of evolutionary change, and (3) determine the evolutionary changes in gene regulatory networks underlying ovariole number in the Hawaiian *Drosophila*. The ultimate goal of my work is to understand the developmental and genetic basis of adaptive evolutionary changes.

1955T **Characterization of Zebrafish Homologs of human P-gp and ABCG2 multidrug efflux transporters** Joanna Thomas, Robert Robey, William Frye, Paula Salazar, Collin Inglut, John Quinlan, Suresh Ambudkar, Andrew Warner, Donna Butcher, Jennifer Matta, Elijah Edmondson, Michael Gottesman National Institutes of Health

The ATP binding cassette (ABC) transporters P-gp (P-glycoprotein, encoded by *ABCB1*) and ABCG2 (*ABCG2*) were identified due to their ability to confer resistance to multiple different cytotoxic drugs in cancer cells. P-gp and ABCG2 are two of the most important multidrug efflux transporters, due to their wide and overlapping substrate specificities and diverse expression patterns. P-gp and ABCG2 are primarily expressed in excretory organs (e.g., liver, kidney, intestines) and at barriers to protected sites (e.g., blood-brain and placental barriers), and are therefore key drivers of substrate drug pharmacokinetics and distribution. Zebrafish are an ideal model to study drug toxicity and tissue distribution, but these efforts require a detailed characterization comparing the zebrafish and human homologs for translational relevance.

Previously, we characterized the 2 zebrafish homologs of P-gp (Abcb4, Abcb5) and found both had similar tissue expression patterns to human P-gp, but Abcb4 was the only homolog at the blood-brain barrier (BBB). A high-throughput analysis of substrate transport demonstrated a high correlation between Abcb4 and P-gp (R=0.94) with near perfect substrate overlap. Abcb5 shared fewer substrates (r=0.67) and is expressed at high levels in the zebrafish gills, skin and ovarian follicles.

Currently, we are characterizing the 4 zebrafish ABCG2 homologs (Abcg2a, -b, -c, -d). *abcg2a, -b* and *-d* shared similar expression patterns to human ABCG2, with all being detected in the liver, kidney, intestines and ovarian follicles. *abcg2c* was

only detected in the kidney and ovarian follicles. *abcg2a* was most highly expressed in the liver and intestine and was the only paralog at the BBB. *abcg2a* and *abcg2d* were the only paralogs expressed in the gills. Abcg2a had the greatest substrate overlap with ABCG2 whereas Abcg2d shared the fewest. This result was surprising as Abcg2d has the second highest amino acid identity with ABCG2. Computational modelling of predicted structures of Abcg2a-d aligned to ABCG2 demonstrated Abcg2d has a more divergent substrate binding pocket than Abcg2a, which may affect substrate recognition or transport.

In conclusion, we have identified Abcb4 and Abcg2a as the most phenotypically similar zebrafish homologs of P-gp and ABCG2, respectively. The similarity of substrate profiles and tissue distribution lends credence to the use of zebrafish for drug toxicology and PK/PD studies. Expression of these conserved transporters at the BBB paves the way for the use of zebrafish to study methods of increasing drug delivery to the brain.

1956T **_Blimp1_ is a pair-rule gene in the hemipteran _Oncopeltus fasciatus_** Leslie Pick, Katie Reding, Abigail Heath University of Maryland, College Park

Subdivision of the *Drosophila melanogaster* embryo occurs through a series of transcription factors that progressively define smaller regions of the antero-posterior (AP) axis. Among these are the pair-rule factors which specify pairs of parasegments along the axis and are encoded by the pair-rule genes (PRGs), which are expressed in alternating segment primordia. Mutation of any of these genes results in loss of every other segment - the classic pair-rule phenotype. First identified through *Drosophila* mutant screens in the 1970s-80s, the functions of the *Drosophila* PRG orthologs have since been studied in other insect species. Interestingly, in the milkweed bug *Oncopeltus fasciatus* (Hemiptera), knockdown of the *Drosophila* PRGs did not result in clear pair-rule phenotypes (1-3), while knockdown of the nuclear receptor-encoding gene *E75A* yielded embryos displaying loss of alternate segments (4). These results suggest that segmentation in *Oncopeltus* likely occurs according to a 'pair rule', but involves a different set of transcription factors from those deployed in the *Drosophila* embryo. In order to identify transcription factor-encoding genes involved in segmentation in the *Oncopeltus* embryo, we sequenced RNA from three time points during *Oncopeltus* embryogenesis. We selected transcription factor-encoding genes with similar transcriptional profiles as *E75A* to screen by in situ hybridization. We have so far identified one gene, *Of-Blimp1,* that is expressed in alternating segment primordia through much of germband elongation, suggesting possible pair-rule function. We used CRISPR/Cas9 to generate germline mutants and isolated five loss-of-function alleles which we have used to characterize the *Of-Blimp1* mutant phenotype. *Hox* gene expression patterns in *Of-Blimp1* homozygous embryos suggest that alternate segments are lost across much of the body axis. Mosaic G0 somatic mutants display fusions of pairs of segments at a register consistent with the patterns of segment loss observed in the germline mutants. To assess whether *Dmel-Blimp1* plays a role in segmentation, we also generated *Dmel-Blimp1* mutant lines and found that *Dmel-Blimp1* homozygotes do not display any defects in segmentation. These results suggest that while segmenting the AP axis according to a 'pair rule' may be ancestral to much of Insecta, the set of genes required for this phenomenon is more evolutionarily labile than previously thought.

