1 **Larry Sandler Award Lecture - How proteolytic degradation, actomyosin contractility, and cell polarity converge to regulate Hippo signaling and tissue growth** Sherzod A Tokamov Plant and Microbial Biology, The University of Chicago

The Hippo pathway is an evolutionarily conserved regulator of tissue growth. At the core of the pathway, a kinase cascade represses the activity of a transcriptional effector, an oncoprotein called Yorkie. Inactivation of the Hippo pathway results in the translocation of Yorkie into the nucleus, where it promotes a pro-growth genetic program. Multiple upstream inputs are known to synergistically activate the kinase cascade from the apical cortex of polarized epithelial cells. However, how these components are organized and the mechanisms by which they are regulated remains poorly understood.

My thesis work explores how Hippo signaling is controlled, focusing on the regulation and organization of a key upstream Hippo pathway organizer, a multivalent scaffold protein called Kibra. Unlike other Hippo pathway regulators, which localize mainly at the junctional cortex of epithelial cells, Kibra's subcellular localization is distinctly partitioned into junctional and medial domains of the apical cortex. Previous work has shown that medial localization potentiates Kibra-mediated Hippo pathway activation, but the mechanisms that control Kibra activity and subcellular organization remain unknown.

In this dissertation, I present evidence that proteolytic degradation, actomyosin cytoskeleton, and apical polarity network converge to control Kibra-mediated Hippo signaling. First, I demonstrate that ubiquitin-mediated degradation is a major mechanism that regulates Kibra abundance. Specifically, upon assembly of the Hippo complex, Kibra is ubiquitinated via the SCF^{Slimb} E3 ubiquitin ligase machinery and is subsequently degraded. Next, I show that ubiquitin-mediated Kibra turnover is modulated by actomyosin-generated cortical tension. Mechanistically, increased tension results in tighter cortical association of the Ser/Thr kinase Par-1, and Par-1 promotes Kibra degradation. Finally, I identify the mechanism by which Kirba is partitioned into junctional and medial pools at the apical cortex. I show that the apical polarity network, in part via aPKC, tethers Kibra at the junctional cortex to silence Kibra-mediated Hippo signaling, whereas medial actomyosin flows untether Kibra from the junctional cortex and promote its medial accumulation, thereby increasing Kibra-mediated Hippo signaling. Together, these findings provide crucial insights into the regulation of the Hippo pathway and reveal functional relationships between upstream Hippo signaling, actomyosin dynamics, and apical polarity network in tissue growth control. More broadly, this work provides a paradigm for understanding how mechanical forces and epithelial cell architecture organize and regulate intracellular signaling events.

2 **Defective *Hoxb8* Microglia are Causative for both Chronic Anxiety and OCSD-like Behavior in Mice** Mario Capecchi Human Genetics, Univ Utah Sch Med

We have shown there are two cell lineages in mice that give rise to microglia with distinct ontogenies; *Hoxb8* microglia and non-*Hoxb8* microglia. Disruption of *Hoxb8* or ablation of the *Hoxb8* cell lineage gives rise to both chronic anxiety and OCSD-like behavior (trichotillomania, compulsive pathological overgrooming, leading to lesions at the sites of overgrooming). There is a strong sex bias for both behavioral pathologies, with females showing much more aggressive disease. By cell transplantation of purified, cell sorted *Hoxb8* microglia progenitors derived from Wt or *Hoxb8* mutant mice we were able to demonstrate causation of defective *Hoxb8* microglia for both behavioral pathologies. Recently we have demonstrated that optogenetic activation of *Hoxb8* microglia in specific regions of the brain induces higher levels of anxiety, grooming or both. Further, these experiments have demonstrated that *Hoxb8* microglia function to reduce anxiety and grooming (function as brakes) whereas non-*Hoxb8* microglia function to increase these behaviors (function as an accelerator). This provides a biological reason for mice having two populations of microglia. We have further extended this work to define the molecular mechanisms used by microglia to communicate with specific neuronal circuits to modulate anxiety and grooming in mice.

3 ***Doublesex* modifies wing circuits in the evolution of courtship song types in *Drosophila*** Dajia Ye, Justin Walsh, Ian Junker, Yun Ding Department of Biology, University of Pennsylvania

Animals exhibit extraordinary behavioral diversity. However, it is unclear how species variation in complex motor behaviors are encoded by evolutionary changes in genes and neurons. To fill in this knowledge gap, we took advantage of the diversification of *Drosophila* courtship songs as a model system to explore the molecular and neural mechanisms underlying species variation in behavior. Males of *Drosophila* species sing species-specific and context-dependent courtship songs by wing vibration. In many *Drosophila* species including *D. melanogaster*, males sing two major types of songs, sine song and pulse song. In contrast, *Drosophila yakuba* has lost the ability to sing sine song. Here we investigated the lineage-specific loss of sine song in *D. yakuba* by comparing its neural circuit with *D. melanogaster*. We found that the loss of sine song is accompanied by a partial loss of TN1 neurons – a group of male-specific wing patterning neurons. Anatomical and single-cell transcriptomic comparisons of TN1 neurons between species support a loss of the TN1A neuronal subtype, which is essential for sine song generation in *D. melanogaster*. Consistent with this cell-type specific loss, optogenetic activation of TN1 neurons in *D. yakuba* triggered the characteristic unilateral wing extension but not sine song. To explore the genetic underpinning

of TN1 neuron divergence, we leveraged the involvement of the sex determination gene *doublesex* (*dsx*) in TN1 neuronal development in *D. melanogaster* males to test if the function of *dsx* evolved to cause the partial loss of TN1 neurons in *D. yakuba*. Whereas *dsx* expression had no effect on the number of TN1 neurons in *D. melanogaster*, we found that in *D. yakuba*, loss of *dsx* led to more TN1 neurons compared to control males. Surprisingly, blocking apoptosis of *dsx* neurons also resulted in a gain of TN1 neurons to the same extent as *dsx* null males, which indicates that *dsx* evolved to promote TN1 apoptosis in *D. yakuba*. Together, our work revealed a causal role of cellular changes in motor patterning circuits during the evolution of complex behaviors, and the evolutionary lability of sex determination genes in reconfiguring sexually dimorphic circuits through programed cell death.

4 **Rock (dove) 'n' roll: the genetic basis of rolling in the domestic pigeon (*Columba livia*)** Atoosa M Samani, Tori M Earl, Emily T Maclary, Michael D Shapiro University of Utah

Hereditary rolling in the domestic pigeon (*Columba livia*) is an unusual behavior characterized by backward somersaults when attempting to fly. Rolling is progressive: it does not present itself until a few weeks after fledging and becomes more severe with age. Roller pigeons walk, eat, and breed normally, suggesting that rolling is a specific context-dependent behavior and not a generalized physiological disorder. Rolling is recessive and highly heritable – Charles Darwin described it as "…one of the most remarkable inherited habits or instincts ever recorded" – yet the molecular genetic basis of this behavior remains unknown. Therefore, rolling offers a unique opportunity to discover the molecular basis of a complex yet genetically tractable behavior. In a laboratory intercross between rolling and non-rolling pigeon breeds, we identified several quantitative trait loci (QTL) associated with rolling behavior, with one major QTL explaining 56% of the phenotypic variance. Comparisons between the re-sequenced genomes of 25 roller and 125 non-roller pigeons confirmed the polygenic control of this behavior, and our complementary QTL mapping and GWAS approaches yielded overlapping results. We also compared the transcriptomes of different brain regions of roller and non-roller pigeons and found that the cerebellum has the highest number of differentially expressed genes. Pathway analysis suggests that translation is inhibited, and synaptogenesis is activated in the hindbrain of rollers, similar to neurodegenerative diseases. Dissection of the candidate loci at the gene level will deepen our understanding of the molecular basis of involuntary and task-specific movement disorders and other progressive vertebrate behaviors.

5 **IGEG-1 is an EGFR ligand that links cellular stress with sleep in *C. elegans*** Cheryl Van Buskirk[1], Andrew Hill[2], Bryan Robinson[3], Paul Sternberg[2] [1]Biology, California State University Northridge, [2]California Institute of Technology, [3]California State University Northridge

Across animals, prolonged wakefulness is associated with indicators of cell stress in both neuronal and non-neuronal tissues, indicating that a core function of sleep is to promote global cellular homeostasis. Further, in both invertebrates and vertebrates, increased sleep is observed in response to conditions that cause cell damage, DNA damage, or disruption of protein homeostasis. The mechanisms by which cellular stress promotes sleep, and by which sleep in turn restores homeostasis, are poorly understood. The nematode *C. elegans* provides a compelling system for addressing these questions, as exposure to damaging conditions triggers sleep rapidly, independent of circadian cues. This stress-induced sleep (SIS) can be modulated by mutations that impact cellular repair processes, and appears to aid recovery from noxious exposure. Neurons that mediate SIS have been identified and shown to depend on EGFR/LET-23 signaling for their sleep-promoting function. However, the putative EGF signal and the mechanism by which it transduces diverse cellular stressors are unknown. We have recently identified IGEG-1, a previously unrecognized *C. elegans* EGFR ligand that is critically required for SIS. We present evidence that the extracellular EGF domain of IGEG-1 undergoes stress-responsive shedding by the ADAM17/TACE homolog ADM-4. We find that inducible overexpression of IGEG-1 potently induces sleep that depends on ADM-4 and LET-23, and that the requirement for ADM-4 can be bypassed using a constitutively-secreted form of IGEG-1. We have employed the cGAL-UAS system to identify the site of IGEG-1 release during SIS and we find that the site of sheddase activity depends on the tissue specificity of the damaging agent. Our data support a model in which IGEG-1/EGF is released from damaged tissues to promote sleep by activating EGF receptors in sleep-promoting neurons. Our study identifies a molecular mechanism linking the accrual of cellular stress in diverse tissues with organismal sleep drive, with potential bearing on our understanding of sleep in humans.

6 **Evolutionary genetics of aggression of the Siamese fighting fish** Pei-Yin Shih, Hiroki Tomida, Alec Palmiotti, Claire P Everett, Marcos Valenzuela Cuevas, Sarah Aktari, Andrés Bendesky Columbia University

Aggression is a fundamental social behavior that animals use for gaining and defending resources, territories, and mates. Genetic variation is known to contribute to individual differences in aggression, but the specific genes involved are still largely unknown. To identify these genes and how their variation mechanistically shapes aggressive behavior, we are leveraging the unique traits of the Siamese fighting fish, *Betta splendens* (betta). Highly aggressive fighting betta have been generated through more than 700 generations (~400 years) of artificial breeding. Their aggressive behaviors are easily triggered by visual stimuli, and their intense fighting continues until retreat or death. To characterize their behaviors, we used highly controlled

and reproducible visual stimuli, including custom fish animations and 3D-printed fish models, and found that fighting betta show more aggressive displays as well as physical biting attacks compared to their unselected wild counterpart. To identify genetic variants under selection in fighting betta, we used population genetic approaches and identified a strong genetic signal of selection in fighting fish peaking at the *neuroligin1* (*nlgn1*) gene. *nlgn1* mediates the formation and maintenance of synapses and its human homologs have been implicated in the etiology of autism spectrum disorder, which often includes high aggression. There were no coding differences in *nlgn1* between fighting and wild fish, but fighting fish express 2–4×-less *nlgn1* mRNA during larval development than wild fish. We are now performing genetic manipulations to confirm the involvement of *nlgn1* and further characterizing its mechanism of action. Notably, we have developed multiple genetic tools in betta fish, including CRISPR/Cas9-mediated knockout, CRISPR/Cas9-mediated knock-in and Tol2-mediated transgenic methods. This study is providing insights into molecular, genetic, and neuronal mechanisms of aggressive behavior, questions of fundamental importance in the study of the evolution and biology of animal behavior.

7 **Cellular and molecular basis of an aversive pathway regulating drinking in flies** Anindya Ganguly[1], Craig Montell[2] [1]Neuroscience Research Institute, University of California, Santa Barbara, [2]Neuroscience Research Institute; Molecular, Cellular and Developmental Biology, University of California, Santa Barbara

Drinking or consumption of water plays a pivotal role in regulating the osmolality of bodily fluids, thus contributing significantly to the maintenance of osmotic balance in the body. In fruit flies, detection of water by their taste system precedes initiation of drinking bouts. Previous studies have identified that *ppk28* an amiloride-sensitive channel functions as the water receptor in specific sub-class of gustatory sensory neurons dedicated to water perception. Knocking out *ppk28* or artificially silencing these neurons substantially reduces drinking time in flies. We report an additional pathway that perceives water as having a negative valence, influencing the duration of drinking and thereby contributing to the regulation of water intake. We observed that *OtopLA*, a proton channel previously been shown to function as a broad-range pH sensor in flies, can also function towards the detection of water. However, contrary to what was previously observed with *ppk28*, drinking time was prolonged by 4-5 times in flies where *OtopLA* was knocked out. By conducting cell-type specific genetic rescue experiments in various subsets of taste neurons, we demonstrated that *OtopLA* function is required in a subset of aversive taste neurons previously recognized for their sensitivity to high salt concentrations. Silencing these neurons significantly extended drinking duration, phenocopying OtopLA mutant flies. We propose a model in which the relative frequencies of action potentials between two subsets of neurons, one detecting water as a positive stimulus and the other perceiving it as a negative one, jointly regulate drinking behavior in flies. Specifically, a higher frequency of action potentials in *ppk28* water taste neurons signals the initiation of drinking, while the *OtopLA* water neurons convey signals to terminate drinking episodes. As the function of otopetrins as proton channels is remarkably conserved, this study lays a solid foundation for investigating drinking regulation in various other animal species.

8 **Caregiving Drives Changes in Male Behavior, Neural Physiology, and Gene Expression in California Mice** Maria E Colt[1], Erica Glasper[2], Heidi Fisher[3] [1]Biology, University of Maryland, [2]The Ohio State University College of Medicine, [3]The Jackson Laboratory

Parental care is critical to offspring survival in mammals but can also lead to measurable changes in parents. In the biparental California mouse, *Peromyscus californicus*, fathers actively groom, huddle, retrieve, and build a nest for their offspring. Previous research has shown that these fathers experience increased memory, decreased anxiety, hippocampal neurogenesis, and increased density of dendritic spines, which improves contact between neurons. However, the trigger, reproduction or caregiving behavior, and molecular pathways that regulate these behavioral and neurophysiologic changes, remain unclear. Here we first compared caregiving behaviors in fathers who have cared for their pups and pup-sensitized non-fathers who have cared for unrelated pups and found that pup-sensitized non-fathers were slower to approach pups but eventually spent more time grooming pups, whereas fathers spent more time nest-building. We also compared recognition memory and anxiety-like behaviors, as well as hippocampal dendritic spine density in fathers, non-fathers with no caregiving experience, pup-sensitized non-fathers, and virgins that were paired with another male and had no caregiving experience. We found that experienced fathers exhibited increased recognition memory and decreased anxiety-like behavior compared to virgins and non-fathers, and that fathers show the greatest dendritic spine density. Finally, we compared hippocampal gene expression in fathers, non-fathers, and pup-sensitized non-fathers and performed network and pathway analyses to identify suites of RNA expression patterns associated with caregiving experience. We found that fathers exhibit an upregulation of genes associated with neuron generation, differentiation, and development, but that pup-sensitized non-fathers also exhibit many of these same gene expression changes. Lastly, we found that caregiving experience is associated with specific biological pathways and newly identified expression modules. Our results suggest that caregiving behavior induces important behavioral, structural, and molecular changes in the brains of males even if the offspring are not their own.

9 **Transgenic worms for interrogating signal propagations in *Caenorhabditis elegans* using GUR-3+PRDX-2 as neuro-actuator** Anuj Sharma[1], Francesco Randi[1], Sandeep Kumar[2], Sophie Dvali[1], Andrew Leifer[3] [1]Department of Physics, Princeton

University, [2]Princeton Neuroscience Institute, Princeton University, [3]Department of Physics and Princeton Neuroscience Institute, Princeton University

The *Caenorhabditis elegans* nervous system has the most mature and comprehensively mapped connectome, or wiring diagram of chemical and electrical synapses of any animal (White, Southgate et al. 1986, Cook, Jarrell et al. 2019, Witvliet, Mulcahy et al. 2021). Although the connectome has been an invaluable resource, it does lack some information about the strength and sign (excitatory vs inhibitory) of neural connections or their temporal properties and cannot capture extrasynaptic signaling of mono-amines and neuropeptides (Bentley, Branicky et al. 2016, Ripoll-Sánchez, Watteyne et al. 2022). Instead functional recordings of neural signaling in living animals, including nematodes (Guo, Hart et al. 2009), can in principle capture these other properties of the nervous system by activating individual neurons and measuring neural activity in response, what we call signal propagation. We sought to achieve signal propagation recordings at whole brain scale. So, we created a suite of transgenic lines to optically measure direct signal propagation between neuron pairs, at brain scale and cellular resolution in the nervous system of the nematode *C. elegans*. Using these strains, we have found that peptidergic signaling also contributes to neural dynamics in the animal's head (Randi, Sharma et al. 2023).

To achieve this, we generated transgenic animals that express the calcium indicator GCaMP6s in nucleus of each neuron and a purple-light-sensitive actuator, the gustatory receptor homolog system GUR-3+PRDX-2 a peroxiredoxin, in each neuron (Bhatla and Horvitz 2015). This combination of indicator and activator allows for 2-photon targeted optogenetic stimulation of GUR-3 while simultaneous 1-photon calcium imaging of GCaMP6s with minimal optical cross-talk. To achieve high expression levels for avoiding neuro-actuator related toxicity, we used the QF-GR drug-inducible system to turn on gene expression only in adulthood (Monsalve, Yamamoto et al. 2019). These optogenetic tools were expressed in a NeuroPAL background to allow each neuron to be uniquely identified (Yemini, Lin et al. 2021). We named it TWISP**,** a Transgenic Worm for Interrogating Signal Propagation, because it enables optical measurements of evoked calcium activity at brain scale and cellular resolution in the nervous system of *C. elegans* (Randi, Sharma et al. 2023, Sharma, Randi et al. 2023).

In addition, new lines with *unc-13 (s69)* & unc-13 *(e51)* as well as *unc-9 (fc16);unc-7(e5)* mutant back grounds by out crossing and *inx-1(wtf511)* & *inx-7 (wtf514)* by CRISPR Cas9 KO are created for further investigations into neurotransmitter and gap-junction mediated signaling. These transgenic worms will be a resource for large scale investigations of functional connectivity in the brain.

10 **Understanding and exploiting murine tolerance of haploinsufficiency in human disease research** Kyle Drover[1], Amrit Puarr[1], Neil Horner[2], Zoe Thomas[1], Kristen Barratt[1], Henrik Westerberg[2], Ruth Arkell[1] [1]The John Curtin School of Medical Research, The Australian National University, [2]Medical Research Council Harwell Institute

In many murine models of human dominant diseases, the analogous phenotype shows recessive inheritance, a feature known as murine tolerance of haploinsufficiency. In fact, analysis of mouse phenotype databases revealed that, of 1346 human autosomal dominant diseases with a corresponding mouse model, 715 (~53%) of the mouse models exhibit murine tolerance of haploinsufficiency such that the disease phenotype is inherited in a recessive manner. We have investigated this phenomenon using the kumba (*Ku*) mouse model of *ZIC2*-associated holoprosencephaly (HPE). In humans this devastating congenital defect, in which the brain fails to split into the left and right hemispheres, is overwhelmingly associated with heterozygous deleterious mutations, with most solved cases associated with loss-of-function mutations in the *ZIC2* or *SHH* gene. Several mouse alleles of *Zic2* exist and all lead to HPE only when the mutation is homozygous. We hypothesised that a combination of differences in the way in which human and mouse populations are studied could account for the altered inheritance pattern. By studying larger populations on a range of genetic backgrounds and using advanced phenotyping tools like those used in humans we found the *Zic2^{Ku}* model exhibits a dominant, incompletely penetrant HPE phenotype on a certain genetic background. This closely mirrors the mode of HPE inheritance in humans and demonstrates that murine tolerance of haploinsufficiency may be an artefact of the way disease models are typically analysed. Furthermore, by using automated analysis of 3D images of embryos heterozygous for the *Zic2^{Ku}* mutation, we identified a HPE signature, facilitating AI-based diagnosis of HPE. We are now combining AI diagnosis with knowledge of HPE permissive and restrictive genomes to identify genes that enhance or suppress the *Zic2*-associated HPE phenotype. Rather than murine tolerance of haploinsufficiency being a drawback of mouse models, it can be exploited to identify alleles of small effect that contribute to clinical heterogeneity, the source of which is difficult to find using human studies alone.

11 **Zebrafish pre-clinical models link oxidative stress with intervertebral ECM defects and identify elevated spine stiffness as a prognostic biomarker and possible therapeutic target for adolescent idiopathic scoliosis** Josh Gopaul[1], Patrick Pumputis[2,3], Ran Xu[2,3], Jenica Van Gennip[2,3], Nikan Fakhari[1,4], Jerome Baranger[1], Olivier Villemain[1,4], Brian Ciruna[2,3] [1]Translational Medicine Program, The Hospital for Sick Children, [2]Developmental & Stem Cell Biology Program, The Hospital for Sick Children, [3]Department of Molecular Genetics, University of Toronto, [4]Department of Medical Biophysics, University of Toronto

Adolescent idiopathic scoliosis (AIS) is a pediatric disorder characterized by rotational spinal deformity, which develops in the absence of obvious congenital or physiological defects. 4% of children will develop AIS, and 1 in 10 patients (predominantly female) will experience severe curve progression. Patient exome/genome sequencing and mouse functional studies have associated genetic variants in musculoskeletal collagen and cartilaginous extracellular matrix (ECM) defects with a fraction of AIS cases. However, GWAS meta-analyses estimate that >95% of total genetic variance underlying AIS remains to be discovered. To date, the biology of AIS remains poorly understood, there are no prognostic biomarkers, and treatment options are limited to restrictive bracing and corrective surgery.

Using zebrafish models of AIS, we have discovered that *oxidative stress* and *pro-inflammatory signals* in the spinal cord, which develop because of cerebrospinal fluid homeostasis defects, are necessary and sufficient to drive spine curvature. Indeed, antioxidant and immunomodulating drugs can efficiently block scoliosis onset and severe curve progression in fish models. Although this provides proof-of-principle that AIS might be managed therapeutically, uncertainties regarding downstream mechanism and their link to human disease pose a barrier to clinical translation.

Here, we demonstrate that oxidative stress in fish AIS models induces an unfolded protein response that is associated with collagenous ECM defects within developing intervertebral spine segments. Using shear wave elastography (SWE), we show that zebrafish scoliotic spines are consequently stiffer than healthy controls - a property also reported for intervertebral discs in human AIS patients. Remarkably, zebrafish are significantly stiffer *prior* to scoliosis onset and increasing axial stiffness positively correlates with curve severity, suggesting a causal role for elevated stiffness in AIS. Finally, we demonstrate that antioxidant drugs known to suppress scoliosis may ultimately function by reducing spine stiffness to normal levels, providing a possible mechanistic link between oxidative stress and connective tissue/intervertebral defects identified in both fish and human AIS studies. As SWE is non-invasive and widely applied in the clinic, tissue stiffness may translate into a valuable prognostic biomarker and therapeutic target for AIS.

12 **Interneuron migration is controlled by *Dyrk1a* dosage via deregulations of actomyosin dynamics during corticogenesis, insights for the *Dyrk1a* haploinsufficiency syndrome pathogenesis** Yann Herault, Maria Victoria HINCKELMANN, Aline Dubos, Victorine Artot, Gabrielle Rudolf, Thu Lan Nguyen, Peggy Tilly, Valerie Nalesso, Maria del Mar Muniz Moreno, Marie-Christine Birling, Juliette Godin, Veronique Brault Institute of Genetics and Molecular and Cellular Biology (IGBMC)

Interneuron development is a crucial step during cortical morphogenesis of the brain. DYRK1A is a dual-specificity tyrosine phosphorylation-regulated kinase whose dosage is crucial for the development and the functioning of the brain. When present in only one copy in the mental retardation autosomal dominant 7, *DYRK1A* induces a syndromic form of intellectual disability, with autism spectrum disorder and epilepsy as common comorbidities. Mutations on *DYRK1A* are the underlying genetic cause of the disease, leading to cortical excitatory/inhibitory imbalance. However, how this imbalance is established remains elusive. Here, using mouse models and live imaging, we show that *Dyrk1a* specifically regulates the development of the cortical GABAergic system. Unlike projection excitatory neurons, we demonstrate that interneuron tangential migration relies on *Dyrk1a* dosage and kinase activity through a mechanism involving actomyosin cytoskeleton remodeling. Interestingly, we further demonstrate that mice with heterozygous inactivation of *Dyrk1a* in interneurons show behavioural defects and epileptic activity, recapitulating phenotypes observed in human patients. Altogether, these data highlight the critical role of *Dyrk1a* in the development of the GABAergic system and the pathophysiology of *DYRK1A*-haploinsufficiency syndrome.

13 **A *C. elegans* Model of Fanconi Anemia Neurological Syndrome (FANS)** Jessica E Leighton[1], Belinda Barbagallo[2], Niall G Howlett[1] [1]Cell and Molecular Biology, University of Rhode Island, [2]Biology and Biomedical Sciences, Salve Regina University

Fanconi Anemia (FA) is a rare genetic disease characterized by increased risk for bone marrow failure and cancer. FA is caused by mutation in one of 23 genes. The FA proteins function together in the FA pathway to repair damaged DNA and to maintain genome stability. In recent years, the prevalence of central nervous system (CNS) abnormalities among FA patients has been increasing. These CNS defects include cerebellar hypoplasia, hydrocephalus, cerebellar lesions with inflammation, developmental delay, and early onset cognitive decline. This constellation of neurological symptoms is referred to as Fanconi Anemia Neurological Syndrome (FANS). The molecular origins of FANS are unknown.

Recent omics data from our laboratory suggests that the FANCD2 protein plays an important role in nervous system development and maintenance. ChIP-seq analysis has revealed that the FANCD2 protein binds to several transcriptionally active large neuronal genes under conditions of replication stress, including genes that function in neuronal differentiation, migration, and cell-cell adhesion. Many of these genes are linked to neuropsychiatric and neurodevelopmental disorders including schizophrenia, autism, and intellectual disability.

To study the role of the FA pathway in nervous system development and maintenance, we have turned to the model

nematode *Caenorhabditis elegans*; *C. elegans* has an exceptionally well-characterized nervous system with exactly 302 neurons and nervous system connectivity has been anatomically mapped at high resolution. Quantitative behavioral analysis of deletion strains of the *C. elegans FANCD2* ortholog, *fcd-2*, has uncovered significant changes in speed, bending angle, and moving wavelength compared to wild-type animals, suggesting a defect in motor neuron circuitry. Using the aldicarb assay to analyze the function of cholinergic (ACh) neurons, we have determined that *fcd-2* mutant animals paralyze at slower rates than wild-type animals under conditions of replication stress, suggesting a defect in the ACh motor neuron circuitry. We have also generated *fcd-2* mutant animals expressing GFP-labeled ACh and dopaminergic (DA) neurons and have uncovered significant differences in numbers of both ACh and DA neurons in *fcd-2* animals compared to wild-type animals. Taken together, our results strongly support an important role for the FCD-2 protein and the FA pathway in nervous system development and function, possibly providing key insight into the molecular origins of FANS.

14 **Mechanisms of photoreceptor stabilization upon chronic vitamin A-deprivation** Deepshe Dewett[1], Khanh Lam-Kamath[2], Joe Bunker[3], Fareeha Syeda[3], Mukesh Kumar[4], Andrej Shevchenko[5], Maryam Labaf[3], Kourosh Zarringhalam[3], Jens Rister[3] [1]Biology, UMASS Boston, [2]Umass Boston, [3]UMass Boston, [4]CST, [5]Max Plank Institute

Vitamin A (vitA) is crucial for the synthesis of the light-sensing pigments and normal photoreceptor morphology. Chronic vitA deficiency results in photoreceptor death and blindness. In *Drosophila melanogaster*, chronic vitA deprivation impairs visual pigment synthesis and damages photoreceptor morphology without inducing photoreceptor death. We hypothesized that an unknown mechanism stabilizes these vitA-deficient photoreceptors. To elucidate this stabilizing mechanism and identify novel factors responding to vitA deficiency, we employed transcriptomics, GeLC-MS/MS mass spectrometry (global proteomics), and MS-Western (targeted absolute protein quantification) in vitA-deficient and vitA-sufficient retinas.

Notably, we identified the transmembrane protein Mps (‘Major photoreceptor stabilizer’) as the most upregulated protein (~140-fold) and the second-most upregulated transcript (~25-fold) in response to chronic vitA deficiency. Immunohistochemistry revealed the localization of Mps in the damaged light-sensing compartments of the photoreceptors (rhabdomeres). Mps stabilized the damaged membranes, since vitA-deficient *mps* null mutants displayed completely unraveled rhabdomere membranes with abnormal invaginations.

To elucidate the molecular mechanism by which Mps stabilizes damaged photoreceptors, we performed a yeast-two-hybrid screen and identified the major photoreceptor scaffolding protein InaD (Inactivation no afterpotential D) as an interaction partner of Mps. In addition, we found that Mps interacts with InaD in a vitA-independent manner during pupal development of the rhabdomeres.

In summary, we identified the transmembrane protein Mps as a novel protein that responds to chronic vitA deficiency and stabilizes the light-sensing compartments by interacting with the major scaffolding protein InaD. These findings offer mechanistic insights into the ocular response to environmental stresses and may inspire novel therapeutic approaches for treating eye diseases.

15 **Transcriptomic landscape of *DEAF1* mutations in zebrafish models of Autism Spectrum Disorder** Mary E.S. Capps[1], Anna J Moyer[1], Claire Conklin[2], Verdion Martina[2], Emma Torija[3], Summer B Thyme[1] [1]UMass Chan Medical School, [2]University of Alabama at Birmingham, [3]University of Alabama

Hundreds of human mutations have been linked to Autism Spectrum Disorder (ASD), but the impacts of these mutations on vertebrate neural development are unclear. The Thyme lab has generated more than 20 zebrafish lines with mutations in orthologs of human genes that increase risk for ASD. In humans with ASD, *DEAF1* is more likely to contain missense than protein-truncating variation compared to other ASD-associated genes. Thus, we generated a loss-of-function mutation and two patient-specific point mutations in zebrafish *deaf1*. We examined brain activity and morphology with phospho-Erk mapping methods and conducted a multi-day larval behavioral study examining sleep and responses to sensory stimulation. All three mutants have a reduced volume in their midbrain, with the loss-of-function displaying a more severe reduction than the two point mutations. Only the line with the C207Y mutation had altered behavior, with movement at night and response to dark flashes being affected. To define how these mutations affect the earliest stages of neurodevelopment, we conducted bulk RNA-seq on 2 days post-fertilization (dpf) larval zebrafish heads. To identify direct targets of deaf1, we focused on a subset of DEGs with DEAF1 binding motifs or ChIP-Seq peaks in their promoters. Notably, several genes, including *khk*, *cdkn1bb*, *creb1b*, *nfyal*, and *atxn7l1*, showed dysregulation across mutants and have DEAF1 ChIP-Seq peaks in human K562 cells. An association of DEAF1 with NF-Y, a trimeric transcription factor, was also observed, with NF-Y binding motifs enriched in the promoters of *deaf1*-regulated genes. Our analysis revealed that the point and loss-of-function mutations in *deaf1* resulted in both shared and distinct transcriptomic changes. In particular, the C207Y mutants exhibited DEGs related to eye development, which could play a role in their altered visual behaviors. Functional analysis of the transcriptome in 6 dpf loss-of-function mutants revealed

downregulation of genes expressed in specific brain regions, including the thalamus, hypothalamus, and telencephalon. These transcriptomic changes could reflect altered development of neurons in these areas, corroborating our microscopy-based brain structure analysis. This study advances our understanding of how mutations in *deaf1* impact early neurodevelopment and sets the stage for future therapeutic development by defining druggable downstream target proteins or pathways in *DEAF1*-related syndromes.

16 **MARRVEL and ModelMatcher: publicly available web services that facilitate collaborative research on rare diseases** Shinya Yamamoto[1,2], Seon-Young Kim[2,3], Michael F Wangler[2,3], Hugo J Bellen[2,3] [1]Department of Molecular and Human Genetics, Baylor College of Medicine, [2]Texas Children's Hospital, [3]Baylor College of Medicine

Diagnosis and therapeutic research of rare diseases require integration of diverse data sets as well as close collaborations between clinicians and scientists. To identify disease-causing genes and variants, clinicians must collect information from various databases such as previously identified disease-gene relationships, population genomic datasets and multiple variant pathogenicity prediction algorithms in addition to the patients' phenotype and genotype information. In addition, if an individual is suspected to have a novel genetic disorder, collecting information associated with the candidate human gene and its orthologs in model organisms, such as mouse, fruit fly, and yeast, becomes essential. For therapeutic research, it is critical to effectively identify collaborative scientists who have expertise in specific genes, biological pathways, or experimental paradigms. However, this information is scattered throughout the internet and is difficult to access comprehensively. Moreover, some valuable information, such as unpublished scientific data regarding poorly characterized genes, is not accessible. To overcome these barriers, we have been developing a suite of bioinformatic tools that are publicly accessible. **MARRVEL** (Model organism Aggregated Resources for Rare Variant ExpLoration, https://marrvel.org/), was designed to integrate many human genomic and genetic databases with various model organism databases to facilitate rare disease diagnosis. **ModelMatcher** (https://www.modelmatcher.net/), is a matchmaking service that was designed to facilitate collaborations between basic scientists with expertise and/or interest in specific genes with clinicians, patients, caregivers, and other stakeholders.

17 **Genome-wide association studies of nephrolithiasis and water transport of renal tubule in *Drosophila melanogaster*** Keqin Li, Shireen Davies, Julian Dow School of Molecular Biosciences, University of Glasgow

Nephrolithiasis, or kidney stones, affects around 10% of adults worldwide. Both genetics and unique environmental factors contribute to the risk of kidney stones. Despite considerable research effort, the lack of understanding about the mechanisms by which stones are formed and of experimentally tractable models hinders the prevention and treatment of nephrolithiasis. The *Drosophila* renal tubule is genetically and functionally comparable to human kidney, making it a suitable translational model of human nephrolithiasis. To identify novel genes involved in the formation of kidney stones, the amount of stone concretion was measured in the renal tubules of ~190 *Drosophila melanogaster* Genetic Reference Panel lines fed on a lithogenic diet. In addition, the capacity of the dissected tubules to secrete fluid was quantified, as insufficient urine volume is thought to be a risk factor for kidney stones. Significant differences were observed both in the percentage of lumens with stone inclusions, which varied between 0 to 21%, and in fluid secretion rates, showing a up to 6.2-fold difference between lines. Using about 2 million common single nucleotide polymorphisms, genome-wide association analyses for the percentage of stone area and fluid secretion were performed. These analyses revealed considerable genetic variation, although no correlation was found between these quantitative traits. A membrane transporter, *CG3380*, with a high expression level in renal tubules was identified by preliminary association analysis of nephrolithiasis, and its knockdown reduced the formation of kidney stones induced by sodium oxalate. Gene Ontology analysis suggested that genes involved in microvilli are important for fluid transport. *Fasciclin3* (*Fas3*), a cell adhesion molecule identified by association analysis, is required for the integrity of renal tubules. The *Drosophila* renal tubules are comprised mainly of principal cells and secondary intercalated stellate cells. In principal cells, loss of *Fas3* resulted in impaired cellular junctions and inflated abdomens, a marker of renal insufficiency. This dysfunction of tubule cellular junctions resulted in increased kidney stone formation and reduced lifespan. In addition, *Fas3* inhibition in stellate cells affected their number and morphology with reduced fluid secretion of tubules. Together, our study provides the first genome-wide association of renal function in animal models and identifies candidate loci as therapeutic targets.

18 **Piwi regulates the usage of alternative transcription start sites in the *Drosophila* ovary via interaction with the FACT complex component Ssrp** Jiaying Chen[1], Na Liu[2], Haifan Lin[2] [1]Genetics, Yale University, [2]Cell Biology, Yale University

Alternative transcription initiation, which refers to the transcription of a gene from different transcription start sites (TSSs), is prevalent in mammalian systems and has important biological functions such as regulating the structure of resulting mRNA and proteins. Although transcriptional regulation has been extensively studied, the mechanism that selects one TSS over others in a gene is still poorly understood. Using the cap-analysis gene expression sequencing (CAGE-seq) method, we identified 87 genes

with altered TSS usage (ATU genes) in Piwi-deficient *Drosophila* ovaries. Piwi differentially regulated TSS usage of ATU genes in germ cells and somatic cells in ovaries as well as in cultured ovarian somatic cells (OSCs). ChIP-seq and CUT&RUN experiments revealed that Pol II initiation and elongation at TSSs of ATU genes were affected in germline-*piwi*-knockdown ovaries and *piwi*-knockdown OSCs. Furthermore, we identified several novel Piwi interactors by Piwi-co-immunoprecipitation of the nuclear fraction of fly ovaries followed by mass spectrometry. Among them, Ssrp is a core component of the FACT complex that acts to reorganize nucleosomes. Temporally controlled knockdown of *Ssrp* affected TSS usage of ATU genes whereas overexpression of *Ssrp* partially rescued the dysregulated TSS usage of ATU genes in *piwi* mutant ovaries. Based on these findings, we propose that Piwi interacts with Ssrp to regulate TSS usage in *Drosophila* ovaries by affecting Pol II initiation and elongation.

19 **Transcriptional adaptation and genetic compensation, from *C. elegans* to mammals** Didier Stainier, Christopher M Dooley, Lara Falcucci, Kuan-Lun Hsu, Gabrielius Jakutis, Brian Juvik, Vahan Serobyan, Jordan M Welker, Lihan Xie, Jie Liang, Cansu Cirzi, Nana Fukuda, Y. Charlie Song, Hamzeh Haj-Hammadeh, Mikhail Sharkov, Greta Ebnicher, Pankaj Kumar Department of Developmental Genetics, Max Planck Institute for Heart and Lung Research

Each human genome has been reported to contain approximately 100 loss-of-function variants, with roughly 20 genes completely inactivated. Some of these completely inactivated genes are essential genes, and yet they are present in a homozygous state in apparently healthy individuals. This totally unexpected lack of phenotype has also been observed in commonly studied model organisms from yeast to mammals. Various hypotheses have been proposed to explain these findings including Genetic Compensation (GC). GC manifests itself as altered gene/protein expression, or function, which leads to a wild-type-like phenotype in homozygous mutant or heterozygous individuals who would be predicted to exhibit clear defects. Traditionally, GC has been thought to involve protein feedback loops such that if one component of a regulatory pathway is deficient, a compensatory rewiring within a network or the activation of a functionally redundant gene occurs. However, not every major regulatory network has evolved to incorporate such complex features. Another mechanism of GC is the newly identified process of Transcriptional Adaptation (TA): some deleterious mutations, but not all, trigger the transcriptional modulation of so-called adapting genes. Depending on the nature of these adapting genes, GC can occur. Notably, unlike other mechanisms underlying genetic robustness, TA is not triggered by the loss of protein function.

We discovered TA while trying to understand the phenotypic differences between knockout (mutant) and knockdown (morphant) zebrafish embryos. Further studies identified additional examples of TA in zebrafish as well as examples in *C. elegans* and in mammalian cell lines. By generating and analyzing several mutant alleles for these genes, including non-transcribing alleles, we found that the mutant mRNA is required to trigger TA. Based on these and other data, we hypothesize that all mutations that cause mutant mRNA degradation can trigger TA. The current model is that mutant mRNA degradation fragments translocate back to the nucleus where they modulate gene expression. Key questions about TA include the identity of the adapting genes and the mechanisms underlying their transcriptional modulation. This presentation will go over our published and unpublished data on TA in several model systems including zebrafish, *C. elegans*, *Neurospora*, and mammalian cells in culture.

20 **Relative enhancer-promoter positioning tunes the kinetics of enhancer-mediated transcriptional activity** Emilia A Leyes Porello, Bomyi Lim, Robert T Trudeau, Emma Dreispiel Juan Chemical and Biomolecular Engineering, University of Pennsylvania

In multicellular eukaryotes, the linear distance between enhancers and promoters ranges from tens to hundreds of kilobases. While the long-range interactions have been studied with bulk genomics assays and some fixed and live imaging approaches, short and intermediate range interactions – particularly the dynamic nature of their contact and resulting transcriptional behaviors – have not been thoroughly characterized . In this study, we probe the regulatory mechanisms underlying enhancer-promoter (E-P) interactions and resulting transcriptional activity at intermediate length scales using early Drosophila embryos. We implemented reporter constructs which systematically modulate various parameters of relative E-P positioning and enhancer strength at distances ranging from 0 kb to 12.6 kb. We also employed the MS2/MCP live-imaging system which enables single cell, real-time quantification of transcriptional activity at the target locus. We find that increasing E-P distances delays the activation of post-mitotic transcription and results in decreased mRNA production per nucleus as distance increases. Strikingly – and in stark contrast to canonical understanding – we also find that placing the enhancer downstream of the promoter and reporter elements drives significantly less transcription with mRNA production falling below the trend set by increasing E-P distance . The downstream positioning of the enhancer does not differentially affect transcriptional activation kinetics with these constructs still fitting the trend of delayed activation with increasing E-P distance. Additionally, quantifying the time spent in the active state (per nucleus) after initial activation, we find that the enhancer downstream subset yielded distinctly diminished activity levels compared to the enhancer upstream subset. These results suggest that increasing E-P distance increases the search space for the elements to find each other thus delaying initiation of transcription; however, once transcription is active and the E-P interaction is established, the linear distance does not seem to affect stability of the active

transcriptional state. Conversely, enhancer positioning relative to the promoter does not influence initiation of transcriptional activity but significantly affects the stability of the active state. These findings suggest there exist additional layers to enhancer-mediated transcriptional regulation that depend on the genomic context within which these elements operate.

21 **Non-additive genetic components contribute significantly to population-wide gene expression variation** Andreas Tsouris[1], Gauthier Brach[1], Joseph Schacherer[1], Jing Hou[2] [1]University of Strasbourg/CNRS, [2]Université de Strasbourg/CNRS

Gene expression variation, an essential step between genomic variation and phenotypic landscape, is collectively controlled by local (*cis*) and distant (*trans*) regulatory changes. Nevertheless, how these regulatory elements differentially influence the heritability of expression traits remains unclear. Here, we bridge this gap by analyzing the transcriptomes of a large diallel panel consisting of 323 unique hybrids originated from genetically divergent yeast isolates. We estimated the broad- and narrow-sense heritability across 5,087 transcript abundance traits and showed that non-additive components account for 36% of the phenotypic variance on average. By comparing allelic expression ratios in the hybrid and the corresponding parental pair, we identified regulatory changes in 25% of all cases, with a majority acting in *trans*. We further showed that *trans*-regulation could underlie coordinated expression variation across highly connected genes, resulting in significantly higher non-additive variance and most likely in some of the missing heritability of gene expression traits.

22 **Chromatin regulatory networks underlying coordinated synaptic gene expression** James Kentro[1], Gunjan Singh[1], Tuan Pham[2], Justin Currie[3], Erica Larschan[1], Kate O'Connor-Giles[4] [1]Molecular Biology, Cell Biology, and Biochemistry, Brown University, [2]Center for Computational Molecular Biology, Brown University, [3]Brown University, [4]Neuroscience, Brown University

During nervous system development, neurons construct intricate circuits that transmit information by passing signals through synaptic connections. These synaptic connections are formed by hundreds of genes encoding proteins for scaffolding, cell adhesion, ion transport, neurotransmitter synthesis and release, signal reception, and more. We have found that hundreds of *Drosophila* synaptic genes share a developmental temporal pattern of expression, with peaks during periods of peak synaptogenesis, that is consistent with coordinated regulation. However, no mechanism for coordinating their expression is known. Using motif discovery, analysis of chromatin binding data, and regulatory network predictions from time-series single-cell transcriptomic and chromatin accessibility datasets, we have identified a candidate gene regulatory network involving several TFs known to interact with chromatin remodelers that may temporally coordinate expression of synaptic genes through opposing influences of repression and activation. In the nervous system, we observe a correlation between the timing of initial synaptic gene transcription and substantial increases in chromatin accessibility at synaptic gene promoters that supports a mechanism of coordination through control of the chromatin environment. We hypothesize that Deaf1, linked to intellectual disability and seizures in humans, interacts with pioneer factor Clamp to negatively regulate synaptic gene expression during periods of low transcription. Consistently, upon loss of either TF, we find an upregulation of synaptic gene transcription. Strikingly, this corresponds to increased glutamatergic synapse formation at neuromuscular junctions. Together, these data support a repressive role for both TFs at synaptic genes during normal development. We are also performing ATAC-seq in the absence of these factors to determine their impact on chromatin accessibility at synaptic gene promoters and potential enhancer sites. We predict that this gene regulatory network coordinates expression of pan-neuronal and subtype-specific synaptic genes upstream of the terminal selectors that establish neuronal identity by controlling chromatin accessibility to coordinate the development of shared traits with the acquisition of distinct neuronal fates.

23 **Interallelic gene regulation promotes robustness and evolvability** Noa O Borst[1], Timothy Fuqua[2], Fabian Ruperti[1], Justin Crocker[1] [1]EMBL, [2]University of Zurich (UZH)

Enhancers drive complex spatiotemporal patterns of gene expression during development, and their evolution is an important driver of morphological and phenotypic diversification. Recently, we found that random point mutations in the *E3N* enhancer of *shavenbaby* in *D. melanogaster* resulted in changes in the level, timing, or location of its activity, suggesting that the enhancer is densely encoded with regulatory information. To explore how such dense encoding of regulatory information might constrain the evolution of this enhancer, we systematically explored all the possible evolutionary paths between the modern-day *E3N* enhancers of *D. melanogaster* and *simulans*. Consistent with our previous results, we observed extensive higher-order epistatic interactions between genetic variants across these evolutionary trajectories, with many paths reducing transcriptional outputs. Strikingly, interchromosomal interactions between heterozygous enhancer alleles resulted in synergistic or antagonistic effects on gene expression, a phenomenon commonly recognized as dominance. Furthermore, we found evidence that these transvection-like interactions are reinforced through transcriptional hubs. Beyond the previously established role of transcriptional hubs in developmental robustness, we propose that these regulatory interactions concurrently promote evolutionary robustness and enable the exploration of novel phenotypes. Consequently, interallelic interactions may provide an additional layer for natural selection to act on in regulatory evolution.

24 **The role of post-transcriptional gene regulation in adaptation to stress** Pieter Spealman[1], Carolina de Santana[2], Titir

De[1], David Gresham[1] [1]New York University, [2]Laboratório de Microbiologia Ambiental e Saúde Pública, Universidade Estadual de Feira de Santana

The importance of divergence in gene expression has been a central concern of evolutionary biology for nearly 50 years. While the majority of research has focused on changes in transcription, recent research suggests that post-transcriptional regulation may play a vital role in adaptive gene expression.

Using a combination of RNA-seq, ribosome profiling, and mass-spectrometry we identify divergence in abundance across three levels of gene expression between 4 strains of experimentally evolved yeast (Saccharomyces cerevisiae) and their ancestor (derived from FY4). Strains were evolved using long-term evolution experiments for 150 and 250 generations in glutamine-limited media conditions; all evolved strains have increased fitness and genomic amplifications that include the GAP1 locus, a general amino-acid permease.

By normalizing each level of expression by the abundances observed at the previous level (ie. RNA/DNA, RPF/RNA, MS/RPF) we identify specific levels of regulation. We find a mean of 1116 genes per strain have significantly different RNA/DNA ratios, a mean of 389 RPF/RNA ratios, and a mean of 153 MS/RPF ratios. We find that a substantial number of genes (mean 25%) with significantly different RNA/DNA ratios are significantly buffered at later levels of expression. We find a mean of 32% of genes are significantly different only at the post-transcriptional level.

We find that translationally regulated genes frequently (mean 27%) have upstream open reading frames (uORFs) and that these are also frequently (mean 35%) enriched in SSD1 binding sites. SSD1 is a known stress-responsive RNA binding protein that has been shown to localize to 5' UTRs and alter translation. An analysis of post-translational buffering finds that few buffered genes are part of protein complexes (mean 8.8%), suggesting that post-translational buffering mechanisms may not rely on stoichiometric imbalances.

Taken together, these results point to extensive changes in gene expression that accrue over the course of adaptation to glutamine-limitation and genomic amplification. They highlight the role of post-transcriptional buffering of transcriptional divergence as well as divergence in expression derived from post-transcriptional mechanisms. They also point towards a novel mechanism of uORF mediated translational regulation driven by stress-responsive RNA binding protein, SSD1.

25 **Social regulation of intergenerational signaling via a defined chemosensory pathway** Jadiel Wasson[1], Susan Mango[2] [1]New York University, [2]University of Basel

Classically, inheritance was believed to be restricted to the passage of information from parent to progeny in the form of genetically encoded material. It has become appreciated that other types of information, including that which informs about the environment, can be passed between generations. However, the mechanisms behind how this information can be both passed on and interpreted by the embryo remain unknown. Recently, we have identified a previously unknown pathway for intergenerational communication that links neuronal responses to maternal provisioning in *C. elegans.* Here, a chemosensory signaling pathway responsive to social cues initiated in the mother alters the pool of maternally provided factors that modulates gene silencing in progeny. This intergenerational signal transmission depends on specific chemosensory neurons and neuronal FMRFamide (Phe-Met-Arg-Phe)–like peptides including FLP-21. Parental FLP-21 signaling dampens oxidative stress resistance and promotes the deposition of mRNAs for translational components in progeny, which, in turn, reduces gene silencing. Furthermore, overexpression of FLP-21 has the opposing effect on gene silencing in progeny suggesting that the levels of FLP-21 signaling in mothers *influences* embryonic stress phenotypes. We are currently investigating different aspects of this maternal signaling pathway including the neurocircuitry, key molecular components, and tissue-specific requirements to identify the relay from environmental social cues to modulation of embryonic gene silencing. To this end, we have identified key receptors that are required for this relay from parental environment to progeny response. Taken together, we hypothesize that loss of social cues in the parental environment represents an adverse environment that stimulates stress responses across generations. This work demonstrates how alterations to chemosensory signaling pathways can have long range consequences via changes in not only what mothers provide to their young, but also how resulting progeny modulate their gene expression changes in response to a challenge. Ultimately, this work will lead to a clearer understanding of the mechanisms involved in cross-generational signaling between mother and progeny.

26 **Repeated, rapid origins of incompatibility in the Mimulus guttatus species complex: the role of shared variation in repeated speciation** Jenn Coughlan Ecology & Evolutionary Biology, Yale University

How new species originate and persist in nature is a fundamental question in evolutionary biology. Although genetic incompatibilities underlying hybrid sterility and inviability can play a central role in speciation, much remains unknown about the evolutionary forces ultimately responsible for incompatibility alleles. Much classical theory highlights the role

of intra-genomic conflict in the origin of intrinsic crossing barriers, yet we are only beginning to empirically test these hypotheses. Here, I combine a series of range-wide crossing surveys, quantitative genetics, and population genomics to dissect the repeated origin of hybrid seed inviability in a group of closely related, rapidly speciating wildflowers; the *Mimulus guttatus* species complex. I find multiple, phenotypically cryptic lineages within this group that are strongly reproductively isolated by hybrid seed inviability, suggesting that this barrier has evolved rapidly and repeatedly. By combining hybrid phenotypes with genetic mapping, I test whether intra-genomic conflict between maternal and paternal interests in resource partitioning to offspring can explain patterns of rapid and repeated evolution of hybrid seed inviability. I find that patterns of hybrid seed inviability strongly support a role of parental conflict in driving speciation, and subsequent meta-analyses suggest that parental conflict may play an important role in angiosperm diversity more broadly. Intriguing, while hybrid seed inviability between *M. guttatus* and several cryptic lineages appears to have evolved repeatedly, crosses between lineages with putatively independent origins of this barrier are viable, suggesting that the alleles underlying these two incidences of hybrid seed inviability are in some way complementary. Using a classical complementation test, I then ask whether the alleles causing independent origins of hybrid seed inviability are shared. In total, I find the rapid and repeated evolution of hybrid seed inviability in this group suggests that parental conflict may play an important and generative force in speciation. Moreover, complex patterns of incompatibility point to a complex genetic origin; potentially involving a combination of hybridization, ancestral polymorphisms and/or de novo mutation in the repeated origin of reproductive isolation.

27 **A programmed Mendelian violation maintains heterozygosity in a parthenogenetic ant** Kip D Lacy, Daniel J.C. Kronauer Laboratory of Social Evolution and Behavior, The Rockefeller University

Parthenogenesis arises sporadically across the animal phylogeny, evolving via mutations that perturb sex and meiosis. The underlying mechanisms are rarely understood, but might provide insights into how meiosis works and how asexuality evolves. Here, we investigate parthenogenesis in the clonal raider ant, *Ooceraea biroi*, which produces diploid offspring via the fusion of two haploid products from a single meiosis. This process should cause rapid genotypic degeneration due to loss of heterozygosity, which results if crossover recombination is followed by random (Mendelian) segregation of chromosomes. However, by comparing whole genomes of mothers and daughters, we show that loss of heterozygosity is exceedingly rare, raising the possibility that crossovers are rare or absent from *O. biroi* meiosis. Using a combination of cytology and whole genome sequencing, we show that crossovers occur regularly, but loss of heterozygosity is avoided because crossover products are faithfully co-inherited. This results from a programmed violation of Mendel's law of segregation, such that crossover products co-segregate rather than segregate randomly. This discovery highlights an extreme example of cellular "memory" of crossovers, which could be a common yet cryptic feature of chromosomal segregation.

28 **Adaptive piRNA pathway tuning tames sex- and lineage-specific selfish genes** Peiwei Chen[1], Katherine C Pan[1], Eunice H Park[1], Grace YC Lee[2], Alexei Aravin[1] [1]California Institute of Technology, [2]University of California, Irvine

Selfish genetic elements subvert fair Mendelian inheritance for their own benefit at the expense of the host, causing intragenomic conflicts that must be resolved to protect host reproduction. Although selfish genes differ between sexes and across lineages, how sex- and lineage-specific selfish genes are tamed remains mostly unknown. Here, using the silencing of *Stellate*—a recently evolved, selfish gene family only active in *Drosophila melanogaster* male germline—as a readout, we conducted an *in vivo* RNAi screen and discovered a novel genome defense factor required for *Stellate* silencing that we named Trailblazer. Contrary to all known protein components of the genome-defending piRNA pathway in flies, Trailblazer is essential for male but not female fertility. By enhancing the expression of cytoplasmic PIWI proteins, Aub and AGO3, Trailblazer enables the destruction of *Stellate* transcripts, whose abundance in the male germline exceeds that of all transposons by two orders of magnitude. While *trailblazer* is conserved outside *D. melanogaster*, it is subject to lineage-specific positive selection, and efficient *Stellate* silencing requires Trailblazer's adaptive changes in recent evolution. Hence, sex- and lineage-specific selfish genes have spurred genetic innovations in genome defense, which tunes ancient defense machinery adaptively to nullify contemporary intragenomic threats—a strategy we suspect is recurrently employed for genome defense.

29 **Genetic conflicts shape rapid evolution of young *Drosophila* protamines** Ching-Ho Chang[1], Isabel Mejia Natividad[1], Aditi Kishore[2], Harmit S Malik[1] [1]Fred Hutchinson Cancer Center, [2]University of Washington

Eukaryotes commonly use histones for packaging their genomes, but many animal species utilize positively charged protamines for tighter genome packaging in sperm. Although histones are ancient and highly conserved, protamines exhibit rapid evolution and positive selection across different animals. The prevailing hypothesis attributes this accelerated evolution to sexual selection favoring competitive sperm morphology, evident from densely packed sperm nuclei. Our previous phylogenomic surveys in 78 *Drosophila* species introduce the idea that genetic conflicts between sex chromosomes might also contribute to the rapid evolution of protamines. Here, we focus on *Mst77F*, a young, subgenus-specific protamine gene that is rapidly evolving but essential for male fertility in *D. melanogaster*. Remarkably, *Mst77F* has undergone 18 duplications on the

Y chromosome of *D. melanogaster*. We hypothesize that autosomal, ancestral Mst77F suppresses X-Y genetic conflicts, while its expanded Y-linked counterparts amplify it. To test this, we conducted gene-swap analyses in *D. melanogaster* to dissect the functional divergence of the Mst77F homologs. We showed that replacing Mst77F-mel with an ortholog from a distantly related species, *D. ananassae*, leads to male sterility. Conversely, replacements of orthologs from closely related species like *D. yakuba* resulted in low male fertility, marked by male-biased progeny due to a scarcity of X-bearing sperm. Furthermore, overexpression of Y-linked *Mst77F* copies in *D. melanogaster* produced a similar phenotype of male-biased progeny. Our findings demonstrate that the rapid evolution of *Mst77F* is driven by its role in suppressing or enhancing X-versus-Y sperm killing. We further suggest that, in addition to sperm competition, genetic conflicts may propel the paradoxical but universal rapid evolution of protamine genes.

30 **Telomere protein coevolution preserves chromosome end protection** Sung-Ya Lin[1], Hannah Futeran[1], Mia T. Levine[1,2] [1]Department of Biology, University of Pennsylvania, [2]Epigenetics Institute, University of Pennsylvania

The terminal ends of eukaryotic chromosomes threaten genome integrity. If left unprotected, inappropriate DNA repair fuses chromosomes end-to-end. Specialized telomere capping complexes protect chromosome ends from this catastrophic DNA repair. Chromosome end protection is essential and deeply conserved across eukaryotes, yet multiple telomere capping proteins evolve adaptively. *Drosophila* has two such proteins, HOAP and HipHop. We previously showed that the end protection protein, HOAP, evolved to restrict telomeric retrotransposons, while the evolutionary pressure on HipHop is unknown. HipHop physically interacts with HOAP and recruits it to the telomere, raising the possibility that HipHop coevolves with HOAP to preserve end protection. To test this hypothesis, we replaced the native *D. melanogaster hiphop* with a highly diverged version from its close relative, *D. yakuba* (*hiphop[yak]*). We discovered that *D. melanogaster* flies encoding only HipHop[yak] were homozygous lethal due to rampant telomere fusions. We also found that HipHop[yak] localized robustly to these telomeres but the *D. melanogaster* HOAP (HOAP[mel]) failed to localize, suggesting that HOAP requires its conspecific HipHop to localize and preserve end protection. To test this prediction, we swapped *HOAP[yak]* into *hiphop[yak]* flies. Excitingly, HOAP[yak] localizes to the *hiphop[yak]* telomeres and rescues both end protection and viability, consistent with HipHop-HOAP coevolution. Furthermore, the viability of *hiphop[yak]/+* heterozygous flies but lethality of *hiphop[yak]* homozygous flies suggests that one copy of *hiphop[mel]* is sufficient to recruit HOAP[mel] to the telomeres and preserve end protection. This inference, however, fails to account for a second, puzzling observation: *hiphop[yak]/+* heterozygous females, which encode one copy of the native *D. melanogaster* HipHop, are severely subfertile. To probe this, we studied the subfertile *hiphop[yak]/+* females. Their embryos die at the first embryonic mitosis, a phenotype caused by paternal chromosome-specific telomere dysfunction. Wildtype, sperm-deposited paternal telomeres lack HipHop and require *de novo* loading of maternally provisioned HipHop, suggesting that maternal HipHop[yak] may interfere with the loading of maternal HipHop[mel] and ultimately impede end protection. Importantly, embryonic lethality is rescued by swapping in *HOAP[yak]*. These results are consistent with HipHop-HOAP coevolution preserving distinct telomere packaging events during development. We propose that HOAP evolution to restrict retrotransposons triggers HipHop evolution to maintain their protein-protein interaction. These data implicate a selfish element-initiated “evolutionary cascade” that sculpts fundamental cellular processes vital for viability and fertility.

31 **Post-insemination sexual selection in males indirectly masculinizes the female transcriptome** Katja Kasimatis[1], John Willis[2], Patrick Phillips[2] [1]University of Virginia, [2]University of Oregon

Sex-specific regulation of gene expression is the most plausible way for generating sexually differentiated phenotypes from an essentially shared genome. However, since genetic material is shared, sex-specific selection in one sex can have an indirect response in the other sex. From a gene expression perspective, this tethered response can move one sex away from their wildtype expression state and impact potentially many gene regulatory networks. Here, using experimental evolution in the model nematode *Caenorhabditis elegans,* we explore the coupling of direct sexual selection on males with the transcriptomic response in females over microevolutionary timescales to uncover the extent to which post-insemination reproductive traits share a genetic basis between the sexes. We find that differential gene expression is driven by female ancestral or evolved generation alone and that male generation has no impact on changes in gene expression. Almost all differentially expressed genes were downregulated in evolved females. Moreover, 80% of these gene were located on the X chromosome and have wildtype female-biased expression profiles. Changes in gene expression profiles were likely driven through *trans*-acting pathways that are shared between the sexes. We found no evidence that the core dosage compensation machinery was impacted by experimental evolution. Together these data suggest masculinization of the female transcriptome driven by direct selection on male sperm competitive ability. Our results indicate that on short evolutionary timescales sexual selection can generate sexual conflict in expression space.

32 **The impact of genomic autoimmunity across the Drosophila genus** Justin Blumenstiel[1], Martina Dalikova[1], Jeffrey Vedanayagam[2] [1]University of Kansas, [2]University Texas San Antonio

Transposable elements threaten genome integrity and small RNA based systems of genomic immunity have evolved to ward against this damage. However, as observed in other immune systems, there is a cost of genome defense when the distinction between self and non-self is blurred. This results in off-target gene silencing, which can be considered a form of genomic autoimmunity. Here we describe several systems of genomic autoimmunity that differ in how off-target gene silencing by piRNA is triggered and transmitted across generations. In one case, genic silencing can be maintained in a transgenerational manner. However, this isn't the case in the second example. The mechanisms underlying these differences are poorly understood. Across the genus Drosophila there is significant variation in transposable element abundance, and we hypothesized that this would lead to significant variation in the degree of genomic autoimmunity. Surprisingly, the impact of genomic autoimmunity is remarkably uniform. To test the hypothesis that the primary driver of rapid evolution of the piRNA machinery is driven by an evolutionary arms race, we developed a new maximum likelihood framework for the McDonald-Kreitman test to compare adaptive evolution in the piRNA machinery across species with low and high TE content. Using this approach, we were able to reject the hypothesis that greater genomic TE content leads to increased adaptation in the piRNA machinery. Together, these results question the hypothesis that rapid evolution of the piRNA machinery is driven by an evolutionary arms race but highlight a complex role of genomic autoimmunity in the evolution of the genome defense based on small RNAs.

33 **Cellular and molecular organization of the Drosophila foregut** Haolong Zhu[1,2], William B Ludington[1,2], Allan C Spradling[1,2,3] [1]Embryology, Carnegie Institution for Science, [2]Biology, Johns Hopkins University, [3]Howard Hughes Medical Institute

The animal foregut is the frontline tissue encountered by ingested food, bacteria, and viruses. Efficiently digesting and absorbing nutrients from this intake, while retaining beneficial microorganisms and rejecting pathogenic ones represents a critical task for this gatekeeper tissue and requires coordinative responses of multiple tissues. To delineate these intricate physiological processes, we characterized the adult Drosophila foregut as a model. Major foregut cell types were identified, validated, and examined using scRNAseq and >150 *in vivo* gene reporter fly lines. Transcriptome analysis revealed potential mechanisms that the foregut-associated neuroendocrine cells including the *corpus cardiacum* and *corpora allata* use to coordinate gut activity with nutrition, the microbiome, and circadian cycles. Multiple intestinal cell types differentially express juvenile hormone binding proteins that likely allow them to respond to changes in juvenile hormone produced by the *corpora allata*. In addition to juvenile hormone biosynthetic enzymes, the *corpora allata* expresses circadian clock genes. Studying all the cell types of the proventriculus, the central foregut organ that secretes the peritrophic matrix lining the intestinal tract, provided a detailed view of the layered structure and dynamic character of the peritrophic matrix. Analyzing cell types synthesizing individual peritrophic matrix layers revealed abundant mucin production close to enterocytes, similar to the mammalian intestinal mucosa. Two previously unrecognized cell groups in the posterior proventriculus produce abundant digestive enzymes likely moving posteriorly together with the peritrophic matrix to join ingested food. The esophagus and salivary gland express secreted proteins some of which may line the esophageal surface and generate a foregut commensal niche for specific gut microbiome species including Lactiplantibacillus and Acetobacter strains (Dodge *et al*. 2023). Overall, our study strongly supports the foregut's role as a central coordinator of intestinal activities, immune defense, and microbiome interactions by virtue of its location near the brain, sensory organs, and esophagus, the most frequent site of pathogen invasion. Our results also suggest that the cells, genes, and functions of the foregut as an interacting group of tissues, have been significantly conserved throughout animal evolution.

Dodge *et al*. (2023). Nat. Comm.14:1557.

34 **Spatial patterning regulates neuron numbers in the *Drosophila* visual system** Jennifer Malin, Yen-Chung Chen, Felix Simon, Evelyn Keefer, Claude Desplan Department of Biology, New York University

Neurons must be made in the correct proportions to carry out their functions. In the *Drosophila* visual system, 20 classes of distal medulla (Dm) neurons are specified with characteristic numbers—from 5 to 800 per optic lobe—to regulate the flow of visual information from photoreceptors. Dm neurons are born from a crescent-shaped neuroepithelium called the Outer Proliferation Center, or OPC. During the third larval instar, neuroepithelial cells are converted into neural stem cells called neuroblasts, which express a series of temporally regulated transcription factors that specify distinct neural classes. Additional diversity is produced via the asymmetric division of transit-amplifying Ganglion Mother Cells, which generate one Notch-on neuron and one that is Notch-off. In addition to temporal patterning, the OPC is partitioned based on the spatially-restricted expression of transcription factors and growth factors: Vsx is expressed at the center of the OPC, Optix is expressed in the middle, and Rx is expressed at the tips. Rx can be further divided into two subdomains based on differences in Dpp/Wg expression.

Using a series of genetic fate mapping tools, including single-cell RNA sequencing based techniques, we characterized the

role of spatial patterning in the regulation of neuronal stoichiometry. We found that the relative abundance of a specific Dm subclass is directly proportional to the size of the neuroepithelial domain from which it is born. Although spatial patterning can explain most Dm cell number variation, it is not sufficient to explain differences in less abundant cell types. Mutations in apoptosis genes caused a small increase in cell number, but were not sufficient to account for gross differences in cell type proportions. In contrast, we found that additional spatial patterning subdivides the OPC to generate additional diversity. We found that the Dm neuron Dm8 is born from the anterior ventral 2/3 of the Optix domain, while Dms 1, 4 and 12 are born from the posterior ventral 1/3 of the Optix domain. To generate this subdivision, we found that the morphogen Dpp (BMP) prevents Brinker (Brk) expression to delimit it to a domain that covers Vsx and the posterior 2/3 of the ventral Optix domain, thereby allowing for differential specification of Dm1/4/12 vs. Dm8 in the Optix domain. Inhibition or overexpression of Dpp and/or Brk changed the relative ratios of Dm1/4/12 vs Dm8 cells, suggesting that Dpp can regulate cell number as well as cell fate. Dpp expression also overlaps with the spatial factor Optix, which forms an additional spatial subdomain within the neuroepithelium. Our scRNAseq lineage tracing data shows that Dm12 is born from the area with highest Dpp expression, while Dm1 and Dm4 are born from areas of lower Dpp expression. Altogether, we show that spatial patterning generates differently sized pools of stem cells to generate neurons in distinct proportions.