1957T **The _PAX_ genes of _Vanessa cardui_, the painted lady butterfly** Ximena Gutierrez-Ramos, Leslie Pick Entomology, University of Maryland

During embryogenesis, genes often work in networks related to a specific developmental process, for example segmentation or eye development. One family of genes that is important in both of these processes is the *Pax* family. The *Pax* genes are conserved across animals. These genes encode conserved transcription factors that share a domain that binds DNA in a sequence-specific fashion, the Paired domain, as well as additional domains that are restricted to specific family members (Blake & Ziman, 2014). *paired* (*prd*), the first described *Pax* gene, is required for embryonic development, functioning as a typical pair-rule gene in the fly *Drosophila melanogaster* (*Dme*). *Dme-prd* is an essential gene for development of alternate body segments, and in *prd*'s absence the embryo is unviable (Kilchherr et al., 1986; Frigerio et al., 1986). In recent work we demonstrated that in malaria mosquito, *Anopheles stephensi*, *prd* was lost and functionally replaced by another *Pax* gene, *gooseberry* (*gsb*) (Cheatle Jarvela et al., 2020). In a phylogenetic analysis we observed that *prd* was independently lost in some Lepidoptera genomes. To determine when during insect evolution *prd* was lost we performed a bioinformatic analysis to identify the Paired domain in 160 lepidopteran genomes. We found that *prd* is absent in all of the species examined, suggesting that *prd* was lost early in the radiation of Lepidoptera. We are using *Vanessa cardui*, the painted lady butterfly, as a model system to carry out functional experiments to understand the mechanism underlying *prd* loss.

Was *prd* replaced by *gsb* in *Vanessa*, as it was in *Anopheles*? Did another *Pax* gene replace *prd* or does a different mechanism explain the loss of a critical regulatory gene? We identified 10 *Pax* genes in the *Vanessa* genome, including *gsb*. We performed an *in situ* hybridization to determine the expression pattern of *gsb*, and at the moment we are doing knock down experiments with RNA interference to determine if *gsb* is functionally substituting for *prd* in the formation of alternate segments in the butterfly. With this work we are examining how gene networks can withstand loss of genes suffer alterations in their gene components and how they can rearrange without affecting important embryogenesis processes.

1958T **An lncRNA master switch for pigmentation and adaptive color variation in butterflies** Luca Livraghi[1,2], Joseph J Hanly[1], Chris D Jiggins[2], Arnaud Martin[1] [1]Department of Biological Sciences, The George Washington University, [2]University of Cambridge

Evolutionary variations in the wing pigmentation of butterflies and moths offer striking examples of adaptation by crypsis and mimicry. The *cortex* locus has been independently mapped as the locus controlling colour polymorphisms in 14 lepidopteran species, suggesting it acts as a genomic hotspot for the diversification of wing patterns, but protein-coding knockouts with CRISPR-cas9 have proven to be difficult to obtain. In this study, we unveil the role of a novel long non-coding RNA (lncRNA) called *ivory*, transcribed from the *cortex* locus, in modulating colour patterning in five nymphalid butterfly species. Strikingly, *ivory* expression prefigures most melanic patterns during pupal development. CRISPR mutants of *ivory* showed transformation of dark pigmented scales into white or light-coloured scales, while G_1 cortex null mutants had no phenotype, showing that *ivory* and not *cortex* is essential for normal pigmentation in butterflies. We suggest that G_0 crispant phenotypes for *cortex* could be explained by large deletions that perturbed non-coding elements. Overall, these results show that an lncRNA, rather than the *cortex* protein-coding gene, acts as a master switch of colour pattern specification that played key roles in the adaptive diversification of colour patterns across Lepidoptera. These findings highlight the significant influence of lncRNAs in developmental regulation, and also underscore their potential as key genetic players in the evolutionary process itself.

1959F **Female-limited color dimorphism in the *Drosophila montium* species subgroup as a model to understand the molecular mechanisms of sex-limited polymorphism and evolution of dominance** Yuichi Fukutomi[1,2], Emily K Delaney[1], Jingqi Liu[1], Olga Barmina[1], Masayoshi Watada[2], Seema Ramniwas[3], Artyom Kopp[1] [1]UC Davis, [2]Tokyo Metropolitan University, [3]Chandigarh University

Many animal taxa have evolved discrete phenotypic polymorphisms where each of the alternative phenotypes is adaptive in one sex and disadvantageous to the other. Theory predicts that the resulting intersexual conflicts can be resolved by the evolution of sex-limited polymorphisms or sex-specific dominance relationships between alternative alleles. Both phenomena have been observed in nature, but the developmental mechanisms that explain them are unknown. Abdominal pigmentation in the *Drosophila montium* species subgroup provides an excellent model for investigating both mechanisms. Many species in this clade display a Mendelian, female-limited color dimorphism (FLCD). GWAS analyses reveal that independent regulatory mutations in the POU domain motif 3 (*pdm3*) gene, a repressor of pigmentation, are responsible for the repeated evolution of FLCD in multiple species. Antibody staining shows that Pdm3 is expressed in both dark and light morphs, and in both males and females, suggesting that subtle quantitative differences in *pdm3* expression may be responsible for FLCD. At the same time, species with FLCD differ in the dominance relationships between dark and light *pdm3* alleles. While dark alleles are dominant in most species, there are exceptions such as *D. bocqueti*. We show that in *D. bocqueti*, the light allele is fully dominant at high temperatures, the dark allele is fully dominant at low temperatures, and the two alleles are co-dominant at intermediate temperatures. Our results are consistent with a hypothesis that abdominal pigmentation in the *montium* clade is a threshold trait, where continuous variation in gene expression is converted into discrete, Mendelian adult phenotypes. To test this model, we will quantify the expression of light and dark *pdm3* alleles in Light/Dark heterozygotes in different species and at different temperatures, and test (1) whether the two alleles cause quantitative differences in *pdm3* expression that explain their adult phenotypes, and (2) whether the expression levels of *pdm3* from light and dark alleles have distinct reaction norms that may explain temperature-dependent dominance in *D. bocqueti* and temperature-independent dominance in other *montium* group species.