35 **Protein-intrinsic and extrinsic features regulating pioneer factor-mediated reprogramming** Eliana F Torres Zelada[1], Elizabeth D Larson[1], Hideyuki Komori[2], Meghan M Freund[1], Abby Ruffridge[1], Christine Rushlow[3], Cheng-Yu Lee[2], Melissa Harrison[1] [1]Department of Biomolecular Chemistry, University of Wisconsin-Madison, [2]Department of Cell and Developmental Biology and Life Sciences Institute, University of Michigan, [3]Department of Biology, New York University

Transcription factors coordinate changes in cellular identity by binding DNA to drive gene expression. However, chromatin is a barrier to transcription-factor binding. Pioneer factors are a unique class of transcription factors that bind DNA in the context of nucleosomes, establish regions of accessible chromatin, and define *cis*-regulatory regions to control gene expression. These properties make them instrumental for driving key developmental transitions. Nonetheless, developmental context regulates pioneer-factor function. To investigate the reciprocal relationship between development and pioneer activity, we study the pioneer factor Zelda (Zld). Following fertilization, Zld is required for reprogramming the specialized germ cells to the totipotent cells of the early embryo. Zld is similarly required to promote self-renewal in neural stem cells, neuroblasts (NB), in the larval brain. We showed that Zld occupies unique regions of the genome in NBs and embryos. Indeed, other pioneer factors show cell-type-specific DNA binding. Thus, while pioneer factors bind to nucleosomes, there are features that shape this binding. Zld a 1596 aa protein that includes six zinc fingers (ZnF). A cluster of four zinc fingers (ZnF3-6) are required for binding the canonical DNA motif, CAGGTA. ZnF2 functions as an auto-inhibitory domain in embryos and cell culture, such that mutations in ZnF2 result in hyperactivation of Zld-target genes. By contrast, ZnF2 is necessary to promote the stem-cell fate in the NB lineage. In NBs and cell culture, ZnF2 is required for binding to chromatin regions lacking the CAGGTA motif, but is dispensable for binding chromatin in the early embryo. Using gel shift assays, we showed that ZnF2 mediates binding to DNA containing a G-rich motif, suggesting that ZnF2 may promote DNA binding. Together our data support the model that in the embryo the DNA-binding activity of ZnF2 may inhibit Zld-mediated activation of target genes, which nearly all contain the CAGGTA motif. By contrast, in NBs ZnF2 binding to G-rich motifs is likely essential for function as many NB enhancers lack the canonical motif. Ongoing studies focus on the role of these two DNA-binding domains in regulating the ability of Zld to promote chromatin accessibility and the tissue-specific cofactors that may mediate the differential dependence on these two domains. Our studies will uncover tissue-specific regulation of a paradigmatic pioneer factors and provide insights into how pioneer-factor activity can be regulated to enable rapid transitions in cell fate.

36 **Secretion and Transportation of the Hedgehog Morphogen in *Drosophila*** Pascal Therond[1], Tamas Matusek[1], Sandrine Pizette[1], Catherine Rabouille[2], Laurent Ruel[1], Laurence Lavenant[1] [1]CNRS, [2]Hubrecht Institute/KNAW &UMC

We focus our studies on the conserved family of Hedgehog (Hh) proteins, which carry hydrophobic lipid modifications essential for their correct spreading in the extracellular environment. Various potential extra-cellular carriers for Hh have been suggested, including soluble multimers, long filopodia, extracellular vesicles (EVs), or lipoprotein particles. The individual contribution of these carriers to the morphogen activity of Hh is still unresolved. We recently provided evidence that Hh activity is divided between two functionally distinct Hh extracellular pools, one basal and one apical, which collectively comprise the morphogen gradient (Gore et al., Development 2021). As the regulation of Hh trafficking is likely critical for Hh loading on one of its carriers for extracellular transportation, we choose to study the different intracellular routes followed by Hh in producing epithelial cells. We demonstrated that Hh followed a primary secretion to the apical plasma membrane before its endocytosis for a secondary secretion (D'Angelo et al., Dev. Cell 2015). We further provided evidence that apical microvilli act as a source for an active pool of Hh secreted on EVs to exert long-range signaling function (Matusek et al., Nature 2014; Hurbain et al., Current Biol. 2022). We recently showed that the major pool of intracellular Hh in producing cells is present in a novel compartment (identified by electronic microscopy) which correspond to recycling tubules emanating from endosomes (Pizette et al., J. Cell Sci. 2021). We proposed a model whereby upon primary secretion by the producing cells, a pool of Hh is

re-endocytosed to Rab11-dependent endosomes and recycling tubules to stimulate high-level signaling and disc pouch growth (Pizette et al., 2021). Using the new RUSH method we recently documented the role of two new players, TMED10 and Rab18, which participate in Hh exit from the endoplasmic reticulum (ER; Bar et al., Cell. Mol. Life Sci. 2023). However, our preliminary data suggests that TMED10 and Rab18 participate also in the loading of Hh onto intraluminal vesicles of MVBs, an unforeseen result that drove us to decipher their role in the incorporation of Hh into EVs and subsequent signalling functions. I will present our last data on the biogenesis of Hh-EVs and the role of TMED10 and Rab18 in this process.

37 **Decoding Butterfly Wing Patterning: Single-Cell Multi-Omics Analysis of the Uncharted *WntA/fz2* Signaling Pathway** Anyi Mazo-Vargas Biology Department, Duke University

The *WntA* ligand emerges as a central orchestrator in instructing butterfly wing color patterning, providing a new opportunity to investigate pattern formation in a simple tissue. Previous studies employing genetic mapping in natural populations, in-situ hybridizations, and CRISPR knockouts have unveiled the profound influence of the *WntA* in delineating distinct boundaries within the developing wings of closely and distantly related butterfly species, resulting in striking differences in patterns. Initial findings suggest that the *WntA/fz2* interaction follows a non-canonical signaling pathway. Yet, the cascade of events and the targets within this transduction pathway that underlie spatial differentiation and its connection to scale determination remain poorly understood. In this study, I employed CRISPR/*Cas9* technology to induce gene and regulatory perturbations in the Gulf fritillary butterfly *Agraulis incarnata*. This approach allowed the modulation of the *WntA* pathway in both directions—utilizing null *WntA* alleles (loss-of-function) and a cis-regulatory deletion resulting in *WntA* overexpression (gain-of-function). Through the analysis of single-nuclei RNA and ATAC-seq profiles during the early pupal development stage, I investigate the impact of these signaling shifts on cell-type specific expression and chromatin-accessibility profiles. The findings identified potential candidate genes associated with alterations in the *WntA/fz2* signaling, contributing to the establishment of diverse wing elements. This research illuminates the intricate molecular processes underpinning butterfly wing pattern development and provides insights into the critical genes and regulatory elements shaping this phenomenon.

38 **Transcriptional control of male-specific tail tip morphogenesis in *C. elegans* by DMD-3** Porfirio Fernandez[1], Karin Kiontke[1], David H. A. Fitch[2] [1]Biology, NYU, [2]NYU

Morphogenesis is characterized by cell shape changes and other cell behaviors carried out by 'effector' proteins that must be regulated in time, space, and sex. However, how transcriptional regulators are connected to effectors is poorly understood. To elucidate this link, we use the C.elegans male tail tip. In both sexes, the larval tail tip is pointed. In males only, its shape changes to round during the L4 stage. This Tail Tip Morphogenesis (TTM) is controlled by a transcription factor, DMD-3, which is required and sufficient for TTM. RNA-seq and differential expression (DE) analysis of tail tips isolated from wild-type (WT) and dmd-3(-) males at the L4 stage identified 1154 genes regulated by DMD-3 directly and indirectly. To find direct targets of DMD-3, ChIP-seq on whole males was done. We found 1755 peaks corresponding to 3636 genes and a DMD-3 binding motif. 147 genes were also DE and represent the genes directly regulated by DMD-3 in the tail tip. To confirm the function of the DMD-3 binding motif, we tiled the motif sequence and injected it as a transgene. Males showed defective TTM, while control animals were WT, indicating that the array could sequester DMD-3 protein. To validate DMD-3 targets, GFP was inserted into endogenous loci and expression dynamics were profiled. We then deleted the candidate peak sequence or the DMD-3 binding motif and screened for altered expression or TTM defects. We found 4 genes in which such deletions had an effect: (1) FOS-1 is expressed in the tail-tip of males and other tissues. Abolishing the DMD-3 binding sites resulted in a specific loss of GFP in tail tips and defective TTM. (2) NMY-2 is expressed in the tail tip during TTM and abolishing the peak reduced tail-tip expression. (3) PAN-1 has 2 peaks; deleting one has no effect, while deleting the other results in 10 % of males with defective TTM. Eliminating both peaks recapitulates the pan-1(RNAi) phenotype in both sexes. (4) HMR-1 localizes to adherens junctions and later forms cytoplasmic puncta. Transcriptional reporter assays showed a male-specific delay in hmr-1 expression when the peak was deleted in the promoter construct. Deleting the peak endogenously has little effect on protein expression; however, adults of both sexes displayed the hmr-1(RNAi) phenotype. Taken together, these data suggest that DMD-3 binds DNA to regulate the expression of sex-shared genes to fine-tune male-specific TTM.

39 **Ancient evolutionary origin of a pluripotency-neural crest gene regulatory network in vertebrates** Joshua York[1], Carole LaBonne[2] [1]Northwestern University, [2]Molecular Biosciences, Northwestern University

Neural crest cells are a vertebrate-specific innovation that helped drive the evolution of early vertebrates. A key feature of this stem cell population is its broad, multi-germ layer developmental potential. Here, we investigate the evolutionary origins of neural crest potential by comparing neural crest and pluripotency gene regulatory networks (GRNs) in representatives of both jawless (lamprey) and jawed (*Xenopus*) vertebrates. Using comparative gene expression analyses and transcriptomics we reveal an ancient evolutionary origin of shared components between neural crest and pluripotency GRNs that dates back to the last common ancestor of extant vertebrates. Focusing on the key pluripotency factor pou5, we show that lamprey genome has

a pou5 ortholog that is expressed in animal pole cells, as in jawed vertebrates, but is absent from the neural crest. However, gain-of-function experiments show that both lamprey and *Xenopus* pou5 promote neural crest formation, suggesting that pou5 was lost from the neural crest of jawless vertebrates. Finally, we show that pou5 is essential for neural crest development in jawed vertebrates and that it acquired neural crest-enhancing activity after evolving from an ancestral pou3-like clade that lacks this functionality. We propose that a pluripotency-neural crestGRN was assembled in stem vertebrates and that the multi-germ layer potential of the neural crest evolved by deploying this regulatory program. Using ATAC and ChIP-seq we show that both stem cell populations pou5 partners with SoxB1 factors to control developmental potential.

40 **Ribosome heterogeneity drives early development in zebrafish** Kamena Kostova Carnegie›s Department of Embryology

In zebrafish (Danio rerio), early embryonic development is characterized by remarkable change in the composition of the ribosome, the molecular machine that translates mRNA to protein. The zebrafish oocyte is loaded with a special type of ribosome, called maternal ribosome, that carries out protein production during the early stages of development. During maternal to zygotic transition the embryonic genome becomes transcriptionally active and the assembly of somatic ribosomes begins. These ribosomes function in all tissues and organs of the adult animal. How the assembly of two structurally different types of ribosomes regulates protein production to drive early development is not known.

Here, we report that maternal and somatic ribosomes differ in their 3D structure, location and identity of post translational modifications, as well as interacting partners. We present in vivo and in vitro approaches to measure how maternal and somatic ribosomes differ in their ability to engage mRNAs and synthesize proteins. We use genetic and biochemical approaches to determine how disruption of the tightly orchestrated transition between maternal and somatic ribosomes interferes with normal development in zebrafish. Our work challenges the traditional mRNA-centric view of early development, uncovering how assembly and deposition of ribosomes with altered structure and mRNA specificity regulates protein production to facilitate embryogenesis.

41 **BindCompare: A Novel Platform to Identify and Analyze Coupled Protein-DNA and Protein-RNA Binding Regions** Pranav Mahableshwarkar, Mukulika Ray, Erica Larschan Brown University

Transcription factors (TFs) and RNA binding proteins (RBPs) work synergistically or antagonistically to mediate gene regulation. However, how TFs and RBPs co-interact with DNA and RNA to drive precise gene expression for cell and sex-specific functions remains unclear. While high throughput techniques like CUT&RUN, ChIP-seq, and iCLIP enable the study of protein-nucleic acid interactions, there is a dearth of computational platforms that integrate multiple protein-nucleic acid datasets to understand how different TFs and RBPs regulate precise function at specific genomic locations. We present BindCompare, a novel platform to identify genomic regions where coordinated gene regulation and RNA processing occur by integrating high throughput protein-nucleic acid binding genomic datasets.

BindCompare uses BED files that list where TFs and RBPs bind to DNA or RNA. Optimized algorithms process the RNA/DNA binding sites in one dataset to find overlapping binding domains in corresponding datasets. The search for overlaps occurs in a user-specified scoped region because co-regulatory binding can occur upstream and downstream of the DNA binding site. The visualized results convey the distribution and frequency of overlaps across the scoped region. These techniques can be split across chromosomes to enable users to see if the co-regulatory activity is concentrated in particular domains. To determine the downstream functionality of co-regulatory regions, the app embeds platforms like GProfiler2 and MEME-Suite, enabling rapid gene ontology and motif analysis.

As a proof of concept, we compared the binding of DNA and RNA binding TF CLAMP, Chromatin-linked adaptor for male-specific lethal proteins, and RNA helicase maleless (MLE). Using BindCompare, we showed the first experimental proof of CLAMP binding to DNA and RNA molecules at proximity, indicative of CLAMP's co-transcriptional activity. It was further shown that this mechanism concentrated on the X chromosome. BindCompare also lends itself to comparisons across TFs. Thus, we are applying BindCompare to analyze MLE and CLAMP's co-regulatory functionality. Because its only inputs are BED files, BindCompare can examine binding in organisms beyond Drosophila, including mice and humans.

A key focus of this platform is accessibility. The use of bioinformatics tools is often hindered by complex setup processes and package conflicts. BindCompare's Docker-mounted GUI interface allows for easy access to the method.

42 **The Effect of Long Non-coding RNA Expression on Vitamin E Concentration in Maize Grain** Morgan A Apolonio[1], Sam Herr[2], Michael A Gore[2] [1]University of California, Berkeley, [2]Cornell University

Tocochromanols are a group of antioxidants synthesized in plant tissues and have varying levels of vitamin E activity,

but tocochromanols with the highest vitamin E activity tend to occur at low levels in maize grain. In efforts to increase tocochromanol abundance in maize grain, Transcriptome-Wide Association Studies (TWAS) have been used to resolve quantitative trait loci (QTL) associated with grain tocochromanol concentrations to the gene level. While the causal loci underlying most of the large-effect QTL have been identified, relatively smaller effect QTL remain unresolved. Our past efforts have not explored the potential role of long non-coding RNAs (lncRNA), which are transcripts longer than 200 bp that do not encode a protein, in the genetic control of natural variation for tocochromanols in maize grain. Therefore, we hypothesize that lncRNAs could account for a portion of the unexplained genetic variation. We tested this hypothesis by conducting a new TWAS analysis in a maize association panel scored for lncRNA expression and grain tocochromanol levels. Nearly 20% of the identified lncRNAs were expressed in more than 10% of the individuals in the panel and were retained for the TWAS analysis. Of these, we found thirteen putative lncRNAs to be significantly associated with tocochromanols and of which four coincided with unresolved grain tocochromanol QTL identified in the maize nested association mapping panel. Our results highlight that including lncRNAs may be useful in resolving vitamin E-associated QTL in maize grain.

43 **Global proteome rewiring in times of desiccation and rehydration** Sheila Ferer, Nadine Zayyad, Hugo Tapia California State University Channel Islands

Most biological processes occur with water as a solvent, making desiccation a major stressor for living organisms. Anhydrobiotes—desiccation tolerant organisms—can overcome such adverse events by going into stasis and regain normal metabolic function once rehydrated. The subcellular localization of proteins can be affected by environmental perturbations. Global protein localization upon a detrimental stress as desiccation has never been evaluated. We will examine changes in the localization of proteins upon drying/rehydrating by utilizing the Yeast GFP-Fusion Collection. The *Saccharomyces cerevisiae* fusion library constitutes 75% of the yeast proteome, providing the opportunity to assay the physiological expression level and subcellular localization of 4,156 proteins. A preliminary pilot study on 20 differently localized GFP-tagged strains has revealed localization changes of the majority of the strains examined. Moving forward, automated-microscopy, alongside custom machine-learning algorithms will be used to capture and analyze images and cluster them based on similarity. Performing this for thousands of strains over different conditions will give us sufficient variability to generate a detailed roadmap of the yeast proteome and assess how it is rewired under desiccation stress. Proteins/protein families that change their localization pattern by a large degree are top candidates for factors implicated in (mal)adaptive responses to desiccation. These candidates will be subsequently characterized using functional assays (i.e., effect of knockdown on desiccation tolerance), as routinely performed in our laboratory. This undertaking will allow us to test how the proteome is rewired under desiccation and assess whether it constitutes an adaptive response priming the cell for recovery. Understanding anhydrobiosis and desiccation tolerance mechanisms is critical for tackling the climate crisis, space exploration, medical innovation, plant breeding, food spoilage, and gene banking.

44 **Using chromosome synthesis to study genetics and molecular evolution across yeast genera** Shawn H. Yang, Alessandro L.V. Coradini, Ian M. Ehrenreich Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California

The phenotypic diversity that evolution has generated is one of our best resources for understanding how organisms' genetic blueprints specify their phenotypes. However, as evolutionary distance between organisms increase, so do reproductive barriers and differences in genome structure, making it difficult, if not impossible, to perform conventional genetic analyses. We hypothesized that this impasse could be overcome through the synthesis of chromosomes possessing the gene content and organization of one genus but the DNA sequences of another. We are using the budding yeast model system to test this possibility. Specifically, we are attempting to make a *Saccharomyces cerevisiae* cell in which Chromosome I has a *S. cerevisiae* architecture but is composed of DNA sequences from *Kluyveromyces marxianus*. These two species diverged ~100 million years ago, show >50% nucleotide divergence, and possess completely different genome organization. As a pilot, we initially focused on ⅙th of the chromosome. We assembled this 1/6th chromosome segment in a single transformation of 27 partially overlapping, synthetic DNA fragments into an *S. cerevisiae* cell. RNA-seq experiments with this 1/6th chromosome segment confirmed that all 17 *K. marxianus* genes in the segment are transcribed and that expression of these *K. marxianus* genes does not cause any major changes in the *S. cerevisiae* transcriptome. We attempted to delete the corresponding 1/6th segment from the native *S. cerevisiae* genome but could not. Experiments with each of the individual genes revealed that a single gene–an essential component of the cleavage and polyadenylation complex (*PTA1*)–is the barrier to substituting the 1/6th chromosome segment between genera. We are now characterizing *PTA1* further, while also extending our work to the rest of the chromosome. This project could establish a new paradigm for how genetics can be experimentally studied across long evolutionary timescales that otherwise permit only descriptive, bioinformatic work.

45 **Investigating the effects of cannabidiol (CBD) on sleep, lifespan, and protein aggregation in a Drosophila melanogaster model of Parkinson's disease** Matthew J Irons, Kathryn A Jewett Biology, Juniata College

Our lab specializes in utilizing a *Drosophila melanogaster* Parkinson›s disease (PD) model featuring a genetic disruption in the human ortholog of the *GBA* gene, responsible for encoding the lipid-modifying enzyme glucocerebrosidase. Human *GBA* mutations are associated with an increased predisposition to PD, often precluded by initial symptoms such as sleep disturbance. With the relatively recent expansion of cannabidiol (CBD) sales within the United States, PD patients are turning to CBD with the hope of alleviating symptoms such as insomnia, pain, and dystonia. We seek to investigate the potential of CBD as a treatment in our PD *Drosophila* model.

Our total *GBA* deletion model (GBA^{Del}) flies are characterized by a shortened lifespan, impaired sleep, and increased protein aggregation. These three characteristics were measured after CBD exposure using STATA software, the Drosophila Activity Monitoring System (DAMs), and western blot. We have employed our GBA^{Del} with the DAMs to track sleep and activity patterns post-CBD ingestion. Leveraging the open-source ShinyR-DAM software, we observed a significant increase in both total and nighttime sleep after CBD exposure in the GBA^{Del} flies with significantly longer sleep bout length and no change in the number of sleep bouts. To further elucidate the effects of CBD with this PD model, we conducted a lifespan assay to assess the longevity of our model post-treatment. Through population sampling and subsequent western blot assays, we appraised the impact of CBD exposure on protein aggregation within our *Drosophila melanogaster* PD model.

46 **Adenylosuccinate alleviates mobility deficits associated with Adenylosuccinate Synthetase deficiency in *Caenorhabditis elegans*** Rishika R Patil, Latisha P Franklin, Wendy Hanna-Rose Biochemistry and Molecular Biology, The Pennsylvania State University

Inborn errors of purine metabolism have been linked to various neurological and muscular disorders that are under-reported and often go undiagnosed or misdiagnosed because their symptoms may often mimic other, more detectable, diseases. The links between purine metabolism and the mechanisms of these diseases remain understudied and effective therapies are unavailable due to our insufficient understanding of them. Therefore, these disorders are of major clinical significance and pose some of the most challenging enigmas in medical diagnosis and treatment. ADSSL1-Myopathy is an ultra-rare muscular disorder caused by a mutation in the purine nucleotide cycle (PNC) gene, ADSSL1. ADSSL1 codes for adenylosuccinate synthetase, an enzyme of the purine nucleotide cycle important for energy in the muscle. Some of the symptoms of the disorder include movement dysfunction, muscle weakness, lipid accumulation in the muscles, and the disruption of proper muscle structure. ADSSL1-Myopathy has been hard to characterize on a molecular level due to a lack of adequate models for its study. We are investigating the biological functions of ADSS using *C. elegans*. We have established that *adss-1* RNAi knockdown animals have slower crawling speed, reduced wavelength, reduced thrashing rate, and uncoordinated movement. They also exhibit an enlargement and accumulation of lipid droplets. We have probed the neuromuscular junction through paralysis assays using aldicarb and levamisole but found no obvious impairments. Additionally, we are currently examining muscle structure. We also hypothesize that the supplementation of PNC substrates will ameliorate phenotypes associated with the lowered expression of *adss-1* and can be used as a potential therapeutic strategy. We have found that the supplementation of adenylosuccinic acid (ASA) rescues movement phenotypes of speed and wavelength and are continuing to analyze other parameters of movement. This supports the use of other PNC substrates as a therapeutic strategy for the disorder.

47 **Tapping into worm conversations: transfer of memory from one *Caenorhabditis elegans* to another and investigating its underlying molecular mechanism** Monmita Bhar[1], Hari Pradeep Narayanan[2], Shrinithi Natarajan[3], Tanumoy Nandi[4], Kamal Kishore[4], Kavita Babu[4] [1]Centre for Neuroscience, Indian Institute of Science, [2]Neurobiology, University of Konstanz, [3]Computer Science and Engineering, PES University, [4]Centre for neuroscience, Indian Institute of Science

Native preference in organisms can be modified through experience. *Caenorhabditis elegans* has been proven to be an extremely important model system to study behavioural plasticity. In this study, we looked at long-term associative memory (LTAM) in *C. elegans* using two cues – the native chemoattractant isoamyl alcohol (IAA) along with heat pulses. After this training paradigm, worms are incubated at ambient temperatures (22°C) in the incubator for the next 20-24 hours. LTAM is seen in the form of loss of attraction towards IAA due to this aversive learning paradigm. Here we report that worms lose this LTAM when removed from the plates they are trained on. This suggests that during training, *C. elegans* release some factors onto the plate that act as signaling molecules for maintaining the LTAM. Hence, removal of worms from these plates causes them to lose their memory despite undergoing aversive training.

Naïve worms that have not undergone the training can also take up these factors if exposed to the trained plates. This leads to LTAM formation in naïve worms, specific to IAA, causing them to lose their attraction towards this chemoattractant. The same is seen for memory-defective mutant worms, where they can take up these factors released by wild-type trained worms, while themselves not being able to release them during training.

To investigate the underlying molecular mechanism, we have performed RNA sequencing to look at differential gene

expression in worms that have LTAM versus worms that lose it. We have identified some candidate genes that may be responsible for this phenomenon. Additionally, to identify the externally released factors, we have performed liquid chromatography mass spectrometry (LC-MS) from the plates worms were trained on.

Here, we propose a mechanism by which *C. elegans* due to aversive training, release some factors onto the plate, which may be in a compartmentalized fashion through environmentally released extracellular vesicles (EVs), which can further be taken up by any worm (naïve untrained or memory-defective mutants) and get processed downstream, leading to similar behavioural phenotype in these untrained worms. Hence, in this study, we report that memory (LTAM) can be transferred from a trained worm to an untrained worm, opening a new avenue of communication and signaling with respect to long-term associative memory formation in *C. elegans*.

48 **TOP-2 is differentially required for meiotic chromosome morphology in spermatogenesis and oogenesis** Christine K Rourke[1], Lauren Salvitti[2], Gabriella Gassaway[3], Aimee Jaramillo-Lambert[1] [1]Biological Sciences, University of Delaware, [2]Charles River Laboratory, [3]Rutgers University

The specialized cell division of meiosis results in the production of haploid gametes from diploid gamete precursor cells. The success of meiosis I is dependent on the proper pairing of homologous chromosomes, synapsis, and recombination. Failure to complete these steps properly results in gamete aneuploidy, which is the leading cause of infertility, progeny inviability, and birth defects. Many meiotic events are sex-specific including chromosome structure. In particular, the degree of chromosome compaction in spermatogenesis is much greater than in oogenesis. Differential chromosome compaction is coordinated by several proteins including sperm-specific histone variants and post-translational modifications, condensins, cohesins, and DNA topoisomerases. Previously, we identified a loss-of-function mutation of *C. elegans* Topoisomerase II, *top-2(it7*). In *top-2(it7)* homologous chromosomes fail to segregate resulting in aneuploid sperm and embryonic lethality after fertilization. Recently, we found that *top-2* plays sex-specific roles in the localization of meiotic chromosome structural components and on chromosome structure during late meiotic prophase. During spermatogenesis, late prophase chromosomes are significantly compromised in their ability to condense and individualize after loss of *top-2* function. During oogenesis, chromosome structure appears to be unaffected in *top-2(it7*), however, diakinesis bivalent length is elongated. These sex-specific differences are likely due to differences in the temporal regulation of late meiotic prophase events. As to*p-2(it7)* changes the chromosome morphology of meiotic chromosomes in both spermatogenesis and oogenesis, we asked if *top-2(it7)* changes the recombination landscape. We examined meiotic double-strand break repair by the assembly and disassembly of RAD-51 foci during spermatogenesis and oogenesis. We found fewer RAD-51 foci in the transition zone through late pachytene in *top-2(it7)* spermatogenic and oogeneic germlines. Even though fewer RAD-51 foci are observed, crossover formation is not perturbed in *top-2(it7)* spermatogenesis nor oogenesis as five and six GFP::COSA-1 foci, respectively, were found per nucleus in the mutant germlines. However, *top-2(it7)* appears to alter the position of crossovers in spermatogenic germlines. Currently, we are further probing the role of TOP-2 through a combination of FISH oligopaint and super-resolution microscopy to analyze chromosome structure.

49 **How does a complex genomic rearrangement affect gene expression?: A research project for undergrads in a classroom setting** Tatiana Maroilley[1,2], Victoria Rodrigues Alves Barbosa[1,2], Diogo Marques[3], Catherine Diao[1,3], David Anderson[1,4,5], Maja Tarailo-Graovac[1,3,5] [1]Biochemistry and Molecular Biology, Cumming School of Medicine, University of Calgary, [2]Medical Genetics, Alberta Children Hospital Research Institute, niversity of Calgary, [3]Medical Genetics, Alberta Children Hospital Research Institute, University of Calgary, [4]Alberta Children Hospital Research Institute, University of Calgary, [5]co-last authors

Structural variants (SVs) are independent large genomic rearrangements (>50 bp): copy number variants (deletions, duplications), inversions, and translocations. Cascades of catastrophic events can create complex genomic rearrangements (CGRs) or chromoanagenesis, involving multiple SVs. Frequent in tumor cell genomes, they can also cause rare genetic diseases. But they are understudied in clinical diagnosis as their detection with low-resolution genetic techniques (FISH, arrays) prevents a complete molecular characterization and interpretation of pathogenicity.

Caenorhabditis elegans balancer strains are well described phenotypically, and their genomes carry SVs/CGRs. We have recently used short-read whole genome sequencing to characterize these events at a base-pair resolution (Maroilley et al. 2021, 2023). In addition, we have reported all SVs/CGRs detectable in the genomes of the strains, beyond the balanced regions, publishing then the first catalog of SVs/CGRs (on average >5 per strain, and overall >100). Here, we explore the effects each SV/CGR has on gene expression by sequencing bulk RNAs using short reads.

We have implemented our research project with a class of undergraduate students over a semester as an innovative teaching tool to introduce research in Bioinformatics. Our curriculum was developed as a CURE, a Course-based Undergraduate

Research Experience for Bioinformatics program students (Bachelor of Health Sciences, Cumming School of Medicine, University of Calgary). We first trained the students in data manipulation and WGS data analysis to detect SVs/CGRs. Then, they analyzed the transcriptome data of the same strains to scrutinize the potential effect of SVs and CGRs on gene expression and splicing. We organized an in-person conference for students to present their findings to a large audience.

We uncovered that the reciprocal translocation *eT1(III;V)* affects two genes: it prevents the transcription of *unc-36* by RNA truncation, explaining the uncoordinated phenotype of the carriers. In addition, our data shows that *eT1* activates the transcription of an understudied gene *H14N18.2*, which is not expressed in control.

Our project combines teaching and advanced Bioinformatics in a research project with original multi-omics data as way to offer a research experience to undergraduate students. Ultimately, our analyses should reveal new genome-transcriptome-phenotype associations and possibly uncover new genes, gene function, or transcripts.

50 **A LIN-42-Casein kinase 1δ interaction is necessary for C. elegans developmental timing** Rebecca K Spangler[1], Guinevere Ashley[2], Kathrin Braun[3], James M Ragle[2], Carrie L Partch[1], Helge Grosshans[3,4], Jordan D Ward[2] [1]Chemistry and Biochemistry, UC Santa Cruz, [2]Molecular, Cell, and Developmental Biology, UC Santa Cruz, [3]Friedrich Miescher Institute for Biomedical Research, [4]University of Basel

All living organisms use timing mechanisms to coordinate developmental, cellular, and physiological processes over time. Two independent but interconnected biological timers drive progression through C. elegans development. The heterochronic pathway is a linear timer that controls the serial progression of stage-specific cellular events. A cyclical molting timer coordinates apical extracellular matrix regeneration and shedding of the old cuticle. Failure to coordinate these two timers leads to animal death, but how these timers are coordinated is unclear. LIN-42, the C. elegans homolog to the mammalian circadian clock protein PERIOD2 (PER2), has been established as a key component of both timers. To gain insight into how LIN-42 coordinates developmental timing, we looked for novel interactors through co-IP mass-spectrometry and found an interaction with KIN-20, the C. elegans homolog of mammalian Casein Kinase 1δ (CK1δ). In mammals, circadian clocks are controlled by a transcription-translation feedback loop of PER2 expression and degradation. The stability of PER2 is largely determined through its interaction with CK1δ, a kinase that binds to and phosphorylates PER2 at one of two regions leading to either stabilization or degradation of PER2. Sequence analysis indicates two highly conserved kinase-binding motifs, and our in vitro pull-down assays show that these domains are conserved enough in LIN-42 to maintain interactions with CK1δ suggesting that a common mechanism may anchor the kinase to LIN-42. The LIN-42 C-terminus is phosphorylated by CK1δ to a similar degree and within the same timeframe as CK1δ phosphorylation of a PER2 substrate. Deleting the conserved kinase binding motifs abolished the interaction with CK1δ and reduced phosphorylation of the LIN-42 C-terminus compared to wildtype. When we engineered the equivalent mutations into the lin-42 endogenous locus, we observed profound developmental delay as well as extended and asynchronous molts. Surprisingly, deletion of the conserved PAS domains which had been previously implicated in the heterochronic pathway, only produced mild heterochronic defects. In contrast, deletion of the unstructured C-terminus of the protein produced much stronger heterochronic defects. Together, these data suggest that PER2/LIN-42 phosphorylation by CK1δ kinases is evolutionarily conserved and that this mechanism may be employed by the molting oscillator to coordinate developmental timing.

51 **The molecular atlas of *C. elegans* glia across sexes reveals sexually dimorphic and heterogeneous glia** Maria D Purice[1], Elgene J. A. Quitevis[1], Richard S Manning[1], Liza Severs[1], Nina-Tuyen Tran[1], Manu Setty[1,2], Aakanksha Singhvi[1,3] [1]Basic Sciences, Fred Hutchinson Cancer Center, [2]Herbold Computational Biology Program, Public Health Sciences, Fred Hutchinson Cancer Center, [3]Department of Biological Structure, University of Washington School of Medicine

Interactions between neurons and glia are essential for nervous system function. Recent studies suggest glia heterogeneity and their functions differ across brain regions and disease. However, the extent of glia molecular diversity across the entire nervous system, across sexes, or how glia molecular diversity impacts circuit function, remains largely unknown. *C. elegans* has an invariant nervous system with the first mapped connectome of a multicellular organism across both sexes. Here we present single nuclear RNAseq evaluation of glia across the entire nervous system of adult *C. elegans* in both sexes, complementing previous single-cell analysis of its neurons and connectome. Our data identify both sex-shared and sex-specific glia. We have identified glia-specific markers of which we have validated *in vivo* using transcriptional reporters. Also, iterative computational and machine learning models reveal glial subclasses, of which we have also identified subtype-specific markers for and validated *in vivo*. Overall, this molecular atlas reveals detailed insights into glial heterogeneity and sex dimorphism in the adult *C. elegans* nervous system. Our data is made available as a searchable atlas at wormglia.org.

52 **Genetic Integration of Multi-Omics Data: Realizing the Promise of Genetical Genomics** Gary Churchill The Jackson Lab

It is now more than 20 years since Jansen and Nap (2001) proposed genetical genomics, a merger of genomics and genetics, as a new approach for unraveling of metabolic, regulatory and development pathways. In the intervening time, advances in our ability to quantify the molecular components of biological samples combined with the development of powerful model organism genetic resources have changed genetical genomics from aspiration to routine practice. This talk will briefly review some of the key advances that made this possible, and present examples of multi-omics integration that leverage genetic variation to establish causal linkages across chromatin structure, gene expression, protein abundance, post-translational modifications, metabolites, and cell-based and whole organism phenotypes.

53 **Effects of sex-linked variation and paternal age on recombination rate in house mice** Andrew P Morgan Department of Medicine, University of North Carolina

Recombination is the defining feature of sexual reproduction. In mammalian meiosis, the formation of crossovers between homologous chromosomes is critical for the faithful segregation of chromosomes to gametes, and thus for fertility. The rate and distribution of recombination across chromosomes modulate the impact of both genetic drift and natural selection on patterns of genetic diversity in populations. Characterizing the genetic and life-history factors that control the rate of recombination is therefore fundamentally important for understanding the evolution of mammalian genomes.

To this end we analyzed genotypes of 503 progeny from reciprocal F1 males between inbred strains representing the three major subspecies of house mice (Mus musculus), a well-established model system for the study of recombination and speciation. Recasting the experiment as a classical diallel design, we apply a hierarchical Bayesian model to estimate the contribution of additive, dominance and parent-of-origin effects to variation in male recombination rate. We show that a paternally-inherited factor from the *M. m. musculus* subspecies increases the global recombination rate by 0.5 crossovers per meiosis (4.3%). Furthermore, aged males transmit an average of 0.6 more crossovers per meiosis (5.1%) than young males independent of the genetic background. Our design also permits direct estimation of the strength of crossover interference. We implement a well-known model of interference in a hierarchical Bayesian framework and show that crossover interference in the male germline weakens with increasing age at paternity; the effect is variable across backgrounds. Our results highlight a previously unappreciated role of the Y chromosome in control of recombination in hybrid males and hint at further links between recombination, the sex chromosomes and speciation in mice.

54 ***De novo* structural variants on the sex chromosomes of CC029/Unc mice cause meiotic segregation errors in F1 hybrid males and lead to a high rate of sex chromosome aneuploidy** Rachel M Lynch[1,2,3], Pablo Hock[1], Matthew W. Blanchard[1,4], Caroline E. Murphy[1], Michelle E Allen[1,2], Timothy A Bell[1], Madison A Drushal[1,2], Martin T Ferris[1,2], Richard Austin Hodges[1,2], Colton L Linnertz[1], Md Taksir Hasan Majumder[5], Darla R Miller[1,2], John Sebastian Sigmon[4,5], Ginger D Shaw[1], Mark J Zylka[6,7], Fernando Pardo-Manuel de Villena[1,2,4,8] [1]Genetics, University of North Carolina at Chapel Hill, [2]Systems Genetics Core Facility, University of North Carolina at Chapel Hill, [3]Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, [4]MMRRC at UNC, University of North Carolina at Chapel Hill, [5]Computer Science, University of North Carolina at Chapel Hill, [6]Cell Biology and Physiology, University of North Carolina at Chapel Hill, [7]UNC Neuroscience Center, University of North Carolina at Chapel Hill, [8]Lineberger CLineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill

XO and XXY sex chromosome aneuploidies (SCA) are the most common types of viable aneuploidies in both mice and humans. In mice, a significant excess in SCA has been reported in the progeny of (CC029/Unc x CC030/GeniUnc)F1 males. Here we characterize the rate, parental and meiotic origin, and genetic basis of this phenomena. We analyzed sex chromosome segregation in 11 crosses that involve CC029 or its F1 derivatives. Eight are 4-way reciprocal F2 crosses between CC029 and other CC strains. Two are outcrosses between B6 females and reciprocal (CC029 x CC030)F1 males, and the last is the CC029 colony itself. We show that increases in SCA rates are restricted to the progeny of F1 males leading to a ~20-fold increase in SCA over baseline (~0.35 +/- 0.04%). However, the two types of reciprocal F1 males differ significantly in the rate and type of SCA observed. F1 males carrying an X chromosome derived from CC029 have the highest SCA rate (9.32 +/- 1.32%) and produce similar numbers of XO females and XXY males. F1 males carrying a Y Chromosome derived from CC029 have a lower SCA rate (2.27 +/- 0.86%) and only generate XO females. Analysis of the XXY progeny of the outcross unambiguously points to errors in chromosome segregation in meiosis I as the origin of SCA. This conclusion is consistent with the data of all other crosses. XO females could also be explained by meiosis II errors in male meiosis. To identify candidate mutations, we scanned the genome sequence of the CC029 sex chromosomes for *de novo* mutations, focusing on structural variants that may impair pairing, recombination and/or segregation of the sex chromosomes. There is a large known Y Chromosome deletion. In addition, we identified a 520 Kb interval of the distal X Chromosome that is translocated to the Y Chromosome. Recombination analysis suggests that this region is excluded from the pseudoautosomal region in males and reduces recombination in females. We will present a unified chromosomal model that is consistent with the observed data. In conclusion, CC029 is a new model for studying the mechanics of sex chromosome segregation in the male germline. It also supports a design to

systematically study the phenotypic consequences of SCA and X chromosome inactivation in genetically variable mice. Finally, researchers using CC029 in crosses should account for the presence of a significant number of aneuploids.

55 **The X and Y of sex disparities in cancer: sex chromosomes contribute to the male bias in melanoma progression** Nora Engel, Gillian McGuire, Daniel Deegan, Kiera Patton Coriell Institute for Medical Research

Melanoma is a quintessential example of a non-reproductive cancer with differences between males and females in incidence, progression, and response to therapy. Long-established epidemiological data show higher incidence and worse outcomes for male melanoma patients. These imbalances have not been explained and suggest that there are protective and susceptibility factors distinct between males and females that could be targeted for better outcomes. Yet currently, standard-of-care therapies for melanoma, or for that matter, any non-reproductive cancer, are delivered without consideration of the biological sex of the patient. Our goal is to elucidate the mechanisms underlying the sex disparities in melanoma and lay the groundwork for future development of sex-aware therapeutic strategies.

The two main factors that contribute to sex differences are the sex chromosome composition and sex hormones, collectively shaping a sex-specific transcriptomic and epigenetic landscape in normal somatic cells as well as in cancers. **Our hypothesis is that sex differences in melanoma result from these two factors via mechanisms that are intrinsic to the tumor cells and mechanisms related to the host.**

Because sex chromosome and sex hormone effects are coupled and covary with each other, we use the Four Core Genotypes model to disentangle these factors by producing XX and XY males and XX and XY females . In this mouse model, the sex chromosome composition is independent of the gonadal sex, allowing us to identify independent and joint effects of each factor. We challenged the FCG mice with male and female melanoma cell lines and compared melanoma growth as well as the transcriptomes and epigenomes of the resulting tumors. The design allowed us to identify sex differences intrinsic to the melanoma cells injected in addition to host effects dependent on the sex chromosome composition and gonad type. With a focus on transcriptional and epigenetic sex-biased genes, we genetically manipulated candidate factors and validated important regulatory nodes that underlie the sex differences in melanoma progression. Our studies establish a compelling framework to identify sources of sex biases in cancer that have traditionally been disregarded.

57 **Cas13d Unveils the Essential Role of Cell-Specific Maternal RNA Degradation in Zebrafish Development** Gopal Kushawah[1], Ariel Bazzini[2] [1]Ariel Bazzini lab, Stowers institute for medical research, [2]Stowers Institute for Medical Research

Maternal transcripts are essential in early embryonic development, providing a foundation for zygotic genome activation. They undergo time-dependent degradation and shift the control from maternal to zygotic transcripts (MZT). Our study focuses on the often-overlooked aspect of spatial regulation of maternal RNA degradation, hypothesizing that both spatial and temporal control are essential for the development of complex, multicellular embryo. Exploring the regulation of dynamic spatiotemporal changes in maternal mRNA degradation, stabilization or localization in a cell-specific manner and their impact on early embryonic development, continues to be a subject of intense investigation. To unravel this, we initially identify and selected the spatiotemporal maternal RNAs through a combination of RNA-seq, Slam-seq, and Seurat- digital RNA *in situ* predication tool. We further validated their degradation patterns by RNA *in situ* hybridization assays in zebrafish embryos. To gain deeper insights into their functional importance, we attempted to deplete maternal RNAs by creating maternal-zygotic Cas9 mutants. However, this approach led to embryonic lethality for few candidates, posing a challenge in validate our hypothesis. Subsequently, we turned to CRISPR-Cas13d to specifically deplete these spatio-temporal RNAs, which led to specific spatial context-specific phenotypes during embryonic development. Notably, the F0 CRISPR-Cas9 mutants for corresponding genes confirmed that these phenotypes were independent of any interference from zygotic genes. Overexpression experiments provided additional confirmation of the significance of the observed spatiotemporal RNA gradient, as the developing embryos could not tolerate the presence of extra copies of these RNAs. Additionally, our RNA reporter assays identified specific cis-elements within maternal RNAs responsible for the spatial-temporal RNA degradation during embryogenesis. Our future objective is to investigate the evolutionary functional significance of these spatiotemporal maternal RNAs during development and diseases.

58 **Characterizing a tissue-biased *tp53*-mediated DNA damage response in early zebrafish development** Sean Lee[1], Eric Upton[1], Kathryn Berg[2], Alexander F Schier[2], Jeffrey A Farrell[1] [1]NICHD, NIH, [2]Molecular and Cellular Biology, Harvard University

DNA damage is a normal occurrence during embryogenesis and a proper DNA damage response (DDR) is essential for maintaining genome integrity and healthy development. A standard DDR is characterized by the activation of a network of repair mechanisms, cell cycle checkpoints, and programmed cell death signals. Previous single-cell RNAseq (scRNAseq) data revealed that zebrafish embryos express a modified DDR module hallmarked by the simultaneous transcription of many developmental regulatory genes (e.g., *aplnrb* and *igf2a*) alongside keystone stress response genes (e.g., *tp53*, *cdkn1a*,

and *gadd45aa*). Single whole embryo bulk RNAseq data suggests that the module genetically regulated by *tp53* and temporally restricted to the blastula stage, prior to gastrulation. Reanalysis of the scRNAseq data highlights a tissue bias: module-expressing cells are more prevalent than expected in the non-neural ectoderm and less prevalent in the axial mesoderm. *In situ* hybridization chain reaction (HCR) in wild-type embryos supports this tissue bias. HCR in the Nodal signaling mutant, *MZoep*, and BMP signaling mutant, *swr*, indicates that this bias is linked to dorsal-ventral patterning signals. Together, our results demonstrate stage-specific activation of a non-neural ectoderm-biased DDR module. My future experiments will investigate: 1) whether non-neural ectoderm identity mediates this bias, 2) whether the bias results from differences in the amount of damage or the response to damage across different cell types, and 3) the mechanisms that mediate the decreased module expression in the axial mesoderm. Funding: NIH Intramural ZIAHD008997 to JAF.

59 **A New Mechanism of Dorsal Axial Organizer Repression by Integrator Complex Subunit 6** William D. Jones, Mary C. Mullins Cell and Developmental Biology, University of Pennsylvania Perelman School of Medicine

The vertebrate body axis is established by the dorsal organizer, an embryonic signaling center that promotes dorsal fates. A unique zebrafish loss-of-function mutant from our laboratory, called *ints6*^{p18ahub}, provides new insights into how the organizer is repressed to specify the proper balance of dorsoventral fates. In this maternal-effect mutant, the progeny of homozygous *ints6*^{p18ahub} mutant females (M-*ints6*^{p18ahub} embryos) display an expanded organizer and multiple body axes. The mutated gene, *integrator complex subunit 6* (*ints6*), encodes a subunit of the Integrator complex, which has not previously been implicated in embryonic patterning. Integrator was first discovered as a spliceosomal small nuclear RNA maturation factor, but it can also regulate gene expression via its endonuclease and phosphatase modules. In this project, I aim to uncover the mechanism by which Ints6 represses the organizer. I have found that *ints6*^{p18ahub} is a hypomorphic, temperature-sensitive (ts) allele, and that maternal-effect nonsense alleles of *ints6* cause an earlier mid-blastula arrest phenotype. To test the timing of Ints6 function, I performed temperature-shifts at different stages using the *ints6*^{p18ahub} ts allele. I found that Ints6 first functions to repress the organizer at a mid-blastula stage, shortly after zygotic transcription begins. Next, I tested the spatial function of Ints6, to put Ints6 into the context of other organizer repressors that act either dorsally or ventrolaterally during zebrafish dorsoventral patterning. Using regional expression of wild-type Ints6 in M-*ints6*^{p18ahub} embryos, I found that Ints6 expressed ventrolaterally can rescue development, whereas Ints6 expressed dorsally in the organizer does not. This indicates that Ints6 acts ventrolaterally, not dorsally, to repress the organizer. Finally, I performed RNA-seq in *ints6* maternal mutant and control embryos and found thousands of differentially expressed genes (DEGs). Surprisingly, over 90% of DEGs were upregulated in *ints6* maternal mutant embryos during the mid-blastula period, supporting the hypothesis that Ints6 represses early zygotic expression of many genes. In general, Integrator can repress gene expression by cleaving nascent RNAs with its endonuclease module or by recruiting Protein Phosphatase 2A to dephosphorylate the C-terminal domain of RNA polymerase II. I will report on candidate dorsalizing genes that I am testing as targets of Ints6 repression to restrict the dorsal organizer.

60 **BMP receptor trafficking and specialization in signal transduction during embryonic patterning in the zebrafish** Jeet Patel, Benjamin Tajer, Mary C Mullins Cell and Developmental Biology, University of Pennsylvania

Bone morphogenetic protein (BMP) signaling is a major driver of developmental processes, including bone development, organ system formation, and patterning of the dorsoventral (DV) axis, neural tube, and limbs. The role of BMP signaling in DV patterning is conserved from insects through humans, one interesting feature of which is signaling by a BMP heterodimer. In zebrafish, this Bmp2-Bmp7 heterodimer signals through a heteromeric BMP receptor complex of the Type I receptors Acvr1l and Bmpr1, along with two Type II Acvr2 receptors. The Mullins lab recently showed that, while both Type I receptors are required for embryonic patterning, the kinase of only Acvr1l is active in phosphorylating Smad1/5 in the zebrafish, while Bmpr1a kinase activity is dispensable. While prior paradigms postulated that both Type I receptors activate downstream Smads, the specialized use of a single kinase when two are available has also been observed in mouse granulosa cell culture. The biological basis for specialized receptor kinase functions presents a range of possible mechanisms by which different receptors could be leveraged to regulate signaling in diverse contexts. Using live-imaging approaches, I have found that Acvr1l is trafficked intracellularly via endocytosis, while Bmpr1a is primarily localized to the membrane and rarely trafficked into endosomes. As Acvr1l is the Type I receptor with required kinase activity, its receptor trafficking may facilitate BMP signal transduction. Indeed, Acvr1l and Acvr2 are frequently found in the same endosomes. Trafficking of these receptors together is consistent with a model in which Acvr2 can phosphorylate Acvr1l to activate Smad5 in the gastrula. Overexpression of both Acvr1l and Acvr2 leads to an increase in Acvr1l positive endosomes and embryonic ventralization, which is not seen with either receptor alone. Interestingly, more Acvr1l endosomes are observed with constitutively active Acvr1l, which obligately phosphorylates Smad5 to ventralize the embryo, suggesting a link between receptor trafficking and signal transduction. Using mutants for extracellular BMP regulators, BMP receptors, and Smad5, I will further interrogate the requirements for endocytosis of Acvr1l in signal transduction and embryonic patterning, defining the cell biological mechanisms of BMP signaling regulation in vertebrate development.

61 **Single-cell temporal dynamics reveals the relative contributions of transcription and degradation to cell-type specific gene expression in zebrafish embryos** Lior Fishman[1], Gal Nechooshtan[1], Avani Modak[2], Florian Erhard[3], Aviv Regev[4], Jeffrey Farrell[2], Michal Rabani[1] [1]Hebrew University of Jerusalem, [2]National Institute of Child Health and Human Development, [3]University of Wurzburg, [4]MIT

During embryonic development, pluripotent cells assume specialized identities by adopting particular gene expression profiles. However, systematically dissecting the underlying regulation of mRNA transcription and degradation remains a challenge, especially within whole embryos with diverse cellular identities. Here, we collect temporal cellular transcriptomes of zebrafish embryos, and decompose them into their newly-transcribed (zygotic) and pre-existing (maternal) mRNA components by combining single-cell RNA-Seq and metabolic labeling. We introduce kinetic models capable of quantifying regulatory rates of mRNA transcription and degradation within individual cell types during their specification. These reveal different regulatory rates between thousands of genes, and sometimes between cell types, that shape spatio-temporal expression patterns. Transcription drives most cell-type restricted gene expression. However, selective retention of maternal transcripts helps to define the gene expression profiles of germ cells and enveloping layer cells, two of the earliest specified cell-types. Coordination between transcription and degradation restricts expression of maternal-zygotic genes to specific cell types or times, and allows the emergence of spatio-temporal patterns when overall mRNA levels are held relatively constant. Sequence-based analysis links differences in degradation to specific sequence motifs. Our study reveals mRNA transcription and degradation events that control embryonic gene expression, and provides a quantitative approach to study mRNA regulation during a dynamic spatio-temporal response.

62 **Defining the Molecular and Neural Roles of the Understudied Kinase *vrk2* in Zebrafish** Jaqueline Martinez[1,2], Vaishnavi Balaji[1,2], Claire Conklin[2], Summer Thyme[1,2,3] [1]BMB, UMass Chan Medical School, [2]University of Alabama at Birmingham, [3]Harvard University

Genetic variation adjacent to vaccinia-related kinase 2 (VRK2) is associated with schizophrenia, bipolar disorder, sleep, and major depression. Preliminary work using phospho-Erk brain activity mapping and behavior analysis revealed altered sleep and reduced brain activity, particularly in the rostral hypothalamus that is involved in sleep. We aim to define the molecular, cellular, developmental, and behavioral processes regulated by *VRK2*. Repeating the behavioral experiments confirmed that these loss-of-function mutants had reduced baseline movement rates during the day but similar nighttime activity to control siblings. This behavioral difference was not retained in the presence of constant light or constant dark, indicating a role for light cycling in the phenotype. We hypothesized the cause for the behavioral disturbances in the mutant zebrafish was a lack of phosphorylation of its targets. To discover these targets, we are using an analog-sensitive kinase approach and biotin labeling pull-down experiment to label nearby interacting partners of *vrk2* that could be its substrates. As a first step in the analog-sensitive kinase method, we have generated versions of *vrk2* that have mutations in the gatekeeper residue to accept ATP analogs. Testing these mutated *vrk2* proteins by injection of mRNA in zebrafish embryos and *in vitro* kinase assays indicates that they retain functionality. We will expose adult zebrafish brain lysate to purified mutant kinases to label substrates and identify them with mass spectrometry. RNA-seq analysis of larval zebrafish heads from the loss-of-function line revealed changes to the levels of genes involved in the brain, such as an acetylcholine transporter, indicating that absent Vrk2 target phosphorylation likely has downstream impacts on neuron development or function. By defining the functions of genes such as VRK2 that are associated with an elevated risk of neuropsychiatric disorders, we aim to establish a foundational understanding of their origins, ultimately leading to the development of novel diagnostics and therapies.

63 **Fate switching of melanophores to leucophores requires Agouti and BMP** Dylan Huang, David Parichy UVA

Plasticity in cell fate allows mature cells to alter their identities and functions and has been most often studied in the context of tissue and organ regeneration. Yet emerging single cell and fate mapping technologies suggest such plasticity is more common during development than previously appreciated. Generalizable features of cell fate plasticity and its specific underlying mechanisms are of fundamental biological interest whereas the salient principles and specific genes and pathways involved have obvious therapeutic potential. Pigment cells in the dorsal fin of zebrafish offer a useful paradigm to investigate cell fate plasticity. In this system black, melanin-containing melanophores transdifferentiate to become white, guanine crystal-containing leucophores. Here we show this transition is regulated by signaling and crosstalk involving Agouti/Melanocortin and Bone morphogenetic protein (BMP) pathways. Leucophores develop from melanophores in the dorsal fin tip where Agouti signaling protein 1 (Asip1) serves as an environmental cue that represses differentiation of new melanophores, while Asip2b serves as a complementary factor that promotes the transition of previously differentiated melanophores into leucophores. Asip2b further promotes the competence of these cells to respond to local BMP signals that are themselves required for transdifferentiation. Our analyses indicate that BMP induces expression of *foxd3*, encoding a bifunctional forkhead family transcription factor that upregulates the purine synthesis gene *purine nucleoside phosphorylase 4a*, which is required to produce white guanine crystals. Taken together, our several approaches reveal an unanticipated signaling network that drives

a pigment cell fate transition in zebrafish, new genes involved in pigment cell differentiation, and new functional contexts for genes previously studied in other aspects of pigment cell development.

64 **Post-transcriptional regulation of gene expression in time and space** Howard Lipshitz University of Toronto

Early animal embryos represent an ideal system in which to study post-transcriptional regulation of gene expression because their genomes are transcriptionally silent and developmental processes are controlled by maternally provided RNAs and proteins. During a process known as the maternal-to-zygotic transition (MZT) a subset of maternal products is eliminated, permitting transcriptional activation of the zygotic genome. RNA-binding proteins (RBPs) play an essential role in post-transcriptional regulation during the MZT. Notably, the Drosophila Smaug RBP is required for repression and degradation of maternal transcripts during the MZT, working together with its partners: Cup, Trailer hitch (TRAL) and ME31B for translational repression; the CCR4-NOT deadenylase complex for transcript degradation. The timing of expression of Smaug and its partners is precisely regulated post-transcriptionally and post-translationally. At the beginning of the MZT, the Pan gu kinase triggers translation of the maternally provided *smaug* mRNA, leading to rapid accumulation of Smaug protein. Subsequently, two E3 ubiquitin ligase complexes – CTLH and SCF – trigger the sequential clearance from the bulk cytoplasm of Cup-TRAL-ME31B and of Smaug, respectively. SCF function and, thus, Smaug degradation, is timed by zygotic synthesis of a novel F-Box protein, Bard. Deletion of the C-terminal region of Smaug abrogates interaction with and clearance by SCF, resulting in persistence of Smaug beyond the end of the MZT and consequent downregulation of zygotically synthesized mRNAs that carry Smaug-binding sites. In contrast to its clearance from the bulk cytoplasm, Smaug protein is transported into and persists in the germ plasm, where it binds to and represses translation of several mRNAs, including *oskar* and *Bruno 1*. Mutation of either Smaug or cis-acting Smaug-binding sites in these targets results in synthesis of excess germ plasm and budding of supernumerary primordial germ cells from the posterior pole of embryos. Temporal and spatial regulation of Smaug expression and function exemplify the crucial role that post-transcriptional processes play during early embryogenesis.

65 **Examining the molecular mechanisms of fat-to-ovary communication in *Drosophila melanogaster*** Alissa R. Armstrong, Tancia R Bradshaw University of South Carolina

Organismal nutritional status influences reproductive output by impacting gamete production. The energy-intensive process of oogenesis requires coordinated nutritional responses between multiple organs, yet not enough is known about how inter-organ communication modulates tissue responses to dynamic nutritional input. In *Drosophila melanogaster* females, the stem cell-supported ovary sustains robust reproductive capacity and is sensitive to dietary changes. Female flies fed suboptimal diets, e.g. protein poor, high sugar, or high fat, display significantly reduced egg production rates. This response to diet is mediated by highly conserved nutrient-sensing pathways that function tissue autonomously, within the ovary, as well as non-autonomously, within the adipose tissue. We leverage the power of *Drosophila* genetics to uncover the cellular and molecular mechanisms that underlie fat-to-ovary communication about diet. We have shown that amino acid sensing, via the amino acid response (AAR) pathway and mTOR, and insulin/insulin-like growth factor signaling (IIS) within adipocytes controls multiple steps of oogenesis, including germline stem cell maintenance, germline survival, and ovulation, in a complex manner. We find that the AAR pathway suppresses translation of unknown adipocyte factors that promote germline stem cell maintenance while mTOR supports translation of unknown adipocyte factors that promote ovulation. In addition to our previous work showing that distinct signaling axes downstream of insulin receptor/PI3 kinase activity control different aspects of oogenesis, we have uncovered a role for activity of the Ras/MAPK signaling axis in mediating fat-to-ovary communication. Our data suggests the Ras/MAPK signaling in adipocytes controls germline cyst survival and ovulation. Ultimately, we aim to identify adipocyte factors downstream of IIS, AAR pathway, and mTOR that modulate *Drosophila* oocyte development. This work will illuminate how inter-organ communication coordinates organismal nutritional status with oocyte production.

66 **Building Tissue Specific Centrosomes** Nasser Rusan NHLBI, NIH

The Rusan lab has a longstanding interest in the mitotic spindle and the centrosome. The biology of these two microtubule-based molecular machines is highly intertwined, as centrosomes nucleate and organize the microtubules required for spindle assembly in most animal cells. To study these machines, we employ a wide range of techniques, including genetics, micro-computed tomography (uCT) scanning, yeast 2-hybrid screening, super-resolution microscopy, and live-cell imaging. Most importantly, we utilize the model organism *Drosophila* in combination with a powerful method of generating novel separation-of-function alleles. Our work has revealed fascinating tissue-specific centrosome functions in the contexts of asymmetric cell division, brain development, early embryo development, and spermatogenesis. Understanding this functional diversity of centrosomes has provided insight into centrosome dysregulation, which has been linked to many human diseases such as microcephaly and infertility. I look forward to sharing my lab's exciting research journey and highlighting our most recent work on the role of centrosomes in establishing proper sperm head-tail linkage.

67 **Centromere Polymorphisms in *Drosophila melanogaster*** Miraz A Sadi[1], Lucas Hemmer[2], Cécile Courret[1], Amanda M

Larracuente[1] [1]Department of Biology, University of Rochester, [2]University of Rochester

Centromeres are chromosomal regions where kinetochores assemble and spindle fibers attach to coordinate chromosome segregation during cell division. Despite their essential role, centromeres evolve rapidly across species. Although they are typically buried in highly repetitive genome regions, the role of DNA sequences in centromere function and specification is unclear, as they are epigenetically defined by the presence of the histone H3 variant CENP-A. To better understand the role of centromere-associated sequences in centromere function and evolution, we study centromere evolutionary dynamics within *Drosophila melanogaster* and examine the relationship between structural variation at the DNA level and functional variation in centromeric chromatin. We have recently shown that in *D. melanogaster* centromeres correspond to islands of retroelements flanked by simple satellite tandemly repeats. To ask if the centromere islands are conserved within *D. melanogaster*, we tested 5 strains with different geographical origins and compared them to the reference strain Iso1. We used long and short-read genomic DNA sequencing to determine the structural organization and CUT&Tag to identify CENP-A-enriched DNA in each strain. We identified the reference centromere islands, compared their organization and composition amongst the strains, and validated our observations with Fluorescence *In Situ* Hybridization (FISH) on mitotic chromosomes from larval brains using oligopaints specific to each centromere island. Our analyses reveal that both the dot and the X chromosome centromeres are polymorphic between strains and in each case, the reference centromere islands are absent from the genome. Thus here we discover structural DNA variation that is associated with a shift in centromeric chromatin, suggesting that the organization of the reference centromere islands is not essential for centromere function. However, centromeres may still have conserved features even when their organization is variable, as we find that CENP-A enriched sequences are similar across strains, including those with polymorphic centromeres. Altogether, our study highlights that the DNA sequences underlying centromeres are plastic and can be highly dynamic within species.

68 **Balanced inversions help maintain sexually antagonistic polymorphism** Christopher S McAllester, John E Pool Laboratory of Genetics, UW Madsion

Inversion polymorphisms are well documented across many taxa, despite the potential generation of unfit, unbalanced gametes from inversion heterozygotes. Inversions may fix because of linkage with beneficial alleles or due to drift, but many inversions are maintained at intermediate, in some cases clearly balanced frequencies, potentially by linking alleles that share conditional benefit. In African *Drosophila melanogaster*, paracentric inversions are common and many inversions are stably polymorphic throughout diverse African lowland habitats, suggesting the involvement of evolutionary forces beyond local adaptation. We hypothesize that balanced sexually antagonistic selection may be responsible for maintaining the stable polymorphism, in line with the active competition among *D. melanogaster* males and the potential for sexual antagonism. We used a novel forward population simulator with parameters based on *D. melanogaster* life history to model inversion evolution in a population under sexually antagonistic selection at infinite loci and with male reproductive skew. Simulations demonstrated (1) balanced polymorphism involving alleles with a range of antagonistic effects, (2) the persistence of such polymorphic alleles at many loci only under linkage due to competitive effects, and (3) the rise in frequency and stable persistence of inversions that establish such linkage associations between sets of sexually antagonistic alleles. In highly antagonistic simulations, some inversion arrangements are only in parents of one sex. We followed with an empirical exploration of the selection dynamics on inversions between a pooled Zambian paternal population and their embryo and aged adult offspring to detect correlations between the inversion status, viability and mating fitness. Results demonstrated non-neutral frequency changes, consistent with a complex fitness landscape in which only Inversion 3RK demonstrated a consistent tradeoff between male reproductive success and viability-longevity under the conditions and frequencies tested. This establishes the potential presence of this modeled dynamic in *D. melanogaster* inversions. This model has implications for sex chromosome evolution, as a segregating autosomal antagonistic inversion would likely have accumulated significant antagonistic character and benefit from linkage to a sex determining locus. Further, balancing selection upon epistatic haplotypes, particularly due to sexual or ecological antagonistic selection, may contribute significantly to genetic diversity and ongoing evolution and local adaptation in natural populations.

69 **The functional consequences of chromosomal inversions in local adaptation to high altitude in deer mice** Kelsie E Hunnicutt[1], Keely R Corder[2], Zachary A Cheviron[2], Jonathan P Velotta[3] [1]Department of Biological Sciences, University of Denver, [2]University of Montana, [3]University of Denver

Local adaptation is critical for species that occupy diverse and physiologically challenging habitats, but migration with non-adapted populations can challenge the establishment and maintenance of locally adapted alleles. Chromosomal inversions can facilitate adaptation by reducing gene flow of locally adapted regions of the genome. Deer mice (*Peromyscus maniculatus*) are a broadly distributed species with the largest altitudinal range of any North American mammal. High-altitude populations of deer mice face intense dual local selective pressures of extreme cold and low-oxygen availability which favors the evolution of system-wide physiological adaptations. However, local adaptation to high altitude in deer mice is challenged by ongoing

gene flow. We use two approaches to investigate how chromosomal inversions have contributed to local adaptation to high altitude in deer mice. First, we use a combination of whole genome and exome sequencing to characterize chromosomal inversions segregating in deer mice across an altitudinal cline ranging from ~400m (Lincoln, NE) to over 4000m (Mt. Evans, CO). Several inversions have been previously documented across North American deer mouse populations, but we find evidence of novel inversions unique to our altitudinal transect. We calculate cline centers and widths of segregating inversions and compare with clines of genes putatively under positive selection and neutral regions. We use four high-altitude populations (>3500m) to investigate parallel evolution of inversion genotypes and estimate population differentiation and the rate of molecular evolution in inverted and non-inverted regions. Second, we investigate the functional consequences of inversions by correlating gene expression variation with inversion genotype. We use RNASeq data from contrasts of highland and lowland deer mice facing hypoxic challenges across 9 tissues from 10 studies to investigate how inversions have shaped gene expression underlying diverse physiological processes including metabolism, thermogenesis, cardiovascular and pulmonary function, and reproduction. We establish which inversions repeatedly contribute to differential expression between highland and lowland deer mice across tissues and which genes are repeatedly involved across diverse physiological processes. Understanding the functional consequences of inversions will provide insight into the mechanisms of local adaptation and the ways in which structural genomic variation can hinder or promote these processes.