1960F **The spatiotemporal evolution of *dumpy* regulation in the rapidly diversifying *Drosophila* genitalia** Catarina Colmatti Bromatti[1], Donya Shodja[2], Ben Vincent[2], Mark Rebeiz[1] [1]Biological Sciences, University of Pittsburgh, [2]University of Pittsburgh

The evolution of complex new structures, so-called “morphological novelties”, is a topic of intense study in the field of evolutionary developmental biology. Gene regulatory networks that control developmental expression are critical to explaining how new structures deploy genes to achieve their unique morphological features. In particular, we need examples that molecularly explain how genes become deployed in new tissues that can contribute to the emergence of a morphological novelty. Here, I use *Drosophila melanogaster* as a model organism to study a recently evolved novel genital structure called the

posterior lobe. Previous work has found that the posterior lobe derived an enhanced accumulation of the apical extracellular matrix (aECM) during its developmental evolution. The terminal effector Dumpy is present in the aECM, and disruption of *dumpy* causes dramatic the posterior lobe defects. In investigating how *dumpy* gained posterior lobe-associated regulation, I have identified multiple enhancers sufficient to drive reporter expression in and near cells of the posterior lobe, as well as elements that drive expression in the claspers and phallus, two other structures where endogenous *dumpy* is expressed in the developing genitalia. This suggests that these enhancers might be pleiotropic. My work suggests that multiple elements underlie the evolution of posterior lobe-associated *dumpy*, providing a much-needed window into how key terminal genes are co-opted in morphological novelties.

1961F **Comparative analysis of *Drosophila* seminal fluid investment: Trade-offs and evolutionary diversification** Dylan J Sims-West[1], Zeeshan Syed[1], Roberto A. Gomez[1], Patrick O'Grady[2], Scott Pitnick[1], Stephen Dorus[1] [1]Biology, Syracuse University, [2]Entomology, Cornell University

Seminal fluid proteins (SFPs) play key roles in reproduction and evolve rapidly. In *Drosophila,* SFPs are produced by the accessory glands (AGs), transferred to females during mating and influence a diverse repertoire of female postmating phenotypes. These effects can be profound and include female remating, sperm storage and use, ovulation and oviposition. Despite their functional importance, relatively little work has been done to examine their evolution in relation to PCSS within a phylogenetic framework. The *Drosophila* genus provides a powerful model for comparative investigations into the evolution of SFP investment, composition and function given the availability of genomic resources and the recent completion of the *Drosophila* Evolutionary Phenomics (DEP) resource. Here, we report preliminary results from an investigation of the impact of PCSS on AG investment across 149 *drosophilid* species, utilizing female remating interval as a proxy for PCSS. Utilizing dry testes mass, we further examine potential trade-offs between spermatogenesis and seminal investment as it relates to PCSS. This work, coupled with ongoing comparative evolutionary proteomics, constitutes the first integrative, comparative study of AG investment and SFP composition in relation to PCSS.

1962F **Is *ftz* a pair-rule gene in *Tribolium*?** Sofia Lopez[1], Ximena Gutierrez-Ramos[2], Leslie Pick[2] [1]Entomology, University of Maryland - College Park, [2]Entomology, University of Maryland

Genes that control segmentation are expressed during early embryonic development and work together to establish the basic body plan. *fushi tarazu* (*ftz*), first identified in *Drosophila* as a pair-rule gene (PRG), is expressed in 7 stripes in the primordia of alternate segments along the anterior-posterior axis. *ftz* mutants develop as inviable truncated embryos, failing to form the regions in which *ftz* would have been expressed. In the red flour beetle, *Tribolium castaneum* (*Tc*), the *ftz* ortholog is expressed in a pair-rule manner but its function does not appear to be conserved. Previous experiments examining a large genomic deletion and RNA interference (RNAi) targeting *Tc-ftz* did not reveal pair-rule-like defects, suggesting that *ftz* is not a PRG in *Tribolium*. To definitively establish whether *Tc-ftz* functions as a PRG in this species, we employ direct parental CRISPR (DIPA-CRISPR), which has allowed efficient gene editing by injecting adult females with Cas9 and gRNAs (Shirai et. al, 2020). For this technique, CRISPR components must be injected during vitellogenesis to allow uptake into oocytes. To determine the best time of injection, we dissected ovaries from 2 to 7 day-old adult females. We found that day 4 to 7 females had more spherical and elongated oocytes that indicated initiation into the vitellogenic phase, and were chosen for injection. Two gRNAs targeting separate regions of *Tc-ftz* were injected with Cas9 protein into 5-day old females to induce directed cleavage and NHEJ. Offspring were screened by PCR with primers flanking the *Tc-ftz* targeted regions to identify heterozygotes with short indels at either of the cleavage sites. In parallel, to understand how *Tc-ftz* is regulated, we are isolating cis regulatory elements that direct pair rule expression. We utilized publicly available datasets - RNA-seq and FAIRE-seq - to identify open chromatin around *Tc-ftz* during early embryogenesis, which are likely to include regulatory sequences. To test these sequences, we generated reporter gene constructs with candidate cis-regulatory sequences upstream of the *Tc-ftz* promoter and tGFP, inserted into piggyBac vectors. After insertion into the *Tribolium* genome via embryo injection and establishment of stable lines, embryonic expression patterns will be assessed. The results of these concurrent functional and gene expression assays will reveal any contributions that *Tc-ftz* provides for segmentation and insight into its genetic regulation.

1963F **Phylogenetic comparative approaches give insight into the ecological selective pressures acting on mammalian retinas** Emily Kopania, Nathan Clark University of Pittsburgh

Vision is important for fitness in many species, but there is variation in visual acuity and the cellular structure of the retina across species. Many vertebrates have specialized high visual acuity regions in the retina defined by the density of retinal ganglion cells. Examples include the *area centralis* (high density region), horizontal streak (high density region elongated across the retina), and fovea (high density region surrounding a pit in the retina). Many have hypothesized ecological conditions that select for these specializations. For example, the *area centralis* may be used by predators for prey detection, and the horizontal streak may be associated with horizon-dominated environments (e.g., ground foraging). Despite the adaptive

potential of these specializations, these hypotheses have not been tested in a phylogenetic framework. To address this, we compiled publicly available retinal specialization phenotypes and ecological data from 83 species and overlayed these traits on a well-resolved mammal phylogeny. We found that both the horizontal streak and *area centralis* likely evolved repeatedly in mammals, and that many species have multiple specializations, such as an *area centralis* within a horizontal streak. We then used a maximum likelihood framework to test if specializations are associated with different ecological traits after controlling for phylogeny. We did not find evidence that the *area centralis* is associated with predators, casting doubt on a popular hypothesis for the role of the *area centralis*. However, we did find that the horizontal streak is significantly associated with ground foragers. Some have proposed more specific hypotheses for the function of the horizontal streak, including predator detection in grazing prey species. Therefore, we tested if the horizontal streak is associated with ground foraging herbivores less than 100kg, as these are putative prey species. We found that the horizontal streak is significantly associated with small, ground-foraging herbivores, specifically when we refined our analysis to species with only a horizontal streak. These results reveal the importance of considering evolutionary history and the complexity of retinal specialization phenotypes when investigating their potential functions. This study performs the first phylogenetic comparative test of long-standing hypotheses regarding the function of high acuity retinal specializations, thus giving insight into the ecology and evolution of visual systems.

1964F **Supergene evolution via allele-specific autoregulation** Nicholas VanKuren, Darli Massardo, Sofia Sheikh, Claire Fu, Wei Lu, Marcus Kronforst Ecology & Evolution, University of Chicago

Complex phenotypes require the coordinated action of many genes across development, yet many species can develop multiple discrete, alternate phenotypes. Recent work shows that development of such polymorphisms is often controlled by alternate supergene alleles, sets of tightly-linked mutations in one or more genes that together produce a complex phenotype. However, the process by which supergenes evolve and the mutations that cause functional differences between supergene alleles remain essentially unknown. *doublesex* is the master regulator of insect sexual differentiation but has evolved into a supergene in multiple *Papilio* swallowtail butterflies, where divergent *dsx* alleles control whether females develop distinct non-mimetic or mimetic wing color patterns. Our previous work in *Papilio alphenor* showed that the mimetic *dsx* allele gained a unique spatiotemporal expression pattern in developing wings, suggesting that the *dsx* supergene evolved allele-specific *cis*-regulatory architectures. Here we characterized the *cis*-regulatory architecture of the *dsx* supergene by identifying *cis*-regulatory elements (CREs), promoter-CRE interactions, and using CRISPR/Cas9-mediated knockouts. Hi-C and ATAC-seq showed that *dsx* is regulated solely by CREs within *dsx* introns, and that each allele has characteristic promoter-CRE loops. Seven of 31 *dsx* CREs active in developing wings (22.5%) were unique to the mimetic allele, while four (12.5%) were unique to the non-mimetic allele. In addition, Dsx CUT&RUN showed that over half of *dsx* CREs are strongly bound by Dsx itself and differentially bound in mimetic and non-mimetic female wings. At least three of these CREs are necessary for mimetic allele expression, as CRISPR/Cas9-mediated knockouts of these mimetic CREs caused females to develop non-mimetic color patterns. Our results thus provide strong evidence that the evolution of novel auto-regulatory interactions played a central role in the evolution of *Papilio* supergene mimicry polymorphisms and suggest a general mechanism for supergene evolution and function in other systems. The evolution of complex polymorphisms may therefore require simple modular changes to otherwise general developmental genes.

1965F **Biodiversity genomics of asexual and anhydrobiotic nematodes in arid and hyper-arid environments** Philipp H. Schiffer, Ann-Marie Waldvogel Institute for Zoology, University of Cologne

Deserts are among the most hostile environments to life on earth. Yet, some animals have adapted to survive and diversify under extreme water limited conditions. Evolutionary strategies for this include parthenogenesis enabling the exploration of transient ecological opportunities by offspring of a single individual, and cryptobiosis enabling organisms to wait for abiotic conditions to become favourable. Using biodiversity genomic assays in an EcoEvoDevo framework with latest sequencing methods it is now possible to study genomes of single minute invertebrates, as well as population structures in many samples from extreme environments to understand the evolutionary strategies of different species.

Here, I will present our genomic, population genetic, and ecological functional analyses of the linked evolution of these traits in nematodes from the hyper arid Atacama in comparison with the younger, more dynamic Namib desert, and the Australian Outback as a comparator system. We have established methods to conduct our genomic, and population genomic assays on-site in these remote areas and are engaged in training local students, and communities to study biodiversity on their territories.

We find locally diverse nematode species assemblages in the desert systems. In accordance with evolutionary theory these are dominated by sexual species, but heterozygosity through polyploidy appears provide an adaptive advantage to parthenogens. We observe species to employ anhydrobiosis, a mode of cryptobiosis, in different ways, to either revive fast or more slowly upon water availability.

We also recently assembled the genome of a triploid parthenogenetic *Panagrolaimus* revived from another extreme environment, the Russian permafrost. Analysing it genetically and biochemically in comparison to *C. elegans* we find resemblances in the genetic mechanisms the model organism's dauer larva and this nematode use for prolonged dormancy.

Using the CRISPR/Cas system we are now able to study parthenogenesis and cryptobiosis in *Panagrolaimus*, allowing us to understand these traits on a genetic level comparing species with different modes of reproduction and from different extreme environments.

1966F **Evolutionary Origins and Developmental Repatterning of a Morphological Novelty, the Pronotal Helmet of Treehoppers** Savanna Brown[1], Cera R Fisher[2], Elizabeth Jockusch[1] [1]Ecology & Evolutionary Biology, University of Connecticut, [2]Velsera

The evolution of morphological novelty is one major driver of species diversification. In arthropods, novel structures such as wings have repeatedly evolved as outgrowths of the body wall. One particularly enigmatic structure is the "helmet" of treehoppers, formed by a highly elaborated pronotum. One approach to investigating the origin of novelty is to characterize the development of novel structures in comparison with other body regions, as well in comparison with homologous structures of other species. Contrary to expectations of transcriptional similarity of serial homologues, our data showed that the transcriptional profile of the pronotum in the treehopper *Entylia carinata* resembles that of the wing much more than that of its serial homologue. This supports the hypothesis that the evolution of the treehopper helmet is the result of striking co-option of the wing patterning network. Furthermore, it raises questions about whether the wing patterning network extends its influence beyond wings alone, with potential involvement in the organization of bilayered epithelia throughout the body. Through RNA sequencing of several diverse treehopper species, a close, helmetless relative *Homalodisca vitripennis*, and a more distant hemipteran relative, *Oncopeltus fasciatus*, we further tested these hypotheses. We predicted that transcriptional profiles of other treehopper species will resemble that of *Entylia carinata*, showing clustering of the pronotum and wing. In tandem, we predicted that the transcriptional profiles of the helmetless but closely-related leafhopper species Homalodisca vitripennis will mirror that of distantly related *Oncopeltus faciatus*, with the clustering of the pronotum and its serial homologue. Preliminary analyses are consistent with these predictions, suggesting that the origin of this unique patterning of the pronotum aligns with the morphological origin of the helmet itself. Second, we predicted that the transcriptional profile seen in the metamorphic treehopper instar, when the pronotal tissue becomes bilayered and folds into the helmet structure, would differ from that of earlier instars. Preliminary data follows this prediction as well, aligning with the hypothesis that similarity between the patterning networks underlying helmet and wing development could be due to the shared bilayered nature of these tissues. By unraveling the genetic mechanisms governing the formation of the novel helmet of treehoppers, we gain comparative insights into the developmental patterning of bilayered epithelia and a deeper understanding of the evolutionary processes driving morphological innovation.