70 **Sex chromosome formation, expansion and turnover in the genus Rumex** Stephen Wright[1], Cassandre Pyne[2], Bianca Sacchi[2], Meng Yuan[2], Mark Hibbins[2], Jana Kružlicová[3], Markéta Bodláková[4], Václav Bačovský[4], Tyler Kent[5], Baharul Choudhury[2], Spencer Barrett[2] [1]Ecology and Evolutionary Biology, Univ Toronto, [2]University of Toronto, [3]Institute of Biophysics Czech Academy of Sciences, [4]Institute of Biophysics of the Czech Academy of Sciences, [5]university of Toronto

What evolutionary forces drive the expansion and turnover of sex chromosomes and what are the consequences? Here we investigate this question using a combination of comparative and population genomics in the genus Rumex, a plant system with highly heteromorphic and dynamic sex chromosomes. Genome assemblies of members of both dioecious and hermaphroditic species in the genus reveals very high rates of chromosomal rearrangements genome-wide, which has contributed to a complex and recurrent buildup of massive sex-linked regions in species with sex chromosomes, coupled with extensive gene silencing and loss over short timescales. Analysis of neo sex-linked regions suggest that transposable element invasion occurs early following sex- linkage, raising the possibility of their early contribution to gene silencing and inactivation. Population genomic analysis of the youngest sex-linked region in the genus provides evidence for a role for selective sweeps due to local adaptation in driving the spread of neo-sex chromosomes and the expansion of sex-linked regions.

71 **Enrichment of hard sweeps on the X chromosome across six *Drosophila* species** Mariana Harris[1], Bernard Kim[2], Nandita Garud[3] [1]Computational Medicine, University of California, Los Angeles, [2]Stanford University, [3]University of California, Los Angeles

The X chromosome is hemizygous in males, leaving it fully exposed one third of the time to the effects of natural selection and, thus, potentially subject to different evolutionary dynamics than autosomes. This is of particular interest given the potential importance of sex chromosomes in local adaptation, speciation, and sexual dimorphism. Here, we investigate the differences in the mode and tempo of adaptation on the X chromosome versus autosomes in multiple species of *Drosophila*. Specifically, we test the hypothesis that hard sweeps, expected when adaptation is gradual, are more common on the X chromosome due to there being a smaller effective population size and a reduction in standing genetic variation resulting from more efficient selection. By contrast, we predict that soft sweeps, expected when adaptation is rapid, are more common on the autosomes. In our recently published work, we find an enrichment of hard sweeps on the X chromosome relative to the autosomes in a North American population of *D. melanogaster*, confirming predictions we make from simulations. Now, we generalize these findings by analyzing diversity patterns across six *Drosophila* species, where we find regions with steep reductions in diversity and elevated haplotype homozygosity on the X chromosome as compared to autosomes. To assess if these signatures are consistent with positive selection, we simulate a wide variety of evolutionary scenarios, spanning variations in demography, mutation rate, recombination rate, background selection, soft sweeps, and hard sweeps, and find that the diversity patterns observed on the X are most consistent with a hard sweep model. Our results suggest that hard sweeps have played a significant role in shaping diversity patterns on the X chromosome across multiple species of *Drosophila*.

72 **Quantitative genetics of sex chromosome evolution** Pavitra Muralidhar University of Chicago

In organisms with separate sexes, the predominant mechanism of sex determination is the segregation of a designated pair of chromosomes at meiosis. While evolutionary transitions among sex chromosome systems have occurred frequently in certain taxa, in others, such as birds and mammals, the sex chromosome system displays long-term evolutionary stability. Many explanations have been proposed for this stasis, invoking, for example, accumulation on the sex-specific chromosome (Y/W) of recessive deleterious mutations or sexually antagonistic alleles. Here, I show that the ordinary operation of natural selection

on quantitative traits alone can strongly promote stability of the prevailing sex chromosome system.

Under stabilizing selection, the genome-wide genetic contribution to a quantitative trait – the 'additive genetic value' – remains close to the optimal trait value in each sex. However, the additive genetic values of individual chromosomes within the genome can drift over time, constrained only in that their sum must equal the optimal value. Therefore, over time, individual chromosomes can come to vary substantially in their average genetic values, in a delicate balancing act where chromosomes that happen to have drifted to high genetic values are complemented by chromosomes that have drifted to low genetic values.

A transition from one sex chromosome system to another necessarily involves the creation of novel sexual genotypes, potentially disrupting this genome-wide balancing act across chromosomes. I show that, under reasonable assumptions about the strength of selection and the genetic correlation between the sexes, novel sexual genotypes will deviate systematically from optimal phenotypic values and therefore suffer substantial fitness costs. These fitness costs impede—and with enough time prevent—the invasion of new sex-determining mechanisms.

The theory described above relies only on the presence of stabilizing selection on quantitative traits. As I show, the fitness costs to novel sexual genotypes—and therefore the barrier to transitions in the mechanism of sex determination—are exacerbated by (i) shifts in optimal phenotypic values, especially if these shifts are sexually antagonistic, and (ii) the simultaneous operation of stabilizing selection on multiple phenotypes. Finally, the 'chromosome-level' mechanism proposed here has implications for when Haldane's rule will most strongly manifest in hybrids between diverged species and populations.

73 **Patterns of genomic ancestry in the house mouse hybrid zone** Megan Frayer[1,2], Leslie Turner[3], Bettina Harr[4], Peicheng Jing[2], Bret Payseur[2] [1]Yale University, [2]University of Wisconsin-Madison, [3]University of Bath, [4]Max-Planck-Institut fuer Evolutionsbiologie

The history of hybridization is recorded in the ancestries of hybrid genomes. Natural selection and demography determine how the genomes of divergent lineages mix, shaping the genomic distributions of ancestries. Recombination in hybrids creates transition points between ancestries along chromosomes called junctions. Although junction patterns are known to be sensitive indicators of demography and selection, these patterns have yet to be characterized in a genome-wide manner in active hybrid zones. We used genome sequencing and probabilistic methods to reconstruct ancestry junctions across the genomes of house mice sampled from two populations from the European hybrid zone between *Mus musculus domesticus* and *M. m. musculus*. We report the identification of hundreds of thousands of junctions (an individual average of 10 junctions per Megabase) and describe junction sharing across individuals and populations using a novel metric, the junction frequency spectrum. Despite being separated by only 7.4 km in the center of the hybrid zone, the two populations display stark differences in genome-wide junction distributions, suggesting a crucial role for demographic processes. We pinpoint regions of the genome that show unusual junction patterns indicative of selection against hybrid incompatibility loci that could underlie reproductive barriers between *M. m. domesticus* and *M. m. musculus*. Our results suggest that the genome-wide distribution of junctions is a promising target for inference of selection and demography in hybrid zones.

74 **Evolutionary origin of the recent allotetraploid *Mimulus sookensis*** Makenzie Whitener, Andrea Sweigart University of Georgia

Polyploidy occurs across the tree of life and is especially common in plants. Because newly formed cytotypes are often incompatible with their progenitors, polyploidy is also said to trigger "instantaneous" speciation. If a polyploid can self-fertilize or reproduce asexually, it is even possible for one individual to produce an entirely new lineage. How often this extreme scenario occurs is unclear, with most studies of wild polyploids reporting multiple origins. Here, we explore the evolutionary origin of the wild allotetraploid *Mimulus sookensis,* which was formed through hybridization between self-compatible, diploid species in the *Mimulus guttatus* complex. We generate a chromosome-scale reference assembly for *M. sookensis* and define its distinct subgenomes. Despite previous reports suggesting multiple origins of this highly selfing polyploid, we discover patterns of population genomic variation that provide unambiguous support for a single origin, which we estimate occurred ~71,000 years ago. One *M. sookensis* subgenome is clearly derived from the selfer *M. nasutus*, which, based on organellar variation, also appears to be the maternal progenitor. The ancestor of the other subgenome is less certain, but it shares variation with both *M. decorus* and *M. guttatus*, two outcrossing diploids that overlap broadly with *M. sookensis*. This study establishes *M. sookensis* as an example of instantaneous speciation, likely facilitated by the polyploid's predisposition to self-fertilize. We also perform RNAseq on newly synthesized and wild *M. sookensis* to investigate the initial and longer-term regulatory effects of whole genome duplication.

75 **Drying Without Dying: Small Metabolites Counteract Proteotoxicity During Desiccation** Alejandra Arroyo, Sheila Ferer, Gabbriella Amador, Jailene Martinez, Alina Vane, Hugo Tapia CSUCI

Most biological processes require water to function, so desiccation can be distressing for many living organisms. Desiccation tolerant organisms, commonly termed anhydrobiotes, can lose significant amounts of water and still function normally once rehydrated. The exact stress(es) that cause lethality in desiccation sensitive organisms and how the lethal stresses are mitigated in desiccation tolerant organisms are poorly understood. We establish that trehalose cooperates with stress-induced glycerol and glycogen in the establishment of desiccation tolerance, its prolonged maintenance, and susceptibility to secondary stresses of heat and cold. We provide evidence that desiccation induces protein misfolding of a luciferase reporter and protein aggregation as evidenced by its ability to cure prions through the hyper-aggregation of prion seeds. Trehalose mitigates excessive protein aggregation but not protein misfolding during desiccation. We suggest that protein aggregation is a persistent stress during desiccation that is mitigated by trehalose.

76 **Impact of α-arrestins on organelle function and cellular metabolism** Elif Filiztekin[1], Annette Chiang[1], Nejla Ozbaki-Yagan[1], Stacy Gelhaus Wendell[1], Florian Fröhlich[2], Allyson F O'Donnell[1] [1]Department of Biological Sciences, University of Pittsburgh, [2]Department of Biology, Osnabrück University

To survive changes in nutrient availability or stressors, cells rearrange their membrane proteome by stimulating vesicle-mediated protein trafficking. The α-arrestins are master regulators of protein trafficking, helping to selectively relocalize membrane proteins. The best-studied class of membrane protein regulated by the α-arrestins are the amino acid transporters (AATs), which allow uptake of amino acids from the extracellular environment. The loss of α-arrestins causes aberrant retention of amino acid transporters at the plasma membrane, which may lead to excess amino acid accumulation in the cell.

Using metabolomics approaches, we find that intracellular concentrations of select amino acids are increased in cells lacking α-arrestins. For instance, we find that cells lacking α-arrestin Art1, a known regulator of the arginine and lysine transporters Can1 and Lyp1, respectively, have elevated intracellular arginine and lysine. What are the consequences of excess amino acids on cellular physiology? Cells lacking Art1 have fragmented mitochondria with reduced membrane potential and defective cellular respiration, as evidenced by their inability to grow on glycerol. We show that these defects can be restored by negating the cells' ability to take up arginine and lysine, either by growing them in the absence of exogenous arginine and lysine or by deletion of the Can1 and Lyp1 transporters. This defective mitochondrial function is linked to impaired vacuole function and morphology. The vacuole proteome and lipid composition are dysregulated in cells lacking α-arrestin Art1, and this contributes to defective mitochondrial function and amino acid imbalances. Our research demonstrates an exciting new link between the maintenance of amino acid homeostasis and regulation of polyphosphate metabolism. Over 80% of cellular arginine is stored in vacuoles, and to increase arginine storage in this organelle, cells lacking Art1 upregulate polyphosphate synthesis. Early studies of polyphosphate demonstrated that it serves as a counter ion in the vacuole, enabling increased storage of the cationic arginine. These dramatic shifts in cellular physiology when α-arrestin Art1 is lost help define the interconnection between cellular metabolism and organelle function.

77 **Glyphosate as an amino acid mimic and the role of human glutamate transporters in glyphosate import** Dionysios Patriarcheas, Jennifer E Gallagher West Virginia University

Glyphosate is the globally predominant herbicide found in RoundUp® and understanding its cellular mechanisms of action is crucial. As an inhibitor of the **shikimate** pathway, glyphosate blocks the biosynthesis of aromatic amino acids and is thus perceived as harmless to humans, who rely on their diet for their intake. Surprisingly, studies have reported various **toxic effects** in animals caused by exposure to high concentrations of glyphosate, including neurotoxicity, reproductive toxicity, and gut microbiome disruption. However, the **mechanism** through which glyphosate is **transported** has yet to be definitively demonstrated. In *S. cerevisiae* glyphosate acts as an amino acid **mimic** and can utilize **Dip5**, a glutamate/aspartate permease, to enter the cells. Knocking out *dip5* confers resistance to glyphosate. Our findings reveal that knocking out *agc1/ymc1*, two **mitochondrial** glutamate **transporters**, appears to significantly increase resistance to glyphosate, which could hint at mitochondrial off-target effects. Previous work from our group has highlighted the central role of mitochondrial metabolism in response to glyphosate. To identify the human transporter responsible for glyphosate transport, we further heterologously express **human glutamate transporters** in *DIP5* and *AGC1/YMC1* knockout yeast and assess their resistance to glyphosate. Human transporters that can transport glyphosate will cause mutant yeast expressing this transporter to be glyphosate-sensitive. Understanding which transporter is responsible for glyphosate import will guide our understanding in identifying the type of tissue that is affected the most through the expression patterns of the transporter. In order to verify that Dip5 and other glutamate transporters are responsible for the cellular import of glyphosate **metabolite** extracts of wild-type and *dip5Δ* will be analyzed through **mass spectrometry**. We predict that the glyphosate-resistant *dip5* mutants will have lower intracellular levels of glyphosate compared to wildtype cells supplemented with aromatic amino acids. Wild-type cells supplemented with aromatic amino acids are able to grow because they bypass the shikimate pathway despite having intracellular glyphosate. Our aim is to lay the foundation for understanding **glyphosate toxicity** in humans by elucidating glutamate transporter roles in resistance and toxicity.

78 **Single-cell RNA sequencing data reveal new energetic constraints on making a (microbial) cell** Leandra Brettner[1], Rachel Eder[2], Kerry Geiler-Samerotte[2] [1]Biodesign Center for Mechanisms of Evolution, Arizona State University, [2]Arizona State University

Previous work has established that the number of ribosomes in a cell represents the primary constraint on how fast cells can grow and divide. This constraint, called a "growth law" is apparent across the tree of life. It is obvious why the number of ribosomes sets a lower limit on how fast cells can make more cells: ribosomes are required to make all the cellular components. But there may exist other constraints that prevent cells from reaching their growth potential even when enough ribosomes are present. These additional constraints may have been missed by previous work because that work largely focuses on cells growing in steady nutrient levels in chemostats. These experiments may miss growth-limiting parameters that dictate the limits of cellular evolution because natural populations of cells are prone to experience feast and famine scenarios. Here, we explore the extent to which ribosome content predicts growth rate in conditions where microbial cells are slowly consuming all available nutrients. It is well known that microbial cell populations "bet hedge" to contend with famine, whereby different cells deploy different strategies in response to nutrient depletion. Therefore, we use a single cell approach to measure ribosomal content. Though we confirm that the growth law holds true for populations of cells that are depleting their nutrients, we find that ribosomal content alone is a poor predictor of the growth rate of single cells. We observe enormous variance in the ribosomal content from cell to cell, and opposite expectations, this variance decreases with decreasing nutrient availability. By analyzing the full transcriptional profiles of cells with different ribosomal content and different growth rates, we begin to reveal additional constraints on making a cell, for example, the degree to which resources are divested towards stress responses. This study, and the novel biology we learned, were made possible because we utilized a new single-cell RNA seq approach that allows sampling the transcriptomes of thousands of microbial cells. We applied this approach to cells of two different microbes, the eukaryotic yeast, S. cerevisiae, and the prokaryote, B. subtilis, both of which appear to grow at rates dictated by constraints in addition to ribosome number.

79 **Divergence of TORC1-mediated stress response leads to novel acquired stress resistance in a pathogenic yeast** Jinye Liang, Hanxi Tang, Lindsey Snyder, Bin He, christopher youngstrom Biology Department, the University of Iowa

Acquired stress resistance (ASR) enables organisms to prepare for environmental changes that occur after an initial stressor. However, the genetic basis for ASR and how the underlying network evolved remain poorly understood. In this study, we discovered that a short phosphate starvation induces oxidative stress response (OSR) genes in the pathogenic yeast *C. glabrata* and protects it against a severe H_2O_2 stress; the same treatment, however, provides little benefit in the low pathogenic-potential relative, *S. cerevisiae*. This ASR involves the same transcription factors (TFs) as the OSR, but with different combinatorial logics. We show that Target-of-Rapamycin Complex 1 (TORC1) is differentially inhibited by phosphate starvation in the two species and contributes to the ASR via its proximal effector, Sch9. Therefore, evolution of the phosphate starvation-induced ASR involves the rewiring of TORC1's response to phosphate limitation and the repurposing of TF-target gene networks for the OSR using new regulatory logics.

80 **Elucidating a Novel Role for Septins During High Temperature Stress Response in *Cryptococcus neoformans*** Stephani Martinez[1], Lukasz Kozubowski[2] [1]Clemson University, [2]Genetics and Biochemistry, Clemson University

The pathogenic yeast *Cryptococcus neoformans* adapts to changes in temperature upon entering human host. *C. neoformans* strains lacking septin proteins Cdc3 or Cdc12 are viable at 25°C but fail to proliferate at 37°C and are likely avirulent. Septins are conserved filament-forming GTP-ases that assemble as higher order complexes at the cell cortex to support cytokinesis and morphogenesis in fungal and animal cells. In *C. neoformans*, four septin homologues, Cdc3, Cdc10, Cdc11 and Cdc12 assemble at the mother-bud neck and contribute to cytokinesis via poorly characterized mechanism. We observed that septin complex also assembles at the plasma membrane specifically when cells are exposed to 37°C and hypothesize that septins play stress-related functions in *C. neoformans*. The *C. neoformans* septin interactome remains unknown. In this study, tandem-mass spectrometry was utilized to identify proteins that associate with septins Cdc3 and Cdc10 in *C. neoformans at either 25 or 37°C. Cdc3 was used as a bait since it's an integral part of the septin complex. Cdc10 is presumably dispensable for septin complex formation and served as "bait" to identify proteins that interact specifically with Cdc10. 196 and 40 proteins, including the remaining 3 septins, were identified based on Cdc3 pull down, at 25 and* 37°C, respectively. In contrast, the total number of Cdc10 binding partners was 112 and 46 at 25 & 37°C, respectively. The Cdc10 interactome also included the entire septin complex at both 25 & 37°C. Furthermore, 14 proteins including the entire septin complex were found as interacting with both Cdc3 and Cdc10 at both 25 & 37°C. Therefore, those 14 proteins might represent the core proteins of the septin complex interactome that is independent of thermal stress for binding. In addition, 9 proteins were identified as binding partners of both Cdc3 & Cdc10 exclusively at 37°C. Those proteins specific to heat stress are involved in GDP-GTP exchange, mRNA processing, microtubule binding, and plasma membrane transport. The association of both septins with a plasma membrane transporter (CNAG_00730) provides an insight into the role of septins during heat

stress. CNAG_00730 is the homologue of 8 ABC transporters in *S. cerevisiae*'s, which are involved in drug resistance, cellular detoxification, general stress response, and sterol uptake when sterol biosynthesis is compromised. Thus, those 9 candidate proteins may represent septin interactome that reflects adaptation of *C. neoformans* to host temperature.

81 **A few essential genetic loci distinguish Penstemon species with flowers adapted to pollination by bees or hummingbirds** Carolyn Wessinger[1], John Kelly[2], Lena Hileman[2] [1]Biological Sciences, University of South Carolina, [2]EEB, University of Kansas

In the formation of species, adaptation by natural selection generates distinct combinations of traits that function well together. The maintenance of adaptive trait combinations in the face of gene flow depends on the strength and nature of selection acting on the underlying genetic loci. Floral pollination syndromes exemplify the evolution of trait combinations adaptive for particular pollinators. The North American wildflower genus Penstemon displays remarkable floral syndrome convergence, with at least 20 separate lineages that have evolved from ancestral bee pollination syndrome (wide blue-purple flowers that present a landing platform for bees and small amounts of nectar) to hummingbird pollination syndrome (bright red narrowly tubular flowers offering copious nectar). Related taxa that differ in floral syndrome offer an attractive opportunity to examine the genomic basis of complex trait divergence. In this study, we characterized genomic divergence among populations of a Penstemon species complex that includes both bee and hummingbird floral syndromes. Field plants are easily classified into species based on phenotypic differences and hybrids displaying intermediate floral syndromes are rare. Despite unambiguous phenotypic differences, genome-wide differentiation between species is minimal. Hummingbird-adapted populations are more genetically similar to nearby bee-adapted populations than to geographically distant hummingbird-adapted populations, in terms of genome-wide dXY. However, a small number of genetic loci are strongly differentiated between species. These "species-diagnostic loci," which appear to have nearly fixed differences between pollination syndromes, are sprinkled throughout the genome in high recombination regions. Several map closely to previously established floral trait quantitative trait loci (QTLs). The striking difference between the diagnostic loci and the genome as whole suggests strong selection to maintain distinct combinations of traits, but with sufficient gene flow to homogenize the genomic background. A surprisingly small number of alleles confer phenotypic differences that form the basis of species identity in this species complex.

82 **Integrating comparative and quantitative genetics to accelerate breeding efforts** John Lovell Genome Sequencing Center, HudsonAlpha Institute for Biotechnology

A single haploid reference genome provides breeders with the resources to connect alleles to traits — a significant step towards accelerating crop improvement through biotechnology. However, breeding programs often leverage highly diverged germplasm, which contain large-scale variants that are not readily identified by a single reference genome but may underlie heritable variation in key traits. To assist breeding and gene discovery efforts, we have built multiple reference genomes in many species across the diversity of plants. In concert with these resources, we developed a comparative genomics pipeline "GENESPACE" to connect and explore putatively functional variants that may affect agricultural productivity. Here, we present some of these variants and describe how comparative and quantitative genomics can be integrated to accelerate breeding efforts in maize, switchgrass, pecan, and sorghum.

83 **The post-domestication history of rice: insights from herbarium genomes and ancestral recombination graphs** Ornob Alam[1], Michael Purugganan[2] [1]Biology, New York University (on leave from Independent University, Bangladesh), [2]Biology, New York University

The dispersal of rice (Oryza sativa) following domestication influenced massive social and cultural changes across South, East, and Southeast (SE) Asia. While recent resequencing of traditional rice landraces from across Asia have revealed possible routes of dispersal across Southeast Asia, the early history and spread of rice across and out of China remain largely unresolved. This is mainly because of sparse sampling of traditional landraces of japonica rice — the ancestral rice domesticate — from China as these have largely been replaced by modern improved or hybrid varieties and indica rice. We addressed this dearth of sampling by collecting historical specimens of domesticated rice from herbaria in France, the UK, and the US, originally sampled from China and other parts of Asia by botanists in the 19th and early 20th century. Here, we performed whole-genome resequencing of 96 herbarium rice specimens and analyzed them alongside a previously published set of 367 japonica rice landraces. We used ancestral recombination graph-based approaches to reconstruct the demography and routes of dispersal of japonica rice following domestication in China. We also utilized the ancestral recombination graphs to investigate the evolutionary history of adaptive and functional variants — including those involved in flowering time, immunity, and taste— in populations of japonica rice, revealing widespread local adaptation as rice spread to different regions, climates, and latitudes.

84 **The Loaded Potato Genome** Sapphire Coronejo[1], Xiaoxi Meng[2], Paul Bethke[3], David Douches[4], Joshua Parsons[5], Vidyasagar Sathuvalli[6], Ek Han Tan[7], Jeffrey B Endelman[8], C. Robin Buell[9], Laura M Shannon[1] [1]University of Minnesota, [2]St.

Jude's Children's Research Hospital, [3]USDA-ARS, [4]Michigan State University, [5]Pepsi Co, [6]Oregon State University, [7]University of Maine, [8]University of Wisconsin, [9]University of Georgia

Potato is essential to cultures and cuisines around the world. However, potato is less well understood than other staples in part due to its highly heterozygous autotetraploid genome. The first eight phased autotetraploid potato genomes were sequenced in 2022. Although these genomes were informative they mostly allowed us to draw conclusions about individual potato varieties, rather than US cultivated potato as a population. Prickle pollination of 4X mothers with a diploid inducer allows us to generate diploid potato plants with two chromosomes from the 4X parent. These individuals give us the opportunity to sequence tetraploid haplotypes using technology for diploids. Through prickle pollination we have generated a panel of 100 diploid potatoes arising from 60 tetraploid mothers and sequenced them to ~20X using Illumina short reads. Although there is some structure arising from differences in market classes, in general population structure is minimal. While observed heterozygosity is slightly higher than nucleotide diversity suggesting some balancing selection in particular on chromosomes 6 and 10, overall population level diversity is high. Among these 100 phased genomes 12 coding sequences are fixed while 34 have 200 alleles. The average number of alleles per loci is 27.86. This suggests, the primary driver of heterozygosity in potato is population level diversity rather than balancing selection. Multiple factors contribute to potato diversity including the relaxation of selection on individual alleles in tetraploids leading to a surplus of deleterious alleles, extensive introgression from 20+ wild species, and transposons. Understanding these various contributors to the potato genome provides insight into cultivated potato evolution and directions for potato improvement as the crop is reinvented as a diploid.

85 **The Barley Cytonuclear Multi-Parent Population (CMPP) as a Novel Resource for Dissecting Cytonuclear Interactions** Schewach Bodenheimer[1,2], Eyal Bdolach[3], Lalit Tiwari[1], Tapish Pawar[4], Joseph Tilstra[5], Gazala Ameen[4], Eyal Fridman[1] [1]The Institute of Plant Sciences, Volcani Agricultural Research Organization (ARO), [2]The Robert H. Smith Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, [3]THe Institute of Plant Sciences, Volcani Agricultural Research Organization (ARO), [4]Department of Agronomy, Horticulture, & Plant Science, South Dakota State University, [5]South Dakota State University

Wild crop relatives possess a wealth of genetic diversity essential for crop improvement, but harnessing this diversity is hampered by the complex genetics of key traits. Cytonuclear interactions (CNIs) between cytoplasmic and nuclear genomic loci may play a critical role in this complexity, but the study of their additive and interactive effects is limited by current population infrastructures and computational tools. We address this challenge by developing the first plant cytonuclear multi-parent population (CMPP) in barley to serve as a unique resource for dissecting CNIs. The CMPP comprises 968 homozygous doubled haploid lines derived from F1 directional hybrids between 10 wild (*Hordeum vulgare ssp. spontaneum*) accessions and a common cultivar (cv. Noga). The ten wild donors represent adaptation to the diverse ecogeography of the southern Levant, a hotspot of allelic diversity. The design of the CMPP, which is a slight modification of the Nested Association Mapping (NAM) concept, includes a reciprocal second backcross and thus involves segregation of both wild cytoplasmic and nuclear genomes in each of the bi-parental subpopulations. We refined a protocol for chloroplast DNA isolation for analysis by next-generation sequencing and found non-synonymous mutations in chloroplast genes. The nuclear genome was characterized through skim coverage sequencing, with imputation from high-coverage founder lines, and with 50K SNP genotyping for easy alignment with previous and ongoing research in this model crop plant. Our population genetics analysis shows, as expected, an average of 12.6% nuclear introgression from the wild donors among the CMPP lines. Analysis of the field phenotype shows significant cytoplasmic effects on grain dimensionality and flowering time in some of the CMPP families. Efforts are now focused on identifying the genetic loci interacting with different cytoplasmic backgrounds and conducting multi-environment field trials to assess the stability of CNI-QTL underlying yield related traits. Ultimately, the CMPP offers a novel genetic resource for enhancing our understanding of nuclear-cytoplasmic genome interactions, and it will be available with its genomic and phenotypic information in the b1kCMPP public database.

86 **Elucidating the genetic architecture governing cytonuclear genomic stoichiometry** Evita Chee[1], Joel Sharbrough[2] [1]Biology/Biotechnology, New Mexico Institute of Mining & Technology, [2]Biology, New Institute of Mining & Technology

Plant genomes are partitioned into three separate cellular compartments: the nucleus, mitochondria, and chloroplasts. Nuclear genomes are bi-parentally inherited via sexual reproduction while the two cytoplasmic genomes are inherited uniparentally. Together, these genomes encode proteins that must interact with one another, in highly specific ratios, to assemble multi-subunit enzyme complexes that carry out essential plant processes like oxidative phosphorylation (OXPHOS) and photosynthesis. The genes encoding nuclear and organelle gene products that interact (*i.e.,* cytonuclear interactions) are known to be highly dosage sensitive, as cytoplasmic gene copy number is upregulated in polyploids, and nuclear-encoded genes whose products are targeted to the chloroplast or mitochondria are among the first to re-diploidize following whole-genome duplication events. The genetic architecture underlying the phenotypic consequences that proceed from

the delicately balanced cytonuclear stoichiometry of plants are entirely unknown. We therefore designed crosses between accessions of *A. thaliana* that exhibit either high or low cytoplasmic genome copy numbers (*i.e*., high x low; low x high) to identify candidate gene regions underlying variation in cytonuclear stoichiometry. We confirmed the success of these crosses using RFLP markers on DNA extracted from F_1s and selfed the F_1s to produce recombinant F_2 offspring. We reared F_2 progeny in a common garden and assayed photosynthetic activity, quantified ratios of cytoplasmic:nuclear RNA and DNA, and plan to sequence whole genomes on an Illumina NovaSeq to perform QTL analysis. As part of this analysis, we also modeled the relationships between cytonuclear ratios of DNA and RNA with photosynthetic traits to determine the effects of variation in cytonuclear stoichiometry on photosynthetic performance. In the future, we will target candidate genes with CRISPR/Cas gene editing to knock genes out (or down) to evaluate functional contributions to cytonuclear stoichiometry. In sum, this project will provide valuable insights into the mechanistic regulation responsible for changes in cytoplasmic genome copy number. More broadly, understanding the effects of cytoplasmic genome copy number variation on photosynthesis represents a key and unsolved mystery in plant biology.

87 **The genetic basis of complex traits in an over-wintering *Arabidopsis thaliana* common garden** Amanda L Peake, John R Stinchcombe Ecology and Evolutionary Biology, University of Toronto

Characterizing the genetic basis of ecologically important traits is one of the main goals of evolutionary biology. Common garden experiments conducted in realistic conditions can be extremely beneficial for identifying ecologically relevant genetic variants given that complex quantitative traits are influenced by an individual's genetic make up as well as their environment. *Arabidopsis thaliana's* abundance of genomic resources and impressive collection of accessions sampled from across the species geographic range make the species ideal for studying the relationships between genetic variation, phenotypic diversity, and fitness. We grew 500 *A. thaliana* accessions, collected from North Africa, Europe, and Asia by the 1001 Genomes Consortium (2016), in an over-wintering common garden experiment in Toronto from September 2022 to July 2023. We measured a variety of ecologically important traits including early life growth rate, flowering time, flowering duration, number of leaves, rosette diameter, winter survival, plant height, branching architecture, above-ground dry biomass, and fruit number. Our goals are 1) to identify novel ecologically relevant genetic variants, 2) determine the effect of Gene-by-Environment interactions (GxE) on the phenotypic traits in *A. thaliana*, and 3) determine the strength of selection acting on the traits during the 2022-2023 growing season. To determine how GxE may be influencing phenotypic variation, we compared our data with other studies that have previously grown the same accessions in growth chambers kept at a constant temperature of 10°C and 16°C. According to our preliminary results, we find an effect of genotype, environment, and GxE when we compare flowering time in our overwintering common garden experiment to flowering time in both growth chambers and we find no difference in flowering time between the two growth chambers. We conducted a Genome Wide Association Study (GWAS) to determine the genetic basis of flowering time in all three conditions. We found a total of 5 genomic regions associated with flowering time in our outdoor common garden experiment one of which overlaps with the well-known flowering time gene *FRIGIDA*. We then compared the genomic regions associated with flowering time in our outdoor common garden experiment to the genomic regions associated with flowering time in the growth chambers. Unsurprisingly, we found overlapping GWAS hits between the two growth chambers. We did however find different genomic regions associated with flowering time in our overwintering common garden experiment compared to the 10°C and 16°C growth chambers. Therefore, phenotyping *A. thaliana* in a more ecologically realistic environment led to novel GWAS hits. We are currently conducting similar analyses for the other traits we measured and we will also be using fruit number as a proxy for fitness to calculate the strength of selection.

88 **Unravelling the molecular genetics of root system architecture in wheat (*Triticum aestivum* L.)** Tanushree Halder[1,2], Guijun Yan[2], Yinglong Chen[2], Hui Liu[2], Kadambot H. M. Siddique[2] [1]Genetics and Plant Breeding, Sher-e-Bangla Agricultural University, [2]The University of Western Australia

Background: Wheat (*Triticum aestivum* L.) production in the world is challenged by different biotic and abiotic stresses, which are increasing with climate change. An improved root system is essential for adaptability and sustainable wheat production. Unravelling the molecular genetics—quantitative trait loci (QTL), candidate genes and proteins—of root traits is essential wheat root trait improvement through breeding.

Materials and methods: 103 recombinant inbred lines (RILs) RILs of Synthetic W7984 × Opata M85 and 14 pairs of near-isogenic lines (NILs: pairs of genetically identical lines except for genomic regions (GRs)) of wheat were used to phenotype root traits in a semi-hydroponic system. Composite interval mapping method was used to discover QTL for root traits from RILs. Candidate genes and proteins for root traits were identified from NILs through and genotype-phenotype association analysis, and label-free proteomics, respectively.

Results: The RILs exhibited significant variation in root traits; 14 QTL for eight root traits were identified mainly on chromosome

groups 5, 6 and 7. Important QTL for shallow root (*Q.rd.uwa.7BL*: *Xbarc50*) and high RM (*Q.rm.uwa.6AS*: *Xgwm334*) were validated in two independent F2 populations of Synthetic W7984 × Chara and Opata M85 × Cascade, respectively. Separately, 10 of 14 NIL pairs showed significant variation between their isolines for root traits; 15 putative candidate genes for root traits, including outstanding genes *TraesCS4A02G185300* and *TraesCS4A02G442700* encoding UDP-glycosyltransferase and *TraesCS4A02G330900* encoding leucine-rich repeat receptor-like protein kinase were identified on targeting GRs on chromosomes 4BS, 4BL, 4AS, and 7AL of NILs. Furthermore, three candidate protein biomarkers for total root length and root dry mass in NIL pairs targeting GRs on chromosomes 4A and 7A—asparagine synthetase (*TraesCS4A02G109900*), signal recognition particle 19 kDa protein (*TraesCS7A02G333600*) and 3,4-dihydroxy-2-butanone 4-phosphate synthase (*TraesCS7A02G415600*)—with consistent gene expressions at protein and mRNA transcription (qRT-PCR) levels were identified.