1967F **The DNA Damage Response gene chk2 regulates reproductive asymmetry across insects** Arjuna Rajakumar[1,2], Claire Ramsay[2], Paul Lasko[2], Ruth Lehmann[1], Ehab Abouheif[2] [1]Whitehead Institute for Biomedical Research, [2]Biology, McGill University

Eusociality is the highest level of social organization in the animal kingdom. A hallmark of eusocial groups is the evolution of a reproductive division of labor between a reproductive queen and non-reproductive worker caste that establishes, in essence, a germline-soma distinction within the colony. Remarkably, despite the evolution of reproductive and non-reproductive castes over 100 million years ago, the worker caste of the vast majority of the over 16 000 ant species retain developmentally plastic ovaries. Within a colony, workers with developed ovaries threaten social organization, and therefore, worker reproduction must be constantly regulated to maintain colony homeostasis. To this end, ant colonies have evolved multiple reproductive constraints within the germline of the worker caste that reduce their reproductive capacity, rendering them functionally sterile. However, how reproductive constraints are developmentally regulated is unknown. Here we show that chk2, a core signaling kinase in DNA Damage Response pathway, regulates multiple reproductive constraints simultaneously, and through its latent capacity to induce caste-specific phenotypes in solitary organisms, was co-opted to facilitate the evolution of reproductive division of labour in ants. Specifically, we discovered in the carpenter ant *Camponotus floridanus* that chk2 activity is increased in the germariums and oocytes of workers compared to queens and demonstrate that inhibition of chk2 in workers results in an up-regulation of numerous reproductive traits, including increased germ cell specification, reproductive activity (number of oocytes per ovariole), and reproductive fitness (percentage of viable to non-viable oocytes). Conversely, we show that overexpressing chk2 in the solitary fruit fly *Drosophila melanogaster* induces reproductive constraints (specification of fewer germ cells and mislocalization of germplasm) similar to those we observe in worker ants. Overall, our findings highlights the power of emerging and model comparative studies to tackle fundamental questions in biology.

1968S **Characterizing actin structures during tube formation in *D. melanogaster* egg chambers** Luana Paleologu[1], Celeste Berg[2] [1]Genome Sciences, University of Washington, [2]University of Washington

The folding of epithelial sheets, processes known as wrapping and budding, are the foundation for creating many tubular organs in nearly all multicellular organisms. Nevertheless, there is much to understand about the molecular mechanisms that drive cell shape changes and tissue folding. The Berg lab uses genetic and imaging techniques to understand tube formation in *D. melanogaster* egg chambers. The egg chambers form tubes that fill with chorion protein, creating eggshell structures called dorsal appendages that help embryos receive adequate oxygen. The egg chamber of *D. melanogaster* serves as a good model system to study tubulogenesis since the tissue folding and cellular shape changes during dorsal appendage formation are well understood. There are two fundamental processes that occur early in dorsal appendage formation that have been well-characterized in other systems: apical constriction and zippering. While we have a strong understanding of how cells are moving during these processes, we do not know how the cytoskeleton is coordinating shape changes, and by what signaling mechanisms these cytoskeletal dynamics are regulated. To assess these processes, we are using phalloidin-stained fixed tissue to characterize actin structures using STED microscopy, as well as live imaging of actin and myosin to characterize dynamics. These approaches revealed dynamic basal actin throughout tube formation in addition to expected apical structures. In addition, we have observed spherical, basal actin structures (50-300 nm) developing late in dorsal appendage formation. Recent studies have pointed to the importance of exosomes and other transport vesicles in aiding cell migration, leading us to hypothesize that these actin-based spherical structures may be implicated in tube elongation. Here we present a study of the changes in the actin cytoskeleton during dorsal appendage formation with a focus on how this remodeling drives cell shape change and movement.

1969S **A genomic hotspot of diversifying selection and structural change in bats (Chiroptera)** Robert S Cornman U.S. Geological Survey

Previous work found that numerous genes positively selected within the hoary bat (*Lasiurus cinereus*) lineage are physically clustered in regions of conserved synteny. Here I report an expanded analysis utilizing an updated *L. cinereus* genome assembly and additional bat species as well as other tetrapod outgroups. A chromosome-level assembly was generated by chromatin mapping and made available by DNAZoo (www.dnazoo.org). The genomic organization of orthologous genes was extracted from annotation data for multiple bat species as well as other tetrapod clades for which chromosome-level assemblies were available from the National Center for Biotechnology Information (NCBI). Tests of branch-specific positive selection were performed for *L. cinereus* using PAML. For comparison, tests were also performed with the Hyphy package and for more inclusive clades within vesper bats (Chiroptera: Vespertilionidae). Fourteen genes exhibiting significant diversifying selection in the *L. cinereus* lineage were clustered within a 15-Mb genomic window. Evaluation of additional phylogenetic branches within Vespetilionidae suggests that the majority of these genes began diversifying under positive selection prior to the divergence of the *L. cinereus* branch. Ten of the 14 genes are landmarks of two distinct blocks of ancient synteny that are not linked in other tetrapod clades. Vespertilionids are further distinguished by frequent structural rearrangements within these synteny blocks that are rarely observed in other Tetrapoda. Patterns of gene order and orientation among bat taxa are incompatible with phylogeny as presently understood, implying parallel evolution or subsequent reversals. In the bat family Phyllostomidae, a switch from pericentric to subtelomeric organization of the orthologous genes coincides with a strong increase in GC content of approximately 20 percentage points, a pattern not seen in any other tetrapod groups surveyed. This study confirms and further localizes a genomic hotspot of protein-coding divergence within Vespetilionidae, one that concomitantly exhibits an increased tempo of structural and compositional change. Most genes in the two synteny blocks have elevated expression in brain tissue in model organisms, and genetic studies implicate the selected genes in cranial and neurological development, among other functions.

1970S **Testing the function of the ebony gene in Oncopeltus fasciatus with CRISPR and RNAi** Veronika Valverde Jimenez, Leslie Pick, Katie Reding University of Maryland College Park

Oncopeltus fasciatus is a model species for the insect order Hemiptera (Chipman, 2017). CRISPR can be performed on this model organism (Reding & Pick, 2020), but visible markers are needed for genetic analyses. The *Of-vermillion* gene is the only visible marker, with homozygous mutants having bright red eyes, clearly different from wild type black eyes. CRISPR co-mutation targeting of *Of-vermilion* has proven useful to detect unlinked mutations at other loci. Since *vermilion* is X-linked in *Oncopeltus*, one quarter of all G1 progeny are not informative with regard to G0 germline mutation. Mutation of the *ebony* gene causes expansion of black melanin pigment deposition in the cuticle of many insect species. Due to this easily observable phenotype in *ebony* homozygotes, *ebony* is an ideal marker for CRISPR co-mutation: G1 progeny can be screened for the clearly visible *ebony* phenotype, and molecular screening at the locus of interest can be concentrated on lines that yield *ebony* progeny. To assess the role of *ebony* in *Oncopeltus*, nymphal and embryonic *Of-ebony* RNAi was performed. This resulted in additional black pigment present on the dorsal and ventral thorax and head. Further, gene knockdown did not appear to reduce viability at either developmental stage, suggesting we will be able to generate a stable *ebony* mutant line. To do so, we are using CRISPR/Cas9 genome editing. Four different guide RNAs were selected based on their specificity to the *Of-ebony* locus. *Oncopeltus* embryos were injected with gRNA-A and Cas9 mRNA, which resulted in a hatch rate of 42.29% (n =

584). The development of these embryos was monitored; 61 adults in the G0 population exhibited a mosaic *ebony* phenotype of varying amounts of expansion of melanin on the head and thorax. G0s were sorted by mosaic or wild type phenotype, and all mosaics were allowed to randomly mate. 139 mosaic G1 offspring were then screened for heterozygosity using a heteroduplex mobility assay, and 6 appeared to be heterozygous. Crosses to establish *Of-ebony* homozygous lines are in progress. The other three gRNAs will be evaluated for off-target effects and efficiency to select the best gRNA for use in CRISPR co-mutation schemes. These preliminary results suggest we will be able to generate a stable *ebony* mutant line, expanding the genetic markers for *Oncopeltus*.

1971S **Developmental transcriptomics in *Pristionchus* reveals the timing, responsiveness, and evolution of a plastic trait** Shelley J Reich, Samantha Nestel, Michael S Werner School of Biological Sciences, University of Utah

The nematode *Pristionchus pacificus* exhibits phenotypic plasticity in mouth form and has emerged as a model system for studying developmental plasticity. These worms can develop either a narrow, bacterivore mouth with a single tooth or a wide, omnivore mouth with two movable teeth that enables predation on other nematodes in addition to feeding on microbiota in the environment. Mouth-form development is sensitive to environmental conditions and biased by the worm's genetic background. Prior studies have uncovered several genes which are required for alternative mouth-form phenotypes. We collated these data into a gene regulatory network (GRN) and performed developmental transcriptomics across different environmental conditions, genetic backgrounds, and mouth-form mutants to identify 1) which genes in the network are environmentally responsive, 2) when during development are they responsive, and 3) how these patterns change over evolutionary time. We found that expression of only a subset of previously identified mouth-form genes is sensitive to environmental conditions. The timing of their expression relative to a critical developmental window informs their role in executing the mouth-form decision. A comparison between strains and species with different mouth-form biases reveals a pruning of the GRN across evolution. Surprisingly, our analyses suggest different roles for the two previously identified switch genes, *eud-1* and *seud-1/Ppa-sult-1*. The former appears to be an environmental sensor, while the latter sets the default mouth form for a given genetic background. A comprehensive analysis of all sample types (environmental, mutant, strain, and species) identifies common pathways involved in regulating mouth-form development. Collectively, our temporal analyses provide a framework for the genetic regulation of developmental plasticity.

1972S **MSS-related family of glycoproteins in *Caenorhabditis* contribute to male sperm competitive fitness via unknown mechanisms** Asan Turdiev[1,2], Jillian Manning[1], Eric Haag[1,2] [1]Biology, University of Maryland, [2]Biological Sciences Graduate Program, University of Maryland

Sperm competition is a major component of sexual selection and is present in all major animal groups. Research from the past decades on several animal models, including flies, mice, and nematodes, has led to the identification of genes with apparent roles in sperm competitiveness. Their molecular mechanisms are generally unknown, but they appear distinct from core fertilization factors. The genetically dispensable nature of sperm-competition genes for reproduction makes them more amenable to genetic manipulation than fertilization genes, yet they may reveal general lessons about gamete biology. Using comparative genomics, the Haag lab previously identified genes encoding small sperm glycoproteins present in outcrossing species but consistently lost in hermaphrodites. These comprise the Male Secreted Short (MSS) family. Restoring *mss* to males of the self-fertile *C. briggsae* via transgene from a close male-female relative *C. nigoni* led to a large increase in male mating success in competitive contexts. While *mss* has been lost in selfing species, *mss-related proteins* (*msrps*) show evolutionary conservation across all *Caenorhabditis*. Here we asked whether *msrps* are retained because they are required for baseline fertility. Our research on *C. briggsae* shows that MSRPs are indeed expressed in sperm. Deletion of a cluster of *msrp* does not affect the mutant hermaphrodite's brood size nor the mutant male's natural ability to compete with WT hermaphrodite's sperm post-mating. However, under competitive settings where male sperm compete for fertilization, MSRP$^-$ sperm display a fitness defect. The precise biological roles of MSRPs on the male sperm inside the female's reproductive tract is the focus of ongoing research.