Conclusion: Our research provides an improved understanding of molecular control of root traits and potential for marker-assisted root breeding in wheat.

89 **A noncanonical GTPase signaling mechanism controls exit from mitosis in *Saccharomyces cerevisiae*** Xiaoxue Zhou[1,2], Stephen P Bell[1], Angelika Amon[1] [1]Massachusetts Institute of Technology, [2]New York University

In the budding yeast *S. cerevisiae*, exit from mitosis is coupled to nuclear/spindle position to ensure successful genome partitioning between mother and daughter cell (bud). This coupling occurs through a GTPase signaling cascade known as the mitotic exit network (MEN). Only when the anaphase spindle is positioned correctly along the mother-bud axis is the MEN activated to promote exit from mitosis. The MEN senses spindle position via a Ras-like small GTPase Tem1. How the GTP/GDP cycle of Tem1 couples the status of spindle position to the activation of its effector protein Cdc15 is not fully understood. Tem1 primarily localizes to the spindle pole body (SPB, yeast equivalent of centrosome) that migrates into the bud when the anaphase spindle is correctly positioned. In contrast, when the spindle is mispositioned the SPB localization of Tem1 is minimized. Here, we show that only the GTP bound Tem1 (Tem1-GTP) localizes to the SPB and, contrary to prior assumptions, Tem1's nucleotide state does not change upon MEN activation. More importantly, by artificially tethering Tem1 to the SPB, we demonstrate that the essential function of Tem1-GTP is to localize Tem1 to the SPB. Localization to the SPB mainly serves to create a high local concentration of Tem1 to activate Cdc15, as we could bypass this essential localization by concentrating Tem1 in the cytoplasm with genetically encoded multimeric nanoparticles (GEMs). We propose that rather than modulating Tem1's nucleotide state, spindle position regulates Tem1-Cdc15 interaction (and thus Cdc15 activation) by controlling Tem1's effective concentration through regulating its localization. Overall, our study reveals a distinct localization/concentration-based GTPase signaling mechanism for Tem1 that differs considerably from the canonical Ras-like GTPase signaling paradigm, in which the GTPase functions as a molecular switch with its nucleotide state modulated to regulate effector binding and activation.

90 **The Evolution of an Inversion Supergene in Deer Mice** Olivia Harringmeyer, Shuonan He, Hopi Hoekstra Harvard University

Supergenes, sets of genetic loci that are inherited together, can facilitate local adaptation through linking multiple adaptive traits. Supergenes are often associated with chromosomal inversions, since inversions link genetic loci through suppressing recombination when heterozygous. Despite growing evidence that inversion supergenes play an important role in adaptation, little is known about how inversions become supergenes. Here, we address two major open questions about the evolution of inversion supergenes. First, how do inversions influence adaptive traits? Second, do inversions become supergenes over time, or immediately upon their formation? To address these questions, we focus on a 40-Mb inversion supergene in the deer mouse (*Peromyscus maniculatus*) that is strongly associated with long tails and dark coats, two traits important for local adaptation to forest habitats. To dissect the molecular basis of the inversion supergene, we first isolated the inversion in a congenic mouse line, enabling quantification of the phenotypic effects of the inversion, on its own, across sibling mice. For coat color, we found that the inversion darkens mouse coats by reducing the expression of *Agouti*, the gene responsible for inducing the switch between dark and light pigment production. The inversion is located on a different chromosome from *Agouti*, suggesting that the inversion affects coat color through causing *trans* regulatory effects. For tails, we found that the inversion lengthens mouse tails by increasing the number of chondrocytes in tail vertebral growth plates. Using a forward genetic cross, we then fine-mapped the tail locus to a narrow 1-Mb region in the center of the inversion, in which we identified *Npr3* as the top candidate gene driving the tail length effects. These results suggest that mutation(s) harbored within the inversion, rather than the inversion breakpoints themselves, cause the inversion's effects on tail length. Finally, we investigated the inversion's phenotypic effects across the species range and found that the inversion consistently affects coat color, but only increases tail length in a portion of its range, indicating that the inversion acts as a supergene in some, but not all, populations in which it occurs. Moreover, we found that the inversion likely became a supergene over time, through the accumulation of the tail length mutation(s). Together, these results reveal how an inversion can alter two different developmental pathways associated with two distinct adaptive traits, becoming a supergene over time through the accumulation of adaptive loci.

91 **Mycobacterial effector EsxM alters macrophage dynamics via the host actin cytoskeleton** Mollie I Sweeney[1], Joseph W Saelens[2], Gopinath Viswanathan[2], Ana María Xet-Mull[2], Carson E Carranza[2], Jörn Coers[2], Jason E Stout[2], Clare M Smith[2], David M Tobin[2] [1]Molecular genetics and microbiology, Duke University, [2]Duke University

Mycobacterium tuberculosis (*Mtb*), the human-adapted pathogen that causes tuberculosis disease, has subverted the immune system to become one of the deadliest pathogens in history. We use the zebrafish-*Mycobacterium marinum* model of TB to study mycobacterial pathogenesis. We identified a secreted *Mtb* effector, EsxM, that induces dramatic phenotypes in infected cells. Clinically, *Mtb* strains that express full-length EsxM cause a high rate of disseminated disease. *M. marinum* infection experiments in both larval and juvenile zebrafish demonstrate that full-length EsxM-expressing *M. marinum* possesses an increased capacity for dissemination from established sites of infection and a tropism for bone infection, consistent with human clinical data. Using heterologous expression of either the modern, truncated version of EsxM or the ancient, full-length EsxM in zebrafish macrophages, we have shown that the full-length effector induces increased motility and migration of macrophages to a wound site. In human cells, we find that infection with EsxM-expressing *Mtb* leads to dramatic filopodial projections, F-actin and Arp2/3 rearrangement, and increased cell migration when compared to infection with *Mtb* strains lacking the effector. We identified a putative interacting partner for EsxM, a subunit of the host WASH complex, and developed a zebrafish *WASHC4* knockout line to test whether the increased macrophage migration and subcellular changes induced by EsxM are mediated via the WASH complex. *M. marinum*-infected mutant fish experience higher infection burdens and increased dissemination. Macrophages in mutant fish migrate at a higher rate, revealing a role for the WASH complex in cell motility. In a mouse *Mtb* infection model, disruption of the WASH complex leads to increased lung and spleen burden, demonstrating the importance of the complex in the context of mammalian mycobacterial infection. Bone marrow derived macrophages from mutant mice display unique actin localization patterns, including strong cortical actin bands, perinuclear localization of actin, and a general lack of cell polarization. Overall, we have identified a secreted mycobacterial effector that promotes dissemination of disease via alterations in the cytoskeleton of infected host macrophages. Our investigations into the putative host target, WASHC4, have implicated the WASH complex in macrophage migration and restriction of mycobacterial disease.

92 **Host genetics, microbiome composition and addiction/addiction-related behavior in mice.** Jason A Bubier[1], Dong-Bing Tran[2], Asaf Peer[2], Hoan Nguyen[2], Robyn Ball[2], Belinda Cornes[2], Jane Adams[3], Hao He[2], Vivek Philip[1], George Weinstock[2], Elissa J Chesler[1], Yanjiao Zhou[4] [1]Center for Addiction Biology, The Jackson Laboratory, [2]The Jackson Laboratory, [3]Northeastern, [4]Medicine, UConn Health

Cocaine use disorder (CUD) is a chronic disease characterized by compulsive drug seeking and use, leading to substantial adverse outcomes. CUD is highly heritable (>70%), and many genes have been associated with addiction. However, these only account for a small proportion of the observed variation, suggesting a role for many other biological and environmental factors. Accumulating evidence supports that the gut microbiome through the gut-brain axis plays a significant role in the behavioral responses to cocaine. Using the advanced mouse populations of the Diversity Outbred (DO)and Collaborative Cross (CC), our objective was to understand the interaction of the microbiome and host genetics in addiction or addiction-related behaviors. We hypothesize that host genetics influences behavior by altering the composition of the gut microbiome. When studied under a controlled diet, the microbiome's composition in animal models is a heritable genetic trait. Leveraging the data collected by the P50 Center for Systems Neurogenetics of Addiction, we used fecal samples and phenotype data from DO mice to test our hypothesis. We have identified microbial abundance QTLs at each level of microbial classification (e.g., family, genus) in fecal pellets and the cecal contents. We analyzed the composition of the gut microbiome to enumerate the microbial communities within these DO mice. We identified microbes associated with behavioral phenotypes using elastic net regularized regression and Permutation-based Maximum Covariance Analysis. To discover how microbes work together to influence behavior, microbes associated with the behavior were included as covariates in each behavior-specific conditional inference tree analysis, i.e., a tree-structured regression with unbiased covariate selection. A dashboard of interactive visualization modules enables the scientific community to interrogate and explore the microbe-microbe interactions and the microbial abundance QTL are also made accessible through an online QTL viewer. Finally, we have utilized CC mice and gene knock-out mutants to test the haplotype and gene effects of the loci on microbial abundance. Using multiple statistical approaches, we have identified numerous microbe and behavior associations. Together these results support the role of host genetics controlling the microbial abundance and microbial community composition being associated with behavior. 93 **Intestinal tumor proliferation requires and promotes wax ester production from hepatocyte-like cells through PDGF/VEGF signaling** Kerui Huang[1], Ting Miao[2], Ying Liu[2], Arpan Ghosh[3], Norbert Perrimon[2,4] [1]Genetics, Harvard Medical School, [2]Harvard Medical School, [3]Dyno Therapeutics, [4]Howard Hughes Medical Institute

The *Drosophila* tracheal system is a model to study angiogenesis as increased tracheal terminal branching is induced by gut

tumors that require oxygen for growth. We specifically induced an active oncogene *Yorkie* (*yki*^{3SA}), the homolog of human Yap1, to induce gut tumor formation. We discovered that tumor growth, in addition to increased tracheal terminal branching induced by gut tumors, required Hepatocyte nuclear factor 4 (*Hnf4*) in hepatocyte-like cells (oenocytes). *Hnf4* was activated by the target of rapamycin complex I (TORC1) in oenocytes. Specifically, over-expressing *Tsc1* and *Tsc2* (TORC1 inhibitors) or knockdown *Hnf4* in oenocytes blocked tumor-induced tracheation, reduced the rate of tumor growth, tumor induced intestinal stem cell (ISC) proliferation, alleviated tumor induced cachexia and increased lifespan. We identified a common downstream target of *Hnf4* and TORC1 specifically expressed in oenocytes, the fatty acid elongase *CG18609,* homologous to human ELOVL7. Interestingly, *CG186*09 is highly induced in flies with *yki* tumors and can be blocked by either *TSC1,2* induction or *Hnf4* knockdown in oenocytes. In addition, gut tumor growth induced the expression of the secreted ligand PDGF- and VEGF-related factor 1 (*Pvf1*), suggesting that Pvf1 from the gut non-autonomously regulates TORC1 and *Hnf4* activity in oenocytes – which is supported by an increase in *CG18609* expression when an active form of PDGF- and VEGF-receptor related (*PvR)* is expressed in oenocytes. Because Hnf4 in oenocytes is a major regulator of lipid metabolism, we performed lipidomic analysis and observed a dramatic increased level of Wax Esters (WEs) in the hemolymph circulation of *yki* flies. As over-expressing *TSC1,2* or *Hnf4* knockdown in oenocytes reduced the level of WEs during tumor formation, we propose that WEs are produced from oenocytes to assist tracheation. Finally, in non-tumor flies, either *TSC1,2* induction or *Hnf4* knockdown decreased tracheation in the midgut. Altogether, our study identifies a new paradigm where gut tumors non-autonomously induce the *Hnf4* activity in hepatocyte-like cells, increases the production of WEs that promote tracheation, which in turn promotes tumor growth.

94 **A novel antidiuretic hormone governs tumor-induced renal dysfunction** Wei Roc Song, Wenhao Xu, Gerui Li, Yuan Chen, Xujun Ye Medical Research Institute, Wuhan University

Maintenance of renal function and fluid transport is essential for both vertebrates and invertebrates to adapt to physiological and pathological challenges. It has been observed that subjects bearing malignant tumors frequently develop detrimental renal dysfunction and oliguria, with previous studies suggesting the involvement of chemotherapeutic toxicity and tumor-associated inflammation. However, the direct modulation of renal functions by tumors remains largely unclear. In this study, using conserved tumor models in *Drosophila,* we characterized isoform F of ion transport peptide (ITP_F) as the first fly antidiuretic hormone that is secreted by a subset of *yki*^{3SA}-gut tumor cells to impair renal function and cause severe abdomen bloating and fluid accumulation. Mechanistically, tumor-derived ITP_F targets the GPCR TkR99D in stellate cells (SCs) of renal-like Malpighian tubules (MTs), an excretory organ equivalent to renal tubules, to activate NOS/cGMP signaling and inhibit fluid excretion. We further uncovered previously unrecognized antidiuretic functions of mammalian neurokinin 3 receptor (NK3R), the homolog of fly TkR99D, as pharmaceutical blockade of NK3R efficiently alleviates renal tubular dysfunction in mice bearing different malignant tumors. Altogether, our results demonstrated a novel antidiuretic pathway mediating tumor-renal crosstalk across species and offered therapeutic opportunities for the treatment of cancer-associated renal dysfunction.

95 ***Drosophila* brain metastasis model uncovers injury-response-like cellular dynamics between host and tumor cells** Chaitali Khan, Nasser Rusan Cell and Developmental Biology Centre, NHLBI/National Institute of Health

The tumor microenvironment, constituted by resident and recruited cells, is critical in metastasis at secondary organ sites. Several studies have dissected the role of recruited immune and stromal cells in metastasis; however, the complexity of organs has limited our understanding of tissue-resident cells and heterogeneity among different cell types in supporting tumor metastasis. Simpler model organism like *Drosophila* provides a tractable system to investigate the function of tissue-resident cells in the context of whole organ and organism. However, to this date, very few *Drosophila* metastasis models exist. To overcome this, we developed a reliable model for studying metastatic tumors at the secondary organ sites by modifying the classic allograft transplantation assay. Our method demonstrates robust metastasis in adult *Drosophila* organs, including the brain and ovaries. We used this fly brain model first to investigate one of the least understood cancer phenomena: how a tumor invades the brain surface and breaches the blood-brain barrier (BBB). Our system allows unprecedented analysis of cellular dynamics of brain tumor invasion at different metastatic stages. Like mammals, fly brains contain a structure equivalent to the BBB, comprising two sets of surface glial cells, the perineurial glia (PNG) and the sub-perineurial glia (SPG). Further, extracellular matrix (ECM) proteins form the outermost layer of the brain - the basement membrane (BM). Our analysis of the early stages of invasion revealed that tumors remodeled the BM by mechanical forces driven by a collective mode of tumor invasion. We discovered that cells were remodeled yet remained associated with the moving invasive front. In addition, the tumor-glial interface at the invasive front contained disorganized ECM components, suggesting that matrix secretion might be essential for brain metastasis. Furthermore, the invasion sites recruited tumor-associated macrophages (TAMs) and exhibited selective upregulation of Jun-Kinase in BBB glial cells. Together, these results suggest invading tumors elicit a response reminiscent of a brain injury in surface glial cells, which helps maintain the invasive front and facilitates brain tumor invasion. The ongoing work investigates the functional requirement of responses generated by glial and recruited TAMs in brain tumor invasion. Thus, our study, for the first time, established a robust *in vivo* system to carry out cellular and

molecular genetic analysis of the metastatic invasion and colonization of the brain.

96 **A high sugar diet, but not obesity, reduces female fertility in *Drosophila melanogaster*** Rodrigo Dutra Nunes[1,2], Daniela Drummond-Barbosa[3,4] [1]Genetics Department, University of Wisconsin-Madison, [2]Morgridge Institute for Reasearch, [3]Genetics, University of Wisconsin-Madison, [4]Morgridge Institute for Research

Obesity is linked to reduced fertility in various species, from *Drosophila* to humans. Considering that obesity is often induced by changes in diet or eating behavior, it remains unclear whether obesity, diet, or both reduce fertility. In this study, we untangle these factors. We show that *Drosophila* females on a high sugar diet become rapidly obese and less fertile due to increased apoptotic death at two oogenesis stages: early germline cysts and vitellogenic egg chambers. They also have high glycogen, glucose, and trehalose levels and develop insulin resistance in their fat bodies (but not ovaries). By contrast, females with adult adipocyte-specific knockdown of anti-obesity genes that act through distinct mechanisms, *brummer* and *adipose*, are obese but have normal fertility. Remarkably, females on a high sugar diet supplemented with a separate source of water have near normal fertility and glucose levels, despite persistent obesity, high glycogen and trehalose levels, and fat body insulin resistance. These findings demonstrate that a high sugar diet affects specific processes in oogenesis independent of insulin resistance; that high glucose levels correlate with reduced fertility on a high sugar diet; and that obesity alone does not impair fertility. We are currently investigating the mechanisms underlying how a high sugar diet affects oogenesis using an unbiased, multi-organ proteomic approach. The functional screening of prioritized candidate genes will provide new insight into how a high sugar diet alters the communication among tissues to cause elevated glucose levels and decreased fertility.

97 **Sensing of dietary amino acids and metabolic regulation through Adipokinetic hormone-mediated brain-fat body axis in *Drosophila melanogaster* larvae** Muhammad Ahmad[1], Norbert Perrimon[1], He Li[2] [1]Genetics, Harvard Medical School, [2]University of Science and Technology of China

Perturbation of the balanced actions of insulin and glucagon can result in a number of physiological diseases. While sugar-mediated control of insulin and glucagon is well-established, little is known about the regulation of glucagon system by dietary proteins compared to insulin. Dietary amino acids promote the secretion of Drosophila Insulin-Like Peptides (Dilps) from the Insulin Producing Cells (IPCs). In this work, we sought to explore the possibility that Drosophila adipokinetic hormone (AKH), which is related to mammalian glucagon, is regulated by dietary amino acids. Using Ca2+-imaging and ex vivo culture of larval brains and fat, we show that secretion of AKH is under the control of specific dietary amino acids. We demonstrate that Akh-producing cells (APCs) in the larval brain directly sense the levels of extracellular amino acids and release AKH in response to changes in amino acid levels. Exposure of the larval brain to physiological concentrations of amino acids increases free cytosolic Ca2+ in AKH-producing neurons, stimulating them to release AKH. This, in turn, triggers waves of intercellular Ca2+ across the larval fat body. Such intercellular Ca2+ waves have also been observed in mammalian adipose tissue, where they have been proposed to have a metabolic pathway role. While dietary sugar and protein are known to positively regulate insulin, our study delineates that certain amino acids can regulate glucagon. This suggests that protein-mediated hormonal control of energy homeostasis is not simply centered around sugars and instead, includes sensing and control by additional nutritional factors.

98 **Vitamin B12 can rescue tissue-fusion mutant survival in *C. elegans* embryonic development by altering mitochondrial metabolism** Erin Hsiao[1], Tushar H Ganjawala[1], Prativa Amom[1], Radmehr Molaei[1], Alekhya Kondragunta[1], Amanda L Zacharias[2,3] [1]Developmental Biology, Cincinnati Children's Research Foundation, [2]Developmental Biology, Cincinnati Children's Research Foundation, [3]Pediatrics, University of CIncinnati College of Medicine

In the natural environment, *C. elegans* embryos develop robustly despite daily temperature shifts, different bacterial food sources, and other variable environmental conditions. In standard laboratory conditions, the worms receive a single food source, *E. coli*, resulting in partial deficiency of vitamin B12, which functions in one carbon metabolism (methionine/SAM cycle) and propionic acid breakdown in mitochondria. In humans, maternal deficiency in vitamin B12 can result in persistent neurological defects, including neural tube closure defects.

We investigated the impact of vitamin supplementation on mutants carrying mutations in the ephrin receptor gene, *vab-1*. Over half of *vab-1* mutant embryos fail to hatch due to defects in the closure of the ventral gastrulation cleft, a tissue fusion event similar to mammalian neural tube closure or palatal fusion. We found vitamin B12 supplementation partially rescues the embryonic lethality of seven different *vab-1* mutant strains, but does not affect neuronal and head morphogenesis phenotypes. The average embryonic hatch rate increased from 40% to 63% for null alleles across multiple days of egg laying. Feeding *Comamonas*, a bacteria which produces vitamin B12, results in a similar level of embryonic rescue. Vitamin B12 supplementation also partially rescued mutants carrying mutations in *vab-2, eph-2, eph-4* (all ephrin ligands), as well as the *sax-3*/Robo receptor, and the semaphorin pathway gene *mab-20*, indicating it affects other signaling pathways that promote ventral cleft closure. Disrupting levels of major B12 processing enzymes prevents vitamin B12 supplementation from

rescuing *vab-1* mutant embryos but disrupting levels of key enzymes in the methionine/SAM cycle did not, in contrast to its function in larval development (Watson et al., 2014). Instead, we found that key enzymes in the mitochondrial propionic acid pathway are required for vitamin B12 to rescue. This pathway converts a toxic byproduct to a source of energy. Consistent with a potential role of oxidative stress, antioxidants can also partially rescue Ephrin and Robo receptor mutants. We are currently investigating the hypothesis that vitamin B12 can partially rescue the tissue fusion event because increasing energy availability and reducing stress in migrating cells might make them more likely to complete the process despite suboptimal signaling. Our findings indicate that *C. elegans* has strong potential to investigate gene-metabolite interactions and study the role of metabolism in basic developmental processes.

99 **Biallelic Variants in *KMO* Cause a Novel Form of Congenital NAD Deficiency** Nathalie M Aceves[1], Chih-Wei Hsu[2], Nanbing Li-Villareal[2], Xiaohui Li[1], Seema Lalani[1,3], Jill A Rosenfeld[1], Angelina Gaspero[1], Denise Lanza[1], Audrey E Christiansen[2], Tara L Rasmussen[2], Mary E Dickinson[2], Brendan Lee[1,3], Ronit Marom[1,3], Undiagnosed Diseases Network[4], Hartmut Cuny[5,6], Sarah H Elsea[1], Sally Dunwoodie[5,6,7], BCM Center for Precision Medicine Models[8], Jason Heaney[1], Lindsay C Burrage[1,3] [1]Molecular and Human Genetics, Baylor College of Medicine, [2]Integrative Physiology, Baylor College of Medicine, [3]Texas Children's Hospital, [4]Undiagnosed Diseases Network, [5]Victor Chang Cardiac Research Institute, [6]School of Clinical Medicine, Faculty of Medicine and Health, University of New South Wales, [7]Faculty of Science, University of New South Wales, [8]Baylor College of Medicine

Deficiencies in enzymes within the kynurenine pathway (KP), which is responsible for synthesizing nicotinamide adenine dinucleotide (NAD+) from the amino acid tryptophan, have been associated with phenotypes that include congenital anomalies, recurrent miscarriages, and NAD deficiency. Biallelic variants in three genes within the KP, *KYNU*, *HAAO*, and *NADSYN1*, have been linked to congenital NAD deficiency disorder (CNDD). Through the Undiagnosed Diseases Network at Baylor College of Medicine (BCM), we identified an individual who inherited biallelic variants in kynurenine 3-monooxygenase *(KMO*), which encodes a KP enzyme. The patient presented with a complex phenotype characterized by short stature, multiple congenital anomalies, elevated levels of precursor metabolites, and low levels of NAD. Our working hypothesis is that *KMO* deficiency represents a novel form of CNDD and increases the risk of congenital anomalies. To test our hypothesis, we generated a knockout mouse model ($Kmo^{-/-}$) and confirmed the deletion with western blot and gene expression analysis. The $Kmo^{-/-}$ mice are viable and fertile when fed a breeder chow and display significantly increased serum kynurenine levels in contrast to their wild-type ($Kmo^{+/+}$) littermates. However, when the $Kmo^{-/-}$ mice are fed a niacin-deficient diet, they lose significant body weight, unlike their $Kmo^{+/+}$ counterparts. This failure to thrive is indicative of a functional deficiency in KMO, as the $Kmo^{-/-}$ mice are unable to efficiently produce NAD+ from tryptophan. Instead, they rely on NAD+ synthesized from niacin via the Preiss-Handler and salvage pathways. A similar genetic and environmental interaction was observed during embryogenesis. $Kmo^{-/-}$ embryos from $Kmo^{-/-}$ dams fed a low niacin diet have skeletal and vertebral anomalies, as well as a higher proportion of external congenital anomalies as compared to $Kmo^{+/-}$ littermates. Additional analyses using micro-computed tomography imaging to assess these embryos for internal soft-tissue abnormalities are ongoing. Overall, these $Kmo^{-/-}$ embryos exhibit phenotypes similar to those observed in human CNDD, such as shortened long bones, vertebral anomalies, and other congenital anomalies. Our ongoing studies aim to assess whether niacin supplementation can mitigate these phenotypes and may provide insight on this novel form of CNDD as well as the roles of NAD and gene-environment interactions during embryonic development.

100 **Drosophila Spaetzle, an Ortholog of Human Nerve Growth Factor–β, induces Squamous Cell Carcinoma** Saurabh Singh Parihar, Jyoti Tripathi, Pradip Sinha BSBE, Indian Institute of Technology, Kanpur

Two broad strategies help decipher the functional conservation of a human protein in *Drosophila*: by expressing the heterologous human protein or by ectopically expressing its *Drosophila* ortholog. Using the latter approach, here we show that Drosophila, Spaetzle, Spz—a distant functional ortholog of vertebrate Nerve Growth Factor-β (NGF-β)—induces squamous cell carcinoma (SCC) in *Drosophila* Male Accessory Gland (MAG), an organ equivalent to mammalian prostate. Thus, an ectopic gain of active-Spz induces SCC, as suggested by cell hypertrophy, disruption of cell cytoskeleton and polarity, increased invasion, and endoreplication. Interestingly, Spz-induced SCC is independent of the canonical Toll-1-mediated signaling. We further showed that the gain of Spz downregulates Yki-mediated signaling and upregulates JNK signaling in the MAG cells. Furthermore, a gain of Spz can cooperate with other oncogenes to induce cachexia and increase morbidity in adult hosts. Additionally, an increased level of Spz in circulation triggers a low-grade chronic renal inflammatory (CI), which in turn can induce nephrocyte dysfunction—an equivalent cell type to the mammalian podocytes. Our study, therefore, reveals a hitherto unrecognized functional orthology between *Drosophila* Spz and human NGF-β and also suggests a novel role of *Drosophila* neurotrophin signaling in carcinogenesis.

101 **Genetic and maternal determinants of adaptive tail length divergence in tropical and temperate house mice (*Mus musculus domesticus*)** Sylvia M Durkin, Michael W Nachman Museum of Vertebrate Zoology and Department of Integrative

Biology, University of California, Berkeley

Adaptive phenotypic variation may reflect a combination of genetic and environmental effects. Describing the relative roles of these effects is essential to understand how adaptive phenotypes evolve and persist in natural populations. However, this is difficult in systems where experimental manipulation is not feasible. Here, we use a combination of behavioral, morphological, and experimental genetic approaches to disentangle the genetic vs. maternal control of adaptive tail length divergence between tropical and temperate house mice. Tail length is longer in tropical mice, likely reflecting adaptation to warmer temperatures through increased extremity length (Allen's rule). This difference in length is due to both a greater number of vertebrae and to a greater length of vertebrae. First, we focused on the maternal environment, as this source of variation may be particularly important in mammals due to the obligate association between mother and offspring during gestation and lactation. Through cross-fostering experiments we show that tail length, but not body weight, is strongly influenced by the postnatal maternal environment. The maternal effect on tail length is likely mediated by differences in nest temperature due to differences in maternal behavior. Further, analysis of tail vertebrae variation in cross-fostered and pure line offspring suggests that the maternal environment influences tail vertebrae length, but not vertebrae number. In contrast, differences in the number of tail vertebrae between tropical and temperate mice appear to be genetically determined. Second, we took a QTL mapping approach to identify candidate genomic regions underlying divergent tail length and tail vertebrae number between tropical and temperate house mice. We measured tail length and counted the number of caudal vertebrae in a large F3 mapping panel of mice derived from crosses between temperate and tropical mice. These mapping studies identify genomic intervals containing genes with developmental mutants known to affect the number of caudal vertebrae, including *Hoxd13* and *Lin28a*. Together, these results provide a detailed account of how both maternal effects and genetic changes influence phenotypic divergence associated with adaptation to differing climates.

102 **Genetic changes underlying adaptation to CO2 in the Drosophila suzukii species complex** Alice Gadau[1], Xin Yu Zhu Jiang[2], Sasha Mills[3], Katherinee I Nagel[4], Li Zhao[5] [1]Zhao Lab, The Rockefeller University, [2]Hunter College, [3]The Rockefeller University, [4]The Nagel lab, New York University Langone, [5]Zhao lab, The Rockefeller University

Adaptation is fundamental to the survival and reproduction of living organisms. However, the genetic and neural basis underlying adaptation to new environments remain largely unknown. *Drosophila suzukii*, commonly known as the spotted wing fruit fly, has evolved to oviposit in ripe fruit. This novel behavior is unlike most *Drosophila* species, which prefer to oviposit in rotten fruit. The two other members in the *D. suzukii* subgroup—*D. biarmipes* and *D. subpulchrella*—show an intermediate preference for rotten fruit. Adaptive behavioral shifts have previously been correlated to changes in the coding sequence (CDS) of *Drosophila* sensory receptors. Morphological adaptation has been attributed to changes in *cis*-regulatory elements. However, the impact of *cis*-regulatory changes on sensory receptor retuning has never been explored. In this study, we focused on one of the CO_2 co-receptors, *Gr63a*, to investigate if adaptive behavioral shifts can be tuned by *cis*-regulatory factors. The CO_2 receptor offers a unique opportunity to address this question as it consistently responds to CO_2 across different Drosophila species, unlike other odorant receptors, which can have ligand shifts between species. Additionally, ripe fruit emits more CO_2 than rotten fruit, to which *D. suzukii* and *D. subpulchrella* may have adapted. We first found key differences in (1.) egg-laying preference in the presence of CO_2 using behavioral trials and (2.) sensitivity changes of the CO_2 neuron between *D. melanogaster*, *D. suzukii*, and *D. subpulchrella* using single sensillum electrophysiology (SSE). We then screened and found that *Gr63a* is under selection in *D. suzukii* and significantly highly expressed in *D. subpulchrella*. This suggests that two separate mechanisms may have evolved, changes in the CDS for *D. suzukii* and changes in the *cis*-regulatory element in *D. subpulchrella*. To test this hypothesis, we developed transgenic *D. melanogaster* flies that are expressing either the *D. melanogaster*, *D. subpulchrella* or *D. suzukii Gr63a cis*-regulatory factor or coding sequence in a common trans environment. We then used SSE, immunohistochemistry, and egg-laying behavior trials to understand how the CDS or *cis*-regulatory element can contribute to adaptive shifts, establishing a connection between genetic and behavioral modifications.

103 **Continuously fluctuating selection reveals extreme granularity and parallelism of adaptive tracking** Mark C Bitter[1], Skyler Berardi[2], Hayes Oken[2], Andy Huynh[1], Paul R. Schmidt[2], Dmitri Petrov[1] [1]Department of Biology, Stanford University, [2]Department of Biology, University of Pennsylvania

Temporally fluctuating environmental conditions are a ubiquitous feature of natural habitats. Yet, how finely natural populations adaptively track fluctuating selection pressures via shifts in standing genetic variation is unknown. We generated high-frequency, genome-wide allele frequency data from a genetically diverse population of *Drosophila melanogaster* in extensively replicated field mesocosms from late June to mid-December, a period of ~12 generations. Adaptation throughout the fundamental ecological phases of population expansion, peak density, and collapse was underpinned by extremely rapid, parallel changes in genomic variation across replicates. Yet, the dominant direction of selection fluctuated repeatedly, even within each of these ecological phases. Comparing patterns of allele frequency change to an independent dataset procured from the same experimental system demonstrated that the targets of selection are predictable across years. In concert,

our results reveal fitness-relevance of standing variation that is likely to be masked by inference approaches based on static population sampling, or insufficiently resolved time-series data. We propose such fine-scaled temporally fluctuating selection may be an important force maintaining functional genetic variation in natural populations and an important stochastic force affecting levels of standing genetic variation genome-wide.

104 **Recent population collapse shapes deleterious variation across subpopulations of the endangered Florida scrub-jay.** Mitchell G Lokey[1,2], Tram N Nguyen[3,4], Elissa J Cosgrove[1], Felix EG Beaudry[5], Nancy Chen[5], Reed Bowman[6], John W Fitzpatrick[4], Philipp W Messer[2], Andrew G Clark[1,2] [1]Molecular Biology & Genetics, Cornell University, [2]Computational Biology, Cornell University, [3]Ecology and Evolutionary Biology, Cornell University, [4]Lab of Ornithology, Cornell University, [5]Department of Biology, University of Rochester, [6]Archbold Biological Station

The "small population paradigm" of conservation genetics predicts that small and declining populations have an elevated risk of extinction due to: 1) weakened purifying selection leading to greater stochastic increases in the frequency of deleterious alleles, and 2) increased homozygosity of deleterious variants due to increased inbreeding. An exciting opportunity to investigate these predictions is in the endangered Florida scrub-jay (FSJ; *Aphelocoma coerulescens*) study system. As anthropogenic factors shrank Florida's scrub habitat over the last two centuries, the FSJ population subsequently declined to less than 10% of its former number. Spatially variable habitat and population decline in combination with the FSJ's non-migratory behavior led them to their current state of semi-isolated genetic metapopulations, with extirpation in some local areas. The diversity in size and stability among the remaining FSJ subpopulations allows us to study the effects of recent decline, fragmentation, small size, and management on genetic variation within a single species. Here we explore the effects of these factors on inferred deleterious variation using 21x whole-genome sequencing of 241 birds sampled from 5 demographically diverse subpopulations over two time points. To identify putatively-deleterious variants (PDVs) we apply gene prediction and conservation-based approaches. We then quantify the impacts of small and declining population size on the efficacy of purifying selection by contrasting the site frequency spectra of PDVs and neutral variation across subpopulations as well as the masked and realized burden of PDVs across individuals. We find that the smaller subpopulations show increased PDV allele frequencies and clearly elevated genetic load, in terms of both the realized and masked load. Finally, we use forward-genetic simulations to 1) explore the evolution of genetic load for subpopulations of different sizes during the demographic history of the FSJ, 2) assess whether the effects of demographic processes are consistent with observed variation, and 3) predict each subpopulation's future trajectory of genetic load.