1973S **Characterizing the composition and morphology of the germ plasm in the wasp *Nasonia vitripennis*** Allie Kemph[1], Jeremy Lynch[2], Alexey Arkov[3], Kabita Kharel[3], Samuel Tindell[3] [1]Biological Sciences, University of Illinois at Chicago, [2]University of Illinois at Chicago, [3]Murray State University

Specification of germ cell fate during embryogenesis is an essential process in sexually reproducing organisms to ensure the correct transmission of parental genetic information to offspring. In many cases it involves germ plasm, a specialized cytoplasmic organelle composed largely of mRNA and RNA-binding proteins. We are working to characterize a uniquely large and dynamic germ plasm found in the wasp *Nasonia vitripennis*, called the oosome (~25um). During early embryogenesis the oosome is initially attached at the posterior cortex, but quickly detaches and migrates a significant distance anteriorly, returns to the posterior cortex where it induces single large pole budding event involving multiple nuclei. This contrasts with germ

plasm in *Drosophila,* which consists of many small (0.2-0.5um) “polar granules”, which are static at the posterior cortex until individual nuclei induce pole cell budding. In order to understand the molecular and structural differences between polar granules and the oosome, we have undertaken a detailed analysis of the oosomes composition and ultrastructure using super-resolution microscopy and TEM. Oosome ultrastructure is characterized by a complex mesh-like network of electron dense material that forms numerous pockets and channels. This network also incorporates and interacts with numerous unusual membrane-bound organelles, and excludes mitochondria. Fluorescent super-resolution microscopy has revealed some of the molecular basis for the unique features of the oosome. We found that highly enriched oosome mRNAs are arranged in a complex pattern consisting of highly concentrated puncta connected by a meshwork of lower concentration regions. Less enriched mRNAs are found in more dispersed puncta along the networks of high-level transcripts. Conserved germ plasm proteins also show unexpected patterns. Tudor accumulates in a shell-like domain encapsulating the oosome, while Oskar and Vasa are found in puncta that do not appear to nucleate mRNA localization. Understanding how these unusual arrangements arise and are maintained will provide unique insights into how mRNA and protein can be deployed to form functional membraneless organelles.

1974V **The Evolution of fem-1 activity in Caenorhabditis** James F Kennedy[1], Ronald Ellis[2] [1]Molecular Biology, Rowan GSBS, [2]Rowan GSBS

Hermaphrodite sex determination is shared between the Caenorhabditis species C. elegans, C. briggsae, and C. tropicalis, but this trait is thought to have occurred independently. The core pathway that makes this determination shares large similarity in the Caenorhabditis genus among which are the FEM complex proteins: FEM-1, FEM-2, and FEM-3. These proteins were discovered in C. elegans where corresponding genes are necessary for male sex determination as evidenced by null mutants producing feminizing mutations in the soma and germline in both XX and XO animals. This phenotype is not shared in C. briggsae where fem-2 and fem-3 null mutants in both XX and XO animals are hermaphrodites. This difference suggests a divergence in the role of the FEM complex in these two species. My research began with developing a fem-1 null mutant by CRISPR/Cas9 injection in C. briggsae.

The mutant strain of fem-1(v508) showed an identical phenotype to C. briggsae fem-2 and fem-3 null mutants producing fertile XX and XO hermaphrodites. XO hermaphrodites were verified through RT-PCR of her-1 mRNA and unc mutant genetic crosses. To place fem-1 in the sex determination pathway, double mutants of this gene with its direct upstream (tra-2) and downstream (tra-1) genes were produced. The expected results were received with tra-1(v181); fem-1(v508) mutants being XX males and tra-2(nm1); fem-1(v508) mutants being XO hermaphrodites. While the FEM proteins were expected to act as a complex, a null triple mutant of fem-2(nm27); fem-3(nm63) fem-1(v517) was produced by CRISPR/Cas9 of fem-1 in an existing fem-2; fem-3 double mutant. This mutant has an identical phenotype to individual null mutants.

A complex relationship between the FEM proteins and germline development is suggested by oogenesis in tra-1; fem double mutants in C. elegans. This was replicated in C. briggsae by germline scoring of tra-1(v181) mutants with corresponding fem genes. A spermatogenesis to oogenesis switch was seen in these tra-1 males. This result suggests that the fem genes serve an unknown downstream function in both C. elegans and C. briggsae.

The epistatic interactions of C. tropicalis between fem-1 and its upstream (tra-2) and downstream (tra-1) genes in the sex determination pathway will be determined with created null mutants by CRISPR/Cas9. These null mutants (tra-1 and tra-2) are XX males. It is expected that the somatic and germline phenotypes of double mutants will show similarity to C. elegans.

1975V **Identification of changes in regulatory sequence underlying the gain of polka-dotted pigmentation pattern in *Drosophila guttifera*** Takumi Karasawa[1], Shigeyuki Koshikawa[2] [1]Division of Biosphere Science, Hokkaido University, [2]Division of Biosphere Science, Graduate School of Environmental Science, Hokkaido University / Faculty of Environmental Earth Science, Hokkaido University

Evolution has produced a variety of traits throughout the history of life. A central goal in evolutionary developmental biology is to reveal how diverse traits are newly gained. Recent studies have shown that the co-option of pre-existing genes or gene regulatory networks is important in the gain of new traits. One factor that can cause co-option is changes in *cis*-regulatory elements, but what kind of changes in sequence occur in the co-option are still poorly understood.

Drosophila guttifera has a polka-dotted pigmentation pattern, which is unique to this species on its wing. This pigmentation pattern is known to have been acquired via the co-option of a developmental gene, *wingless*. The pigmentations are formed around longitudinal vein tips, intersecting points of longitudinal veins and crossveins, and campaniform sensilla, and *wingless* is expressed in the center of these positions during the pupal stage. In *Drosophila melanogaster*, which does not have a pigmentation pattern on its wing, *wingless* is expressed only in the crossveins in the pupal wing. A previous study has identified a *cis*-regulatory region that regulates expression in the crossveins and longitudinal vein tips (gutCVT-core) and

showed that this *cis*-regulatory activity is gained via changes in the ancestral regulatory element, which activates expression only in the crossveins. However, the changes in sequence that brought expression in the longitudinal vein tips are still unknown.