105 **Gene amplification as a driver of insect adaptation to transgenic crops: The case of *Helicoverpa zea*** Katherine L Taylor, Jane Quackenbush, Cara Lamberty, Kelly A Hamby, Megan Fritz University of Maryland

The evolution of insect resistance to agricultural management practices is a long-standing problem in food production systems, which results in crop failure and economic losses. Historically, most cases of field-evolved insect resistance have been attributed to *de novo* mutations of large effect at a single locus. As a result, many U.S. agricultural policies and practices for insect resistance management have been shaped under assumptions of single locus resistance evolution. The phytophagous North American insect pest, *Helicoverpa zea*, has recently evolved high levels of resistance to corn and cotton expressing transgenes from the bacterium *Bacillus thuringiensis* (Bt). Our work has examined the genome architecture of field-evolved Bt resistance in *H. zea* using whole genome sequencing, differential gene expression analysis, and functional assays. We show that adaptation to Bt crops by *H. zea* does not result from *de novo* mutation at a single locus, but is the result of multi-locus selection on standing genetic variation across the genome. Interestingly, one moderate effect locus includes a cluster of 7 paralogous genes, and up to 5 copies of this gene cluster are present in resistant *H. zea* populations. Our findings provide empirical evidence that evolutionarily novel resistance traits can arise as a result of polygenic adaptation from standing genetic variation. Moreover, they suggest that a paradigm shift in policy development is needed to more effectively detect and delay resistance evolution in agricultural ecosystems.

106 **Comparative genomics for California's wildlife: linking estimated migration rates and population demographics** Erik Enbody[1], John Novembre[2], Russ Corbett-Detig[1] [1]UC Santa Cruz, [2]University of Chicago

Population genomic methods to infer population structure and health are commonly employed in diverse datasets, but the results are rarely compared among taxa. Such multi-taxa comparisons on the geographical structure of populations have broad implications for understanding how the landscape shapes community dynamics while mitigating the idiosyncratic effects of individual taxa. In conservation genomics, most studies to date are single-taxa, but a general application to decision-making and land purchasing requires integrating genomic data across entire communities. Here, we take advantage of a massive taxonomically diverse population genomic dataset comprising over 150 species (nearly 20,000 samples) sampled densely across a uniform landscape as part of the California Conservation Genomics Project. This presents a unique opportunity to ask how the landscape impacts population genetic change across an entire community. Existing single-taxon methods have

successfully applied circuit theory to visualize geographic structure using maps of varying migration rates that can explain the observed genotype frequency among geographically clustered samples. We will share an overview of a methodology for comparing effective migration surfaces across different species on a uniform landscape. We recover major biogeographic breaks, common across as diverse taxa as birds, mammals, and insects, and examine taxa with properties that show different patterns. We ask how migration histories influence population health, such as inbreeding history, and the impact of life history characteristics on these patterns. Together, our methodology provides a powerful framework for future large-scale landscape and conservation genomics projects interested in understanding the landscape genomics of entire communities.

107 **Systematic mapping of natural variants that bypass essential genes** Amandine Batté[1], Núria Bosch[1], Carles Pons[2], Marina Ota[1], Maykel Lopes[1], Jolanda van Leeuwen[1] [1]Center for Integrative Genomics, University of Lausanne, [2]IRB Barcelona

Mutations often show phenotypic differences across genetically distinct individuals. In the most extreme case, a gene can be essential in one genetic background but have no effect on viability in another. Here, we investigated the frequency and underlying causes of differences in gene essentiality across 19 genetically diverse natural yeast strains. We identified 68 context-dependent essential genes that were not required for viability in at least one genetic background, suggesting that the strain contained variants that could bypass the requirement for the essential gene. Although some genes appeared to be essential in the reference background only, the vast majority of genes were nonessential in only one or two genetic backgrounds. We identified and validated the causal bypass suppressor variants for all 68 context-dependent essential genes using bulk segregant analysis and allele replacements. Bypass suppression was generally driven by a single, strong modifier gene, and involved both genes directly counteracting the molecular defect caused by loss of the context-dependent essential gene, as well as general modifiers bypassing the requirement of many genes. For example, a variant in the karyopherin *MSN5* could bypass the essentiality of the checkpoint kinase *RAD53* by modulating histone levels. Our findings highlight the frequency of genetic background effects and range of underlying mechanisms, providing insight on how genetic variance accumulates during evolution and affects genetic traits.

108 **Epigenetic Silencing of Transposable Elements Drives Variation In Recombination Landscapes** Yuheng Huang[1], Zita Y Gao[1], Kevin HC Wei[2], Grace Yuh Chwen Lee[1] [1]UC-Irvine, [2]UBC

Meiotic recombination is a prominent force shaping genome evolution, and understanding the causes for varying recombination landscapes within and between species has remained a central, though challenging, question in the field of evolutionary genomics. Across species, chromosome-wide recombination maps have shown strongly suppressed rates of recombination around pericentromeric heterochromatin, and the enrichment of repressive epigenetic marks in this genome compartment has been attributed as the cause. Interestingly, in the euchromatic regions of the genome, repressive epigenetic marks are also found enriched at transposable elements (TEs), widespread genomic parasites, as a consequence of the host-directed mechanism to epigenetically silence TEs. Building upon these observations, we hypothesize that the epigenetic silencing of polymorphic TEs in the euchromatic genome could locally suppress recombination, driving varying recombination landscapes between individuals. To test our hypothesis, we studied the associations between the distribution of crossover events, one of the two important recombination products, and epigenetically silenced TEs in two *Drosophila* strains with distinct TE insertion profiles. We developed a novel approach that uses PacBio long-read sequencing to efficiently identify crossover events among a large number of pooled recombinant individuals. According to our benchmark data, our approach has a low false positive rate (6.5%) and randomly distributed false-negative events. For each strain, we identified ~1,400 crossover events in a single PacBio sequencing reaction, with a high resolution of crossover breakpoints (within 1kb). Supporting our hypothesis, we found that TEs, mainly those leading to local enrichment of repressive epigenetic marks, negatively impacted crossover rates. Such an effect contributes to varying crossover maps between individuals of the same species. By performing forward population genetic simulations, we uncovered that this suppressive effect on recombination could further drive the evolution of enhanced epigenetic silencing of TEs. Overall, our investigations reveal how the selfish genetic elements could be active modifiers of the recombination landscapes through epigenetic mechanisms, shaping genome evolution within and between species.

109 **Temporal Dynamics of Phase Transitions: Transcriptome Profiling in Swarming Locusts** Maeva A. Techer, Alyssa Canova, Vivian A. Peralta Santana, Hojun Song Entomology, Texas A&M University

Density-dependent polyphenism has evolved multiple times in insect taxa, but locusts often embody this phenomenon (Orthoptera: *Acrididae*). In response to conspecific population density changes, solitary, shy and cryptic grasshoppers can develop into gregarious, swarming, and conspicuous locusts (i.e., gregarization); or revert (i.e., solitarization). Extensive research on the mechanical and physiological aspects of these phase transitions has focused on the swarming desert locust (*Schistocerca gregaria*), one of the 19 recognized locust species. Despite differing temporal dynamics in gregarization and solitarization in desert locusts, both processes are triggered by a sensory cues, including sight, smell, and tactile stimulation.

These mechanosensory-induced developmental changes are accompanied by significant gene expression changes in nervous tissues following the phase change. Yet, the intricate molecular mechanisms underlying the early stages of locust phase transition remains unknown.

We aim to unravel the temporal gene expression changes and regulatory networks underlying phase transitions in lab-reared desert locusts. To induce gregarization, solitarious nymphs isolated for two generations were exposed to crowded cages with high conspecific densities (> 300 individuals) for durations ranging from 30 minutes to 72 hours. Conversely, to induce solitarization, long-term gregarious nymphs were isolated in sensory-independent cages. At each time point, we collected and sequenced various nervous and chemosensory tissues involved in environmental cue processing. In this talk, we will share insights from 520 tissue-specific transcriptomes sequenced using Illumina short-reads. The time course transcriptomic analysis was guided by the six new reference chromosome-length *Schistocerca* genomes (~8.5Gb) developed by the BPRI and USDA. Ultimately, we will sequence and compare the temporal transcriptomic landscapes of six *Schistocerca* species displaying varying degrees of density-dependent phenotypic plasticity to pinpoint the molecular origins of locust swarming.

110 **A Telomere-to-Telomere (T2T) complete mouse genome** Thomas Keane[1], Bailey Francis[1], Mohab Helmy[1], Kevin Costello[2], Jingtao Lilue[3], Laura Reinholdt[4], Anne Czechanski[4], Emma Betterbridge[5], Iraad Bronner[1], Anne Ferguson-Smith[2], David J Adams[5] [1]EMBL-EBI, [2]Department of Genetics, University of Cambridge, [3]Oujiang Laboratory (Zhejiang Lab for Regenerative Medicine, Vision and Brain Health), [4]Jackson Laboratory, [5]Wellcome Sanger Institute

The generation and assembly of a reference genome for C57BL/6J revolutionized our ability to relate sequence to function. Despite over twenty years of effort, the current mouse reference genome (GRCm39) has over 170 known gaps and unresolved issues. Many important loci such as the centromeres, major histocompatibility complex (MHC) on Chromosome 17, the pseudo-autosomal region (PAR), and Krüppel-associated box (KRAB) domain-containing zinc-finger protein (KZFP) loci on Chromosome 2 and 4, remain incomplete or inaccurate. By using a combination of long and ultra-long read sequencing technologies, we have generated the most complete mouse reference genome for two strains from a C57BL/6J x CAST/EiJ F1 animal. Through a combination of automated genome assembly and manual curation, all of the C57BL/6J and CAST/EiJ autosomes are full length, which represents a major milestone in the journey towards a fully complete mouse reference genome. We have added approximately 240 Mbp of novel sequence compared to GRCm39, largely consisting of satellite sequence in the centromeres and telomeres. We have fully sequenced all but seven of the remaining autosomal gaps in GRCm39, which added approximately 12.7 Mbp of additional sequence containing tens of predicted protein coding genes. We find that telomeres are consistently longer in the C57BL/6J strain compared to CAST/EiJ, whilst telomere length varies dramatically between chromosomes. We compared the architecture of the PAR region between *Mus m. molossinus*, *Mus m. domesticus*, and *Mus m. castaneus*, identifying a larger PAR in *Mus m. castaneus* due to a multi copy expansion of the *Erdr1* gene. Finally, we have built the first complete picture of chromosomal inversions between two inbred mouse strains, finding five inversions larger than a megabase. Not only do our assemblies unlock some of the most challenging loci in the genome, but with the completed genomic sequences for two mouse strains, our work enables comparative analyses in these complex regions for the very first time.

111 **Convergent and lineage-specific genomic changes contribute to adaptations in nectar-taking birds** Ekaterina Osipova[1], Meng-Ching Ko[2], Maude Baldwin[2], Michael Hiller[3], Timothy Sackton[1] [1]Harvard University, [2]Max Planck Institute for Biological Intelligence, [3]Senckenberg Research Institute

Understanding the genomic basis of dietary adaptations can provide insights into the evolution of metabolic processes as well as into the extent and degree of convergent evolution. Remarkably, although high-sugar diets are associated with metabolic diseases in humans, several bird lineages have independently evolved to primarily subsist on simple sugars from flower nectar or fruits. In this study, we address a key question regarding the repeatability of molecular evolution by investigating the convergent and lineage-specific molecular mechanisms underlying dietary adaptations in four major nectar-feeding bird lineages: hummingbirds, parrots, honeyeaters, and sunbirds. We generated ten high-quality genomic assemblies for nectar-feeding species and their closely related non-nectar-dependent counterparts, and obtained tissue-specific transcriptomes for six key species. Our comprehensive genome-wide investigation, encompassing both protein-coding and non-coding regulatory sequences, reveals evidence of adaptive evolution in processes related to glycolysis, blood pressure regulation, and heart function across all four nectar-feeding groups. Importantly, these convergent signals of selection may manifest at various levels - from pathways to individual genes and regulatory elements, highlighting the interplay of different types of changes in altering or regulating metabolic pathways. Furthermore, although we find that individual genes are rarely targeted in all lineages, our integrative analysis pinpoints key candidate genes, such as MLXIPL, that is vital for carbohydrate and lipid metabolism and which exhibits repeated signals of selection and shifts in expression levels across nectar-feeding lineages; functional assays demonstrate changes in nectarivores corresponding to these selection signals. Our findings suggest that both convergent and lineage-specific strategies have played roles in the evolution of nectar-feeding adaptations and underscore the complex

patterns of molecular convergence in both protein-coding loci and regulatory elements in shaping metabolic pathways.

112 **Evolutionary invention of a thermocouple-like sensor by adaptation of cytochrome c oxidase in a subterrestrial metazoan** TreVaughn S Ellis[1], Megan N Guerin[1], Mark J Ware[1], Alexandra S Manning[1], Ariana S Coley[1], Ali Amini[2], George C Chung[3], Kristin C Gunsalus[3], John S Bracht[1] [1]Biology, American University, [2]Data Science, American University, [3]Ceneter for Genomics and Systems Biology, NYU

In this study we report a naturally evolved temperature-sensing electrical regulator in the cytochrome c oxidase of the Devil Worm, *Halicephalobus mephisto*. This extremophile metazoan was isolated 1.3 km underground in a South African goldmine, where it adapted to heat and potentially to hypoxia, making its mitochondrial sequence a likely target of adaptational change. Here we report the full mitochondrial genome sequence of this organism, and show through dN/dS analysis statistically robust evidence of positive selection in *H. mephisto* cytochrome c oxidase subunits. Seventeen of these positively-selected amino acid substitutions were localized in proximity to the H- and K-pathway proton channels of the complex. Direct experimental measurement of the mitochondrial proton gradient confirmed that proton translocation is altered in *H. mephisto* relative to *C. elegans*. The *H. mephisto* cytochrome c oxidase proton pump completely shuts down at low temperatures leading to approximately five-fold reduction in the transmembrane proton gradient voltage (ΔΨm) when comparing 37°C with 20°C. Correspondingly, the lifecycle of *H. mephisto* slows by the same amount, becoming five-fold longer at the low temperature. By this simple mechanism the organism can sense the environmental temperature and adjust its growth rate correspondingly. A thermocouple device senses temperature fluctuations by voltage changes. Because the cytochrome c oxidase of *H. mephisto* has evolved to regulate its mitochondrial proton gradient voltage (ΔΨm) by temperature, it represents the first known example of a naturally evolved biological thermocouple-type device in the mitochondrion of any organism.

113 **Metabolic profile of Drosophila exercise-trained flies suggests NRF2 pathway as a link between exercise & oxidative stress** Tolulope R Kolapo[1], Miled A Maisonet-Nieves[2], Laura K Reed[2] [1]Biological Sciences, The University of Alabama, [2]Biological Sciences, University of Alabama

Metabolic Syndrome (MetS) is a cluster of several disorders that includes obesity, type II diabetes, and cardiovascular diseases. Various exercise-related studies in humans have identified the ameliorating effects of exercise on MetS. However, human experimental studies face several limitations due to the small population size, expensive sampling procedures, & uncontrollable environmental factors. *Drosophila melanogaster* is a suitable model to mimic various disease-related studies as seen in humans. The negative geotaxis tendency of flies has been studied to develop devices to exercise flies. The Power Tower and TreadWheel are devices used to study large sample sizes of fruit flies to determine the effects of exercise. However, controversies exist on the relatedness of fly exercise to human exercise. This is because indicators like physiological conditions, muscle biopsies, blood lactate, and V02 max cannot be measured *in situ* while exercise is ongoing in flies as it can in humans. To further determine the close relatedness of fly exercise research to humans, we conducted an untargeted metabolomics analysis of exercise-trained fruit flies and their controls after a five-day exercise regime. We also trained flies on the Power Tower and the TreadWheel to understand the devices effect on metabolic profiles of flies. Correlating device effects to metabolic profile could aid the classification of exercise devices for endurance, strength and resistance training as observed in human exercise research. Our result reveals close relatedness of fly exercise outcomes and human exercise outcomes at the metabolite levels. We identified increased urea, TCA cycle substrates such as aconitic acid and citric acid, and increased levels of protein synthesis, which are all exercise indicators. Also, we observed an upregulation of exercise-induced oxidative stress indicators and the induction of the *NRF2* pathway that regulates oxidative stress and antioxidant production. To further confirm the induction of oxidative stress we performed a gene expression study of six oxidative stress-related genes. Increased expression levels of these genes further suggest exercise-induced oxidative stress in trained flies. The downregulation of the *Gagr* gene suggests a localization of stress induced in the mitochondria. Through this study we confirmed that exercise activates pathways of oxidative stress in *Drosophila* and similarities exist in the metabolome of exercised fruit flies and humans.

114 **Pangenome analysis of 1,098 *Saccharomyces cerevisiae* isolates reveals the hidden genomic and genetic basis behind the phenotypic variation** Victor Loegler[1], Elie Teyssonniere[1], Pia Thiele[1], Andreas Tsouris[1], Jing Hou[1], Anne Friedrich[1], Joseph Schacherer[1,2] [1]Université de Strasbourg, CNRS, GMGM UMR 7156, Strasbourg, France., [2]Institut Universitaire de France (IUF), Paris, France.

Pangenomes from large natural population allow to capture the exhaustive genomic diversity and explore more deeply the cause of the missing heritability of complex traits. Identifying at a population-scale all type of genetic variants and measuring their phenotypic contribution is now essential. In this context, we sequenced and *de novo* assembled 1,409 chromosome-level genomes using a long-read sequencing strategy for more than a thousand natural isolates of *Saccharomyces cerevisiae* yeast, coming from diverse ecological and geographical origins. This dataset led to the detection and definition of an exhaustive

catalog of structural variants (SVs) present in yeast, highlighting adaptative and clade-specific SVs. Interestingly, our results showed different evolutionary trajectories in terms of accumulated mutational events, with wild clades having an enrichment in single nucleotide polymorphisms (SNPs), whereas some domesticated clades are enriched in SVs. We also constructed a high-resolution pangenome, showing a significant variation of the accessory genome at the species level. The pangenome clearly revealed signatures in terms of gene content related to specific populations. Using phenotypic data generated on this large population (fitness, transcriptomes and proteomes), this pangenome was then used for genome-wide association analyses to generate a detailed map of loci involved in the variation of fitness (QTL), transcript (eQTL) as well as protein abundance (pQTL). Increasing the number and type of genetic variants, such as SVs, involved in association analysis improves the power to identify causal factors and decreases the missing heritability. Finally, the data we generated represents a unique resource for the development of graph-based pangenome methods. To our knowledge, our study constitutes the most comprehensive study of genetic content and structural variations combined with their effect on phenotypic variation in any eukaryotic species.

115 **Unexpected roles for the bud site selection machinery in the establishment and maintenance of polarity in *S. cerevisiae* spores** Benjamin Cooperman, MICHAEL MCMURRAY Cell and Developmental Biology, University of Colorado Anschutz Medical Campus

Many mechanisms controlling the establishment and maintenance of eukaryotic cellular polarity were first discovered in *S. cerevisiae*. In mitotically dividing (vegetative) yeast cells, bud site selection both requires and directs the placement of stable landmark proteins that direct future bud sites. Landmark proteins are integral to the membrane and anchored to the cell wall. Landmarks interact with the cytoplasmic polarity machinery through the Ras-family GTPase Rsr1 module that recruits and activates Cdc42. Polarity landmarks can be overridden by mating pheromone, which redirects secretion toward the pheromone source. Sporulation is different: Newly made double-bilayer membranes grow from the meiotic outer plaques of the spindle pole bodies and engulf the haploid nuclei produced by meiosis. Following membrane closure, the outer bilayer is lost as a specialized cell wall is built between the bilayers. The spores remain encased in the ascus, the original wall of the diploid cell. It was thought that these newly made cells lack polarity landmarks and that germinating spores break symmetry when they bud or mate.

We previously discovered that, even before germination, *S. cerevisiae* spores are polarized in a manner that promotes polarized growth during germination away from the points of spore-spore contact. Consequently, if a spore buds, the bud penetrates the ascus. If sister spores mate, they do so only after first elongating away from each other, then repolarizing toward each other, creating a zygote with a distinctive morphology. Thus mating by sister spores involves a predetermined polarity program that initially overrides pheromones.

The septin Cdc10 was the only known constituent of the spore polarity site and the assembly mechanism was entirely unknown. We have now determined that the polarity site also contains the landmark protein Bud8 and Bud5, a soluble GEF for Rsr1. Exocyst subunits and the Myo2 motor protein arrive at the polarity site after spore membrane closure, followed by Bud8, which persists for months at a single site. The arrival of Myo2 before Bud8, and Myo2 departure afterwards, suggests that Bud8 is actively delivered via actin cables. We find that the Rsr1 module is dispensable for polarity site assembly, but is required for its use as a bud site. Our data support a model in which polarized trafficking to the meiotic outer plaque ultimately deposits Bud8 in the membrane, where it acts as a stable landmark to direct polarization upon germination. Because trafficking occurs at spindle poles, anaphase II pushes the sites to the ascus periphery. In addition to ensuring that buds are not trapped inside the ascus, polarized growth in these directions may sensitize pheromone detection by positioning receptors away from mixed, highly concentrated signals in the ascus center. Our work reveals unanticipated roles for the canonical polarity machinery in a previously unexplored context.

116 **The Role of Hemocytes in Cell Debris Clearance in the *Drosophila* Ovary** Alexandra Chasse[1], Kim McCall[1], Shruthi Bandyadka[2] [1]Biology, Boston University, [2]Boston University

Cell death is an important process in the body, as it occurs throughout every tissue in the body during different development, disease, and tissue regeneration. However, when a cell dies, it must be cleared away or the persistence of the corpse can be damaging to the organism. Phagocytes are responsible for clearing away these dying cells and are typically characterized as either professional or nonprofessional phagocytes. Professional phagocytes, such as macrophages, are found in nearly every part of the body while nonprofessional phagocytes, such as epithelial cells, are found in every tissue type. However, there are organs that are considered “immune-privileged” as they have little to no immune surveillance and rely on nonprofessional phagocytes to engulf dying cells. These organs are surrounded by barriers to protect the tissue from viruses, bacteria, and perhaps even immune cells. The Drosophila ovary is considered immune-privileged, however the presence of hemocytes, the macrophages of Drosophila, around the ovary suggests they may have a potential function. Using several fluorescent and

genetic tools, we were able to identify and analyze hemocyte localization and potential functions in response to starvation-induced cell death in the ovary. Using RNAi, hemocytes were genetically ablated and it has been determined that the presence of hemocytes affects oogenesis and that they phagocytose ovarian cell debris. Signaling mechanisms between hemocytes and follicle cells are currently under investigation. Since the mechanisms of cell death and clearance are highly conserved, these experiments will increase our knowledge of immunosurveillance of immune-privileged tissues and cross-talk between professional and non-professional phagocytes. Since the mechanisms of cell death and clearance are highly conserved, these experiments will increase our knowledge of immune surveillance of the ovary. It is likely that these findings will have implications in understanding and treating human disease, development, and fertility.

117 **From Drosophila to a human immunodeficiency and enhanced cancer cell immunotherapy: hyperactive Rac stimulates cellular cannibalism** Abhinava K. Mishra, Melanie Rodriguez, Lauren Penfield, Morgan Smith, Anthony Rodriguez, Meghan Morrissey, Denise J. Montell Molecular, Cellular, and Developmental Biology, University of California Santa Barbara

The small GTPase Rac is an essential regulator of cell shape and migration. Here we show that in Drosophila, hyperactivating Rac (Rac^{G12V}) stimulates ovarian follicle cells to cannibalize neighboring cells, destroying the tissue. Hyperactive Rac is sufficient to drive three different types of whole cell engulfment and/or killing. Rac^{G12V} expression in border cells is sufficient to cause them to engulf but not kill whole, living polar cells. In contrast, Rac^{G12V} expression in individual epithelial follicle cells induces caspase-dependent apoptosis in neighboring follicle cells and leads to engulfment. Border cells expressing Rac^{G12V} can also kill the entire germline in a process that begins with trogocytosis (nibbling) of the most anterior nurse cell followed by rapid and nearly synchronous non-apoptotic germ cell death.

In mammals, Rac2 is predominantly expressed in hematopoietic cells where it is essential for survival and motility. The hyperactivating mutation $Rac2^{E62K}$ also causes a human immunodeficiency, although the mechanism is unknown. Taking cues from the fundamental cell biology in the fruit fly ovary, we show that hyperactive $Rac2^{E62K}$ stimulates human HL60-derived macrophage-like cells to engulf and kill living T cell leukemia cells. Primary mouse $Rac2^{+/E62K}$ bone-marrow-derived macrophages (BMDMs) also cannibalize primary $Rac2^{+/E62K}$ T cells due to a combination of macrophage hyperactivity and T cell hypersensitivity to engulfment. Additionally, bone-marrow-derived $Rac2^{+/E62K}$ macrophages non-autonomously stimulate wild type macrophages to engulf T cells. $Rac2^{E62K}$ also enhances engulfment of target cancer cells by chimeric antigen receptor-expressing macrophages (CAR-M). We propose that Rac-mediated cell cannibalism may contribute to $Rac2^{+/E62K}$ human immunodeficiency and enhance CAR-M cancer immunotherapy.

118 **RAS and PLK-1 signaling intersect to control nuclear envelope dynamics in early embryogenesis** Han Bit Baek[1], Debabrata Das[2], Hongyuan Li[2], Shin-Yu Chen[2], Swathi Arur[2] [1]UT MD Anderson Cancer Center, [2]MD Anderson Cancer Center

Rat Sarcoma (RAS) is a small GTPase that transmits extracellular growth factor signals through a downstream kinase cascade to regulate genes that promote proliferation, differentiation, and survival. Constitutively active mutations in RAS promote tumor onset and metastasis, and germline mutations are associated with birth defects in humans. However, it is unclear if activating mutations in RAS drive both cancer progression and birth defects through similar mechanisms. RAS L19F is an activating mutation in the RAS GTPase domain and is found in human cancers. I used *C. elegans* to track the impact of this activating RAS mutation on embryonic development. In *C. elegans*, I discovered that the oncogenic RAS mutation inhibits nuclear envelope breakdown (NEBD) in the 1-cell embryo. Loss of NEBD at this stage impedes the fusion of the oocyte and sperm nucleus. This failure to merge the maternal and paternal nucleus in the 1-cell embryo blocked the formation of the zygotic nucleus, resulting in nuclear defects and impaired embryonic development. Strikingly, I found that RAS functions through Polo like kinase 1 (PLK-1), a master regulator of nuclear envelope dynamics across cell types and species. Specifically, I uncovered a direct regulation of PLK-1 by ERK (Extracellular signal-regulated kinase), the final downstream effector of RAS signaling wherein ERK phosphorylates PLK-1. To assess the *in vivo* outcomes of this phosphorylation, I mapped the ERK dependent PLK-1 phosphorylation sites and generated a phospho-null PLK-1 allele in *C. elegans*. The phospho-null PLK-1 allele in the oncogenic RAS background resulted in a significant rescue of the nuclear defects. Thus, I propose that RAS-ERK signaling directly regulates PLK-1 to control NEBD during development. This is the first observation that an oncogenic RAS mutation can lead to defects in NEBD and the first reported intersection between RAS signaling and PLK-1 activity, setting the stage to uncover a novel role of RAS during cell division.

119 **Aneuploidy-induced defects in Ribosome Quality Control disrupt quiescence and aging in wild *S. cerevisiae*** Leah E. Escalante[1], James Hose[2,3], Hollis Howe[3,3], Norah Paulsen[3,4], Audrey P. Gasch[2] [1]Center for Genomic Science Innovation, Univ Wisconsin-Madison, [2]Genetics, Univ Wisconsin-Madison, [3]Univ Wisconsin-Madison, [4]CGSI, Univ Wisconsin-Madison

Karyotype imbalance due to an abnormal number of chromosomes is deleterious during development, for reasons that remain unclear. In humans, Trisomy 21 that causes Down syndrome leads to myriad defects in development, stem cell

maintenance and renewal, and aging including premature neurodegeneration and shortened lifespan. However, the molecular causes remain murky despite decades of study. In the course of studying aneuploidy determinants in a wild-yeast model, we discovered that chromosome duplication in yeast causes phenotypes related to those seen in Down syndrome, including defects in nutrient-dependent cell-cycle arrest and quiescence entry along with shortened lifespan. These defects are independent of which chromosome is duplicated and observed across multiple wild-strain backgrounds. Remarkably, we discovered that cell cycle and quiescence defects are caused in part by defects in Ribosome Quality Control (RQC) upon chromosome amplification. Aneuploid cells show increased ribosome stalling on an RQC reporter, and genetic analysis confirms involvement of the RQC pathway. Aneuploidy-dependent defects can be alleviated by overexpressing limiting RQC subunits, including Rqc1 and E3 ubiquitin ligase Ltn1 (whose mammalian ortholog is implicated in neurodegeneration), or deletion of CATylating enzyme Rqc2 that can produce protein aggregates. In contrast, inducing ribosome stalling in euploids mimics aneuploid defects. We show that genetic perturbation of ubiquitin metabolism can either alleviate or exacerbate aneuploid defects. Our working model is that the accumulation of ubiquitinated RQC intermediates depletes free ubiquitin, disrupting turnover of cell-cycle regulators and other proteins while producing protein aggregates that disturb healthy physiology. These results expand our understanding of the mechanisms of aneuploidy toxicity and raise important implications for Down syndrome as well as aneuploid cancers.

120 ***Getting there in one piece:*** **The Rac pathway is required to maintain cellular integrity during long distance leader-cell migration in *C. elegans* gonadogenesis.** Noor Singh, Kacy L. Gordon Biology, University of North Carolina at Chapel Hill

In larval *C. elegans* hermaphrodites, the long-distance migration of two leader cells, the distal tip cells (DTCs), drives the morphogenesis of two gonad arms that make up the reproductive system. Each DTC also serves as a stem cell niche that maintains a continuously proliferating germline stem cell population in the distal gonad. Loss of the Rho GTPase CED-10 (ortholog of human Rac1) or any component of its activating GEF module (composed of CED-5/DOCK180, CED-12/ELMO, and CED-2/CrkII) has been shown to lead to DTC migration defects and aberrant gonad morphology through an unknown mechanism. Rac1 typically functions at the leading edge of protrusively migrating cells to drive cytoskeletal rearrangements and the formation of dynamic protrusions, but the DTC has been shown to migrate non-protrusively. With the use of genetic mutants, tissue specific and whole body gene knockdown, and live confocal imaging of cells and endogenously tagged proteins, we show that loss of these *ced* genes results in fragmentation of the DTC as it migrates. Both products of fragmentation—the now-smaller DTC and the membranous patch of cellular material—localize important stem cell niche signaling, migration, and adhesion factors to their surfaces. However, only one retains the DTC nucleus and the ability to maintain gene expression and new protein synthesis over time. Strikingly, this enucleate patch can lead a branch bifurcating off the gonad arm that grows through germ cell proliferation driven by aberrant LAG-2/Delta signaling to germ cells adjacent to the patch, mimicking the stem-cell niche activity of the DTC. However, germ cells in this branch differentiate as the patch loses LAG-2 signaling (the stemness cue) in adulthood. These results drive the conclusion that although the DTC does not undergo lamellipodial-driven migration, it still relies on cytoskeletal regulation under the control of the small GTPase, Rac1, to retain its integrity, shape and position at the tip of the growing gonad. This work also adds insights to DTC migration as a model for migration events in other organisms that are led by smooth edged leader cells, such as branching morphogenesis during the development of tubular organs in vertebrates.

121 **Actin filament stiffness regulates the rate of embryonic wound closure in *Drosophila*** Ji Hong R Sayo, Ana Maria Carmo, Rodrigo Fernandez-Gonzalez Institute of Biomedical Engineering, University of Toronto

Mechanical forces drive key cell behaviours for embryonic development, tissue repair, and metastasis. Force generation is often associated with a protein network formed by actin and the molecular motor non-muscle myosin II . During embryonic wound healing, the cells surrounding the wound preferentially localize actin and myosin at the wound edge, forming a supracellular cable around the wound that contracts to guide cell movements. But force generation can also occur in the absence of myosin motor activity, for example during cytokinesis, through a combination of actin filament severing and crosslinking. Whether motorless contraction contributes to embryonic wound closure is unknown. We are investigating the role of the actin-severing protein cofilin during *Drosophila* embryonic wound healing. We found that cofilin inactivation by overexpressing the upstream cofilin inhibitor LIM kinase slowed down wound repair by 33%, indicating that cofilin is necessary for rapid embryonic wound closure. We found that in controls, wounds transitioned from elliptical to circular in shape as tension increased around the wound. In contrast, cofilin inactivation caused wounds to remain elliptical, despite contractile force at the wound edge being similar to controls. In addition to severing filaments, cofilin can reduce actin fiber stiffness by up to a factor of four. Thus cofilin-induced actin severing, actin softening, or a combination of both could contribute to rapid wound closure. To distinguish between these possibilities, we developed an *in silico* molecular model of actomyosin cable contraction during wound healing. In the model, changing the degree of actin severing did not affect the rate of wound closure for a constant level of myosin motor activity. In contrast, a four-fold stiffening of the actin filaments slowed down wound healing by 64% and led to wounds that were significantly more elliptical. Together, our results suggest that

cofilin-mediated actin softening facilitates actomyosin cable contraction to drive rapid embryonic wound repair.