In this research, we compared the sequence and the regulatory function of gutCVT-core with the homologous region of a close relative, *Drosophila angularis* (angCV-core), and identified the changes in sequence that brought the *wingless* expression in the longitudinal vein tips.

We compared the sequence of gutCVT-core and angCV-core and identified several blocks of sequence that mismatch between the regulatory regions. We then made chimeric regulatory sequences in which each mismatched sequence in gutCVT-core is replaced with the corresponding sequence in angCV-core. Testing the regulatory function of these chimeric sequences by EGFP reporter assay, we identified several sequences that function in driving expression in the longitudinal vein tips and are newly gained in gutCVT-core. Our results suggest that not a single, but multiple changes in sequence were required to cause the co-option of *wingless*.

1976V **Identifying co-factors for TRA-1 activator function** Jibran Imtiaz, Youngquan Shen, Ronald Ellis Molecular Biology, Rowan-Virtua STBES

Gli proteins are conserved transcription factors with five zinc fingers. The first one discovered was Cubitus interruptus (Ci) in *Drosophila*. Humans have three Gli proteins, which play a key role in many tissues and organ development, and their misregulation causes some cancers and birth defects. Human Gli proteins and Ci are all involved in Hedgehog (Hh) signaling pathways. However, what other co-factors they utilize, which co-factors are essential for activator function, and how they interact with them remain poorly understood. We are analyzing co-factors of TRA-1, the only Gli protein in *Caenorhabditis*, which is even conserved in the distantly-related nematode *Pristionchus pacificus*. Like all Gli proteins, the TRA-1 zinc fingers are highly conserved and TRA-1 is cleaved to form a transcriptional repressor. In nematodes, TRA-1 controls all sexual fates, largely by repressing genes needed for male development, and it also plays a central role in self-fertility. These traits make it easy to assay mutant phenotypes. Furthermore, worms lack classical Hedgehog signaling, so study of nematode TRA-1 should reveal other types of regulation.

Our lab has shown that full-length TRA-1 can work as an activator and promote spermatogenesis, and that the mutation *cbr-tra-1(v48)* disrupts this process and prevents spermatogenesis. We suspect that regulation of TRA-1 activator plays a major role in the evolution of hermaphrodite spermatogenesis in nematodes. Because *v48* was isolated in a classical EMS mutagenesis, we recently made other activator mutations to confirm that all of its phenotypes were due solely to the alteration of TRA-1.

TRA-1 activator is likely to interact with a diverse set of co-factors, whose activities might help determine whether specific targets are activated or repressed. Our results have shown that TRR-1 works directly with TRA-1 activator to promote expression of the *fog-1* and *fog-3* genes. We also purified TRA-1::N-OLLAS using dynabeads and are now characterizing the products obtained from these tagged worms and are preparing to analyze them with mass spectrometry. While doing so, we will look for important modifications to TRA-1 itself, as well as the precise site of cleavage that forms the repressor. In addition, we hope to identify TRA-1 co-factors and learn how they regulate Gli activity. Finally, we will see if any of these co-factors has a novel role in species that produce self-fertile hermaphrodites.

1977V **Evolution and Development of Egg Tooth Across Aminotes** Jingjing Wang Life Science Institute, Zhejiang University

Egg tooth is essential for the egg-laying amniotes to break out of the eggshells toward the end of hatching, and sheds shortly. Little is known about the mechanisms of egg tooth initiation, propagation and detachment progress from the beak/mouth part, as well as the factors contributing to the morphological diversity across species, despite their vital role. It severs a paradigm to study the evolution and developmental mechanisms that can be applied to many other important yet puzzlingly diversified body appendages. To address these questions, I collected developing embryonic egg tooth samples from a variety of oviparous amniotes that possess epithelial egg teeth composed primarily of keratins. These species include chicken, duck, emu, ostrich, crocodile, and turtle. I found that the development of egg teeth is initiated with gradual keratinization starting from a transparent bump on the beak/mouth that subsequently spreads, and merges with the complete keratinization of the beak. We test the hypothesis that the initiation of egg tooth is associated with that of subsequent keratinization of beaks in chicken. To do that, we removed the primordium of egg tooth in chicken at different stages. We find that the beak keratinization process is not affected by removal of early egg tooth primordium, but by that of the later stages. Keratinization of all beaks occurs during the late stages of chicken egg tooth development. Interestingly, our study revealed that crucial transcription factors, including *HOXC13*, *FOXN1*, and *KLF5*, play central roles in initiating egg teeth development across different species. Furthermore, the distinct variations in the unique number of alpha and beta keratin genes, as well as their

expression patterns across different species, provide pivotal insights into understanding the complex mechanisms of egg teeth development and evolution.

1981T **NCBI Datasets: an innovative resource for finding and downloading NCBI sequence and metadata for organisms across the tree of life.** Nuala O›Leary, Eric Cox, Terence Murphy, Valerie Schneider NCBI, National Institutes of Health

The National Center for Biotechnology Information (NCBI) maintains the largest global depository of genome sequences, annotations, and associated metadata, encompassing a wide variety of life forms. However, the burgeoning size and complexity of genomic information pose significant obstacles for researchers attempting to locate and obtain complete genome datasets in user-friendly formats suitable for their specific analytical processes. Moreover, there is a pressing need for data infrastructures and sharing protocols that comply with the FAIR principles, ensuring data is Findable, Accessible, Interoperable, and Reusable. Toward this goal, NCBI introduces NCBI Datasets, a new resource that develops web, command-line, and API interfaces for accessing NCBI sequence data that are intuitive and user-friendly. Datasets delivers data as a coherent data package including sequence, annotation, and metadata for assembled genomes, genes, and orthologs. This presentation will highlight the most recent advancements in Datasets and illustrate and highlight how NCBI Datasets is supporting CGR is an NIH-funded, multi-year NLM project to establish an ecosystem to facilitate reliable comparative genomics analyses for all eukaryotic organisms in collaboration with the genomics community.