122 **Ribosomal proteins, Splicing and Cell Competition. Connecting the dots.** Eleni Tsakiri, Myrto Potiri, Kyriaki Kanakousaki, Martina Samiotaki, Panagiota Kafasla, Marianthi Kiparaki Biomedical Sciences Research Center «Alexander Fleming»

Cell competition phenomenon, where cells are eliminated via a non-autonomous mechanism in genetic mosaics but not in a homogeneous environment, was first documented in *Drosophila* between wild-type cells and cells with heterozygous dominant mutations in ribosomal protein (*Rp*) genes (known as *Minute* genes). In *Drosophila* 66 of the 79 *Rp* genes belong to the Minute class. During my tenure in Nicholas Baker's lab, we discovered that the transcription factor Xrp1 is responsible for almost all of the cellular responses of *Minute* cells, including reduced competitiveness, slower growth, reduced translation, and even for the developmental delay of the Minute flies. We identified the RpS12 protein (encoded by a non-*Minute* gene) mediating the Xrp1 activation. Interestingly, the RpS12-Xrp1 pathway is responsible for the competitive elimination of cells with segmental aneuploidies, since loss of chromosomes can lead to Rp gene haploinsufficiency. In addition, work from us and others revealed that Xrp1 and cell competition result from multiple other stresses (such as translation defects, ER stress), highlighting the significance of unraveling the mechanisms of Xrp1 activation. Ongoing work from my lab has revealed that RpS12 is involved in alternative splicing of the Xrp1 transcript both in wild-type and in *Minute* cells, producing the short isoform of Xrp1 protein. RpS12 overexpression in wild-type cells is sufficient to activate the Xrp1 pathway. We employ multiple approaches, including genome-wide alternative splicing analysis and proteomic analysis, along with classical genetics, to investigate the mechanism of splicing regulation of Xrp1 by RpS12 and the role of the two Xrp1 isoforms in $Rp^{+/-}$ responses. Our findings will contribute to the elucidation of the mechanisms of the Xrp1 pathway in cell competition, and additionally to the understanding of the underlying causes responsible for the Minute phenotype.

*Eleni Tsakiri (PhD) and Myrto Potiri (MSc) contributed equally in this work

123 **Cryo-EM structure of the retrotransposon Copia capsid hints at structural antagonism with dArc1 to regulate structural synaptic plasticity** Peter G M›Angale[1], Adrienne Lemieux[1], Yumeng Liu[2], Jasmine Graslie[1], Shuhao Wang[1], Brian Kelch[2], Travis Thomson[1] [1]Neurobiology, University of Massachusetts Chan Medical School, [2]Biochemistry & Molecular Biotechnology, University of Massachusetts Chan Medical School

Copia, a Drosophila retrotransposable element, has a physiological role at the Drosophila larval neuromuscular junction (NMJ) where it antagonizes the "master regulator" of synaptic plasticity, the activity regulated cytoskeleton-associated protein 1 (dArc1). Previous presynaptic downregulation of dArc1 resulted in a reduction in plasticity. Our current works shows that synaptic downregulation of Copia at the larval NMJ results in an increase in plasticity, marked by increased number of boutons and activity-dependent plasticity. Interestingly, we observe this phenotype when knocking down the precursor mRNA for the Copia capsid, as Copia is known to form viral-like particles much like dArc1. We determine there is an inverse relationship between Copia and dArc1, as the knockdown of dArc1 results in an increase in Copia mRNA and protein at the NMJ, while the inverse occurs with the knockdown of Copia. Interestingly, the knockdown of Copia in a dArc1 null background indicates that Copia is epistatic to dArc1 and the Copia phenotype is predominant to dArc1 as we observe an increase in plasticity in this genetic background. We observe that Copia acts antagonistically to dArc1 and together regulate structural synaptic plasticity at the larval NMJ. To elucidate the mechanism of Copia-dArc1 function, we employed single-particle cryo-EM methods, and resolved the structure of the Copia capsid to ~3.3-Å. From this structure we observe that Copia self-assembles into T=9 icosahedral capsid-like particles. We therefore formulate that the Copia-dArc1 antagonism could be at the monomer level, where the incorporation of either monomer to the nascent capsids results in the premature termination of the assembly, which we have named the "poison pill" model.

124 **Chromosome-level organization of the regulatory genome in the Drosophila nervous system**Xiao Li[1], Maria Gambetta[2], Michael Levine[1] [1]Princeton University, [2]University of Lausanne

Recent high-resolution 3D contact maps for the *Drosophila* brain have identified 58 meta-loops that hold together 28 pairs of distant topological associating domains (TADs) separated by distances of 1-20 Mb across individual chromosome arms. The meta-loops are formed by both boundary-boundary and tether-tether associations, although the *sns/hbs* TADs appear to be held together solely by tethering elements. *sns* and *hbs* are paralogs that encode similar cell adhesion molecules (CAM) containing Ig and Fn repeats, which are important for the formation of specific synapses in the fly brain. Larval brains obtained from mutants lacking the GAF POZ domain exhibit a specific reduction in sns/*hbs* interactions, resulting in diminished associations of an optic lobe enhancer in the *hbs* regulatory region with the *sns* promoter located ~6.2 Mb away. In addition, deletion of a putative enhancer within the *hbs* TAD led to decreased expression of *sns.* Many of the other meta-loops are also associated with CAMs, such as Dprs (defective proboscis extension response) and DIPs (Dpr-interacting protein). These

interactions are also controlled by sequence-specific tethering elements that work over vast distances and bypass intervening TADs. Understanding the specificity of these long-range interactions would open the door to chromosomal engineering efforts, whereby distant genes could be brought together in shared 3D hubs for coordinate regulation.

125 **Developmental remodeling repurposes larval neurons for sexual behaviors in adult *Drosophila*** Julia A Diamandi, Julia C Duckhorn, Kara E Miller, Mason Weinstock, Sofia Leone, Micaela R Murphy, Troy R Shirangi Villanova University

Most larval neurons in *Drosophila* are repurposed during metamorphosis for functions in adult life, but their contribution to the neural circuits for sexually dimorphic behaviors is unknown. Here, we identify two interneurons in the nerve cord of adult *Drosophila* females that control ovipositor extrusion, a courtship rejection behavior performed by mated females. We show that these two neurons are present in the nerve cord of larvae as mature, sexually monomorphic interneurons. During pupal development, they acquire the expression of the sexual differentiation gene, *doublesex*, undergo *doublesex*-dependent programmed cell death in males, and are remodeled in females for functions in female mating behavior. Our results demonstrate that the neural circuits for courtship in *Drosophila* are built in part using neurons that are sexually reprogrammed from former sex-shared activities in larval life.

126 **Toll-7 acts with Fra/DCC to promote commissural axon guidance across the midline** Sarah Gagnon[1], Yixin Zang[2], Greg J Bashaw[1] [1]Neuroscience, University of Pennsylvania, [2]Columbia

During embryonic development, commissural neurons send their axons across the central nervous system midline to connect to contralateral targets. In flies, the guidance receptor Frazzled (Fra), like its vertebrate ortholog Deleted in Colorectal Cancer (DCC), induces cytoskeletal rearrangements that facilitate growth toward the midline in response to its ligand Netrin. Fra also acts independently of Netrin to activate expression of *commissureless*, a negative regulator of the repulsive axon guidance receptor Roundabout. Fra therefore promotes midline crossing through Netrin-dependent attraction and Netrin-independent inhibition of repulsion. Elucidating the signaling mechanisms of Fra is essential to understanding how distinct receptor outputs are coordinated to achieve precise neural circuit wiring. We performed an affinity purification-mass spectrometry screen in fly embryonic neurons to identify novel Fra interactors and identified the toll-like receptor family member Toll-7. Like Fra, Toll-7 is expressed on commissural axons as they cross the midline. Previous work has shown that Toll-7 promotes motor and olfactory axon targeting, but its earlier developmental functions and potential role in midline circuit formation are unknown. Here we present evidence that Toll-7 acts with Fra to promote axon growth across the midline. Our work reveals that *toll-7* mutant embryos display axon guidance defects reminiscent of *fra* mutants, including defective projection across the midline and breaks in longitudinal axon tracks. Using a sensitized genetic background, we also find that like Fra, Toll-7 promotes midline crossing. Moreover, loss of a single copy of *toll-7* enhances the midline defects of mutants with attenuated Fra signaling, suggesting that Toll-7 promotes midline crossing through the Fra pathway. However, *fra, toll-7* double mutants show more severe midline crossing defects than *fra* single mutants, suggesting that Toll-7 plays additional, Fra-independent roles to promote midline crossing. In addition, biochemical results demonstrate that Fra and Toll-7 physically interact through their cytoplasmic domains. Future experiments will determine which Fra pathway Toll-7 acts through to promote midline crossing, and whether canonical Toll/NF-κB signaling underlies the Fra-independent function of Toll-7. Altogether, our work sheds light on uncharacterized mechanisms of Fra and Toll-7 signaling, providing insight into the assembly of neural circuits.

127 **LET-381/FoxF and UNC-30/Pitx2 control fate specification and maintenance of *C. elegans* mesodermal glia that regulate motor behavior.** Nikolaos Stefanakis[1], Jessica Jiang[1], Yupu Liang[1,2], Shai Shaham[1] [1]The Rockefeller University, [2]Alexion

Glia are cellular components of nearly all nervous systems and are anatomically positioned to affect every aspect of signal transduction and processing. While most glial cells are derived from neuroectodermal precursors, some, like microglia, are mesodermally derived. Mesodermal glia development is not well understood. *C. elegans* glia can broadly be divided into two classes: 46 sensory-neuron associated glia (sheath and socket cells) and ten synapse associated glia consisting of four CEPsh glia and six GLR glia cells, wrapping around the exterior and interior aspect of the *C. elegans* “brain” neuropil, respectively. Unlike sheath, socket and CEPsh glia that derive form a neuroepithelial lineage, GLR glia derive from a mesodermal-like lineage that mainly generates body wall muscle cells. To understand mesodermal glia development and functions we used FACS followed by RNAseq to identify the GLR transcriptome, and assessed how loss of GLR-enriched transcription factors affects GLR gene expression and morphology. Through temporally manipulated mutant analysis and CRISPR/Cas9 mutagenesis we exposed a regulatory network orchestrated by two transcription factors, LET-381/FoxF and UNC-30/Pitx, required for GLR glia development. LET-381/FoxF has an early role in specifying GLR glia fate and is also continuously required to maintain GLR gene expression by autoregulating its own expression. Using online motif analysis tools, we discovered putative *let-381* binding motifs in the promoters of several GLR expressed genes. Mutagenesis of such motifs disrupts endogenous GLR gene expression, suggesting that *let-381* directly controls GLR molecular identity. *unc-30/Pitx2* acts downstream of *let-381* to control GLR glia morphology and to repress gene expression of another mesodermal cell type in GLR glia. Together, *let-381* and *unc-*

30 are sufficient to induce GLR gene expression when ectopically expressed. We used the transcription factor mutants we identified to explore functions of GLR glia, whose anatomy and gene expression profile suggest involvement in motor behavior. Remarkably, GLR-defective animals display various motor behavior defects including increased reversal frequency and locomotory pausing. This study shows that like neurons, glia differentiation requires autoregulatory Terminal Selector genes that define and maintain glial fate. Transcriptome analysis raised the hypothesis that GLR glia may merge astrocytic and endothelial functions suggesting that GLR glia may represent a fate-merger combining characteristics of different vertebrate Blood Brain Barrier cells. Future studies deciphering roles of GLR glia in the function of the *C. elegans* nervous system may thus be crucial for a deeper understanding of the evolution of glia and brain barriers.

128 **A gene expression program induced by neuronal inactivity that regulates neuronal plasticity** Zhonghua Zhu[1], Jennifer Lennon[1], Seana Lymer[1], Justin Blau[2] [1]NYU Biology Department, [2]Biology, NYU Biology Department

Synaptic plasticity is essential for many processes including learning and memory, while defective plasticity is associated with neurological conditions such as autism spectrum disorder. We are using the dramatic daily structural plasticity of the Drosophila circadian pacemaker sLNv neurons to identify novel plasticity pathways.

Like many neurons, sLNvs use activity-regulated genes (ARGs) – also known as immediate early genes (IEGs) – that are rapidly activated via sLNv firing and increase the size of sLNv projections. We previously showed that rhythmic expression of the Rho1 GEF Pura drives the daily retraction of sLNv projections by rhythmically activating the Rho1 GTPase. Here we show that a Pura transcriptional reporter gene is repressed by neuronal activity and induced by hyperpolarization, which is the opposite of an ARG. Activation of Pura transcription by neuronal inactivity requires the transcription factor Toy, whose expression itself is also induced by hyperpolarization. Therefore, toy and Pura are inactivity-regulated genes (IRGs). We also show that toy transcription is induced by decreasing intracellular calcium – again opposite to ARGs. Thus intracellular calcium levels seem to represent two cellular states that act as a binary switch to control distinct gene expression programs: high calcium induces ARGs while low calcium induces IRG expression. Toy is an ortholog of mammalian Pax6, which is expressed in many adult neurons. We propose that inactivity-regulated genes are a general property of plastic neurons.

129 **Balancing act: exploring pH dynamics in stem cell fate regulation** Bernice Lin[1,2], Isabella Maag[1], Ashley Bielawski[1], Beverly Piggott[1,2,3] [1]Division of Biological Sciences, University of Montana, [2]Neuroscience, University of Montana, [3]Center for Biomolecular Structure and Dynamics, University of Montana

It has traditionally been held that cells strictly maintain their pH within a narrow physiological range, with deviations occurring mainly in disease states like cancer (leading to a more basic pH) or neurodegeneration (resulting in a more acidic pH). However, an increasing body of evidence suggests that different cell types, across species, do not merely regulate their pH to prevent pathology but actively fine-tune their pH levels to govern molecular interactions and cellular behaviors. Sodium (Na^+) proton (H^+) exchangers (Nhes) play a pivotal role in intracellular pH (pHi) regulation by facilitating the efflux of H^+ ions in exchange for the influx Na^+ ions. The influx of Na^+ ions has been observed to influence mitotic swelling due to hydrostatic interactions, thereby elevating pHi. While it has long been supported that a relatively basic pHi supports cell proliferation, the extent to which cells inherently control pH to optimize molecular mechanisms of asymmetric division remains elusive. *Drosophila* neuroblasts (NB), the neural stem cells of the *Drosophila* brain, serves as a powerful model to study neural stem cells *in vivo* thanks to their highly conserved mechanisms and precise genetic tools. While there are nine NHE (NHE1-9) proteins in humans, there are only three in *Drosophila* (*dnhe1-3*), providing a straightforward model to study the role of Nhes in neurogenesis. Our preliminary data has identified critical roles for Nhe proteins in brain development. We find that loss or knockdown of Nhes reduces proliferation. Using a genetically encoded pH sensor, we find that NB are more basic than their differentiated progeny. Our data suggests that Nhes may also regulate cellular division machinery, as Nhe knockdown manifests in defects that result in smaller brain sizes. Our hypothesis posits that Nhe proteins regulate stem cell fate and proliferation by maintaining a basic pHi that supports neuroblast physiology and behavior. Given that mutations in human NHEs are associated with various neurodevelopmental disorders like Christianson syndrome, microcephaly, and cognitive impairment, these findings may offer valuable insights for future therapeutic interventions.

130 **Ancient enlargement of complex neuronal genes** Matthew J McCoy[1], Andrew Z Fire[2] [1]Pathology, Stanford University School of Medicine, [2]Pathology and Genetics, Stanford University School of Medicine

The evolutionary origins of nervous systems and their complex wiring are key questions in biology. This study investigates a distinct class of extremely large, multi-isoform genes enriched for expression in neurons at synapses. These genes, often spanning hundreds of thousands to millions of base pairs in the genome, are frequently mutated or misregulated in neurological disorders. While many of these genes have been studied individually, it remains unknown whether there are any overarching principles governing their parallel evolution. To address this, we conducted a comparative analysis of orthologous

gene sizes across diverse eukaryotes. Our findings reveal a unique class of large genes predating animal diversification and in many cases the evolution of neurons. We traced this class of ancient large genes through evolution and found orthologs of the large synaptic genes implicated in driving the immense complexity of metazoan nervous systems, including in humans and cephalopods. Notably, these genes exhibit low dN/dS scores, indicating strong purifying selection, yet have simultaneously undergone enlargement and gained numerous isoforms in animals. This research provides a new lens through which to view the evolution of this distinctive gene class, and highlights how intrinsic genomic properties, like gene length, can provide flexibility in molecular evolution and allow groups of genes and their host organisms to evolve toward complexity.

131 **Elucidating shared and dimorphic circuitry regulating aggression in *Drosophila*** Catherine E Schretter[1], Hui Chiu[2,3], Mei Shao[1], Alice A Robie[1], Kristin M Branson[1], David J Anderson[2], Gerald M Rubin[1] [1]Janelia Research Campus of HHMI, [2]California Institute of Technology, [3]Yale

The regulation of aggression has important implications for survival as its engagement risks injury and alters group dynamics. Both male and female fruit flies, *Drosophila melanogaster*, display aggression, yet there are sex-specific differences in component behaviors and environmental contributions. Previous work by our lab and others implicated two neuronal populations in aggression, CAP and aIPg, which modulate approach behavior in both sexes and female aggressive behavior, respectively (Chiu et al., 2021; Schretter et al., 2020). However, it has previously been difficult to elucidate the connections between such shared and sexually dimorphic neuronal mechanisms due to the lack of a complete circuit diagram.

In the present study, we used the female fly connectome to map the connections between these cell types, elucidating the circuit components and environmental variables that underly monomorphic and dimorphic components of aggression. Further, we uncovered a novel glutamatergic cell type that appears to downregulate aggression in both sexes. In addition to furthering our understanding of aggressive behaviors, this work has important implications for uncovering how the brain flexibly regulates social behaviors in both sexes.

132 **Experience-dependent control of sex-specific cadherin expression defines sexually dimorphic neurite adjacency and synaptic connectivity** Chien-Po Liao[1], Maryam Majeed[2], Oliver Hobert[3,4] [1]Biological Sciences, Columbia University, [2]Allen Institute for Brain Science, [3]Biological Science, Columbia University, [4]Howard Hughes Medical Institute

Juvenile experiences can shape sexually dimorphic synaptic connectivity in the nervous system of the nematode *C. elegans*. We reveal here the molecular mechanisms that establish the juvenile starvation-dependent and sex-specific innervation of the AVA interneuron by the PHB sensory neuron. We show that food-dependent serotonin signaling in the PHB sensory neuron of juvenile animals establishes proper expression of the Zn finger transcription factor LIN-29A via G-protein coupled 5HT receptor signaling and the CREB transcription factor, specifically in male animals. Through the regulation of an intermediary, Doublesex-like transcription factors, DMD-4, male-specific LIN-29A represses the expression of an atypical cadherin protein FMI-1/Flamingo in PHB. In hermaphrodites, FMI-1 promotes the physical adjacency of the PHB and AVA neurites thereby enabling *en passant* synaptic innervation. The experience- and serotonin-dependent promotion of LIN-29a expression in male PHB results in FMI-1 downregulation, resulting in decreased PHB/AVA adjacency and therefore limiting PHB>AVA connectivity in males. Our findings reveal the dynamic control of neurite adjacency as a mechanism for controlling dimorphic synaptic connectivity.

133 **Regulation of Sex Differences in Innate Immunity by Sex-Determining Gene *transformer* in *Drosophila*** MD Mursalin Khan, Rita Graze Biological Sciences, Auburn University

Sex dimorphism is a common fundamental characteristic of sexually reproducing organisms, exerting influence over nearly all aspects of life history. However, the regulation of genes underlying sex dimorphism is underexplored for many complex traits, including immunity. To investigate the regulatory basis of sex dimorphism in immunity in Drosophila, we focused on a key switch gene of the sex determination hierarchy, *transformer (tra)*. Animals with wild-type sex determination, XX and XY, were compared to *tra*-mutant animals lacking functional Tra and *tra*-overexpression animals expressing Tra ubiquitously. Survival, bacterial load, and transcriptomic profiles were assessed in controls and upon infection with *Providencia rettgeri* Dmel, a pathogenic strain collected from *Drosophila melanogaster*. To the best of our knowledge, this is the first genomic analysis delineating the nature and extent of the role of *tra* in regulating sex dimorphism of the immune response in insects. We find that *tra* likely regulates observed sex differences in survival as well as sex differences in the expression of core innate immune response pathways. Our study identifies a significant regulatory role of *tra,* or its downstream targets, in the expression of genes involved in Toll signaling with significant enrichment, including signal detection, transduction, antimicrobial peptides, and negative regulators of the pathway. We also find key genes in the IMD pathway show patterns consistent with regulation by or downstream of *tra*, but genes in this pathway are not significantly enriched amongst the putative targets identified in this analysis. In addition, the overexpression of Tra^F in XY animals results in a surprising outcome, much higher survival relative to both XX and XY controls, and an altered pattern of bacterial load over time. This suggests that increased dosage or the altered expression pattern of Tra^F in *tra*-overexpression animals drives increased efficiency of the immune response. Overall,

our results point to a complex role of the sex determination pathway in modulating sex dimorphism of the immune response and suggest a need for further exploration of the direct regulators and individual targets, as well as the dynamics of expression during infection.

134 **Functional genomics of sexual dimorphism : Doublesex mediates sex-specific control of ultraviolet iridescence in sulphur butterflies** Ling Sheng Loh[1], Martina Tsimba[2], Joseph J Hanly[2,3], Arnaud Martin[2] [1]Biology, George Washington University, [2]George Washington University, [3]Duke University

What is the genetic regulatory logic behind the elaboration of sexually dimorphic traits during evolution? To answer this question, we are deciphering the regulatory factors behind the development of ultraviolet iridescence in sulphur butterflies, a color signal involved in male courtship displays. Given that this trait is absent or found in rudimentary states in females, it is likely maladaptive in this sex, presumably due to the added conspicuity to bird predators with UV vision. Based on phylogenetic analyses, it is likely that the evolution of UV-iridescence was accompanied by regulatory mechanisms to repress the UV trait in females. In the orange sulphur butterfly Colias eurytheme, UV color scales are repressed by the Bric-a-brac (Bab) transcription factor, but it remains unclear how the expression of this gene became sexually dimorphic. Here we sought to elucidate this question using single-nuclei transcriptomics, ChIP-seq, fluorescent mRNA/protein stainings, and CRISPR/Cas9 induced gene knock-outs. Single-nuclei transcriptomes in four time points during pupal wing development revealed upstream components in UV cell fate determination. We found that Doublesex (Dsx) and bab are expressed in a mutually exclusive manner in wing scale precursor cells, implying that Dsx repressed Bab in males. ChIP-seq profiling of these two modulators of sexual differentiation further refines the potential target genes involved in UV-scale differentiation, including the identification of negative feedback loops reinforcing somatic sex identity. Functional knockouts confirmed the roles of Dsx and bab in the binary decision of recruiting or repressing the UV scale-making network, bringing in the interaction of sex-determinating factor dsx and a sex-linked gene bab in regulating an ancestral gene network underlying a sexually dimorphic trait.

135 **The TGF-β hormone *amh* is a convergently evolved sex determination gene in threespine stickleback (*Gasterosteus aculeatus*)** Matthew Treaster, Michael White Department of Genetics, University of Georgia

Master sex determination genes have evolved independently in many taxa. Across vertebrates, a wide variety of genes are used to initiate the critical developmental process of sex determination. However, the gene *anti-mullerian hormone* (*amh*) has convergently evolved as a sex determination gene in multiple species of teleosts. Ancestrally, *amh* is dispensable for male determination, thus how *amh* initiates testis development in some species and how it repeatedly evolves this novel function is not known. In threespine stickleback (*Gasterosteus aculeatus*), *amh* was duplicated onto the Y chromosome (*amhy*) approximately 20 million years ago. To determine whether the Y-linked *amhy* is the master sex determination gene in this species, we have targeted two different exons with CRISPR/Cas9 to knock out *amhy*. Histology of XY *amhy*-KO gonads shows complete male to female sex reversal. XY *amhy*-KO fish produce fully developed ovaries with mature oocytes rather than testes, demonstrating that *amhy* is necessary for male sex determination. To test whether *amhy* is sufficient for male sex determination, we have introduced a CMV-driven *amhy* transgene into XX fish and will analyze these XX *tg(CMV:amhy)* fish for female to male sex reversal. Preliminary characterization of the transcriptome across development shows that *amhy* is expressed more highly than its autosomal paralog, *amh08*, in larval stickleback while *amh08* is expressed more highly in adult testes. This expression divergence highlights clear regulatory evolution that has occurred during neofunctionalization of *amhy* as a sex determination gene. To identify the core regulatory elements responsible for this novel function, we have created a transgene consisting of *amhy* and its surrounding non-coding sequence from the Y chromosome. Our findings establish threespine stickleback as a powerful model to investigate how *amh* regulates gonadal development and how this gene repeatedly evolves novel function as a master sex determination gene.

136 **The RNA-binding protein, Rbpms2, regulates mTOR signaling via the GATOR2 complex protein, Mios, to promote oogenesis and female fate in zebrafish** Miranda L Wilson[1], Shannon Romano[1], Nitya Khatri[1], Devora Aharon[1], Yulong Liu[2], Odelya Kaufman[3], Bruce Draper[2], Florence Marlow[1,3] [1]Cell, Developmental, and Regenerative Biology, Icahn School of Medicine at Mount Sinai, [2]University of California, [3]Albert Einstein College of Medicine

Differences of sexual development (DSDs) occur in 1:5000 live births and encompass various congenital conditions with diverse phenotypes resulting from genetic, developmental, or hormonal anomalies that arise during embryogenesis and persist throughout sexual development into adulthood. RNA binding proteins (RNAbp) control post-transcriptional gene expression and have been implicated in sex determination and DSDs. We previously identified the vertebrate specific RNAbp of multiple splice forms 2 (Rbpms2) as a positive regulator of female sex determination in zebrafish. To determine how Rbpms2 promotes oocyte development, we isolated Rbpms2-bound RNAs in adult ovaries (*rboRNAs*). We find that these *rboRNAs* are associated with testis and ovary fates, suggesting Rbpms2 functions to both repress testis and promote ovarian developmental pathways. Further, our data indicate Rbpms2 regulates *rboRNAs* via translational control. We evaluated potential ovary

promoting *rboRNAs* and their associated pathways, particularly ribosome biogenesis-related targets as *rbpms2*$^{-/-}$ oocytes have nucleoli deficits. Specifically, we investigated the Gator2 component Mios (missing oocyte), which activates the ribosome biogenesis-associated mTorc1 pathway. We show that *mios* contains Rbpms binding sites in its 3' UTR and that Mios is absent in *rbpms2*$^{-/-}$, placing Mios downstream of Rbpms2. Further, *mios*$^{-/-}$ have nucleoli deficits and develop exclusively as fertile males. To evaluate mTorc1 signaling in ovary determination, we genetically reduced negative regulators, *SPO11 initiator of meiotic double stranded breaks* (*spo11*) and *TSC complex subunit 2* (*tsc2*), in *mios*$^{-/-}$. We show that loss of *spo11*, unlike in *Drosophila* (*mei-W68*), failed to restore oogenesis in *mios*$^{-/-}$. Similarly, reducing Tsc2 or constitutive activation of its downstream target Rheb (Ras homolog, mTor binding) was insufficient to suppress oocyte loss. Conversely, germline expression of constitutively active *mTOR* restored oogenesis in *mios*$^{-/-}$. Cumulatively, our results indicate early gonocytes are in a poised bipotential state where an RNAbp-mediated binary fate switch dynamically regulates testis and ovary-specific factors and activates a Gator2-mediated oogenesis checkpoint, integrating sexual differentiation and nutrient status during zebrafish sex determination. Further, our findings have broader implications for understanding the genetic mechanisms regulating sex determination, differentiation, and DSD etiology in humans.

137 **Combining transcriptomic and epigenetic data to understand the sources of sex-specific ageing in bats** Jack Rayner, Danielle M. Adams, Gerald Wilkinson Department of Biology, University of Maryland, College Park

Lifespan differs dramatically across taxa, but extensive variation in size, life history, and large phylogenetic distances complicate interpretation of these differences. Lifespan is also frequently found to differ drastically between sexes of the same species, a nuance that is often missing from phylogenetic comparisons. Given that sexes largely share a genome, exaggerated differences in sex-specific survival offer a promising avenue for illuminating non-genetic factors associated with ageing and longevity. Bats are a model taxon for ageing research, typically living considerably longer than other mammals of a comparable size. However, as in many fields of biology, sex differences in longevity of bats and other species are often overlooked. These sex differences are sometimes striking: for example, we find that females of the greater spear-nosed bat live more than twice as long as males of the same species. To address this, we have collected gene expression and methylation data from males and females of multiple bat species, across a representative range of ages, to compare transcriptomic and epigenetic signatures of ageing. By incorporating intra- and interspecific sources of variation, we can begin to disentangle forces of sexual and natural selection underlying patterns of ageing and longevity in this exceptionally long-lived lineage. For instance, in species exhibiting striking sex-differences in longevity, accelerated patterns of ageing and biological dysfunction in the shorter-lived sex might illustrate the effects of divergent life history strategies shaped by sexual selection. Our findings will inform understanding of the evolutionary forces shaping age-related variation and lifespan, with particular attention to sex differences, and contribute to knowledge of signatures and potential of ageing more broadly.

138 **Ancient structural variation controls heterodichogamy across Juglandaceae** Jeffrey Groh[1], Kristian Stevens[2], Pat J. Brown[3], Charles H. Langley[1], Graham Coop[1] [1]Evolution and Ecology, University of California, Davis, [2]Computer Science, Evolution and Ecology, University of California, Davis, [3]Plant Sciences, University of California, Davis

The maintenance of stable mating type polymorphisms is a classic example of negative frequency dependent sexual selection, the principle underlying nearly ubiquitous 50/50 sex ratios in species with separate sexes. One lesser known but intriguing example of sex ratio selection resulting in a balanced mating polymorphism in some angiosperms is heterodichogamy - polymorphism for opposing directions of sequential hermaphroditism. While rare and poorly understood, this mating system is characteristic of Juglandaceae, the family that includes important nut and timber crops, the walnuts (*Juglans*), pecans and hickories (*Carya*). We show that the genetic locus controlling alternate flowering morphs (H-locus) in *Juglans* is an ancient balanced polymorphism that arose in the common ancestor of the genus, ~60 Mya. The *Juglans* H-locus maps to a ca. 10kb structural variant adjacent to a flowering time gene, a homolog of which regulates flowering time in Arabidopsis. An insertion in the dominant (protogynous) haplotype contains 8-12 complex tandem duplicates of the 3' UTR of the gene, whereas the recessive haplotype contains a derived CACTA-like DNA transposon. A phylogeny of repeats in the protogynous haplotype reveals both deep conservation of ancestral repeats as well as lineage-specific repeat turnover. We examine the functional relevance of these repeats for gene expression of the candidate flowering gene. We find that the H-locus is not shared across genera within Juglandaceae, and that a separate, non-syntenic structural variant controls flowering morphs in *Carya*. Finally, we discuss potential mechanisms underlying the lability of the genetic basis for heterodichogamy.

139 **The Interplay of peroxisome and mitochondrial dynamics during aging in Drosophila melanogaster** Ankur Kumar[1], Hua Bai[2] [1]Genetics Development and Cell Biology, Iowa State University, [2]Iowa State University

Healthy mitochondria play an essential role in maintaining cellular homeostasis. It is known that mitochondrial structure and function are impaired during aging, likely due to dysregulated mitochondrial fission and fusion processes. Through TEM and confocal imaging analysis, we find that mitochondrial size increases in aged oenocytes, the hepatocyte-like cells in Drosophila. Interestingly, we find that mitochondria from aged oenocytes do not exhibit paraquat-induced mitochondrial fission in contrast

to young flies. Additionally, aged flies have decreased numbers of mitochondria but increased size compared to young flies. Our preliminary studies suggest impairment in peroxisomal function in adult oenocytes results in mitochondrial morphology alterations similar to the old flies. However, peroxisomal impairment in indirect flight muscle did not show mitochondrial morphology alteration.Further imaging analysis showed that muscles have fewer peroxisomes than the oenocytes, which again supports the involvement of peroxisomes in regulating mitochondrial morphology. Therefore, we screened peroxisomal genes; among those, only Gnpat showed similar mitochondrial morphology. Further, we find that the knockdown of plasmalogen biosynthesis enzymes (e.g., Gnpat and Kua/PEDS1 Glyceronephosphate O-acyltransferase) blocks paraquat-induced mitochondrial fission and the recruitment of fission factor Drp1 to mitochondria, which was also confirmed by utilizing our newly developed live cell imaging technique. We discovered the decrease of mitochondrial plasmalogen C18:0/C18:1-PE aged flies using Mass spectrometry. To discover the involvement of plasmalogen in mitochondrial fission, we performed the lipid pull-down assay using synthetic biotinylated C18:0 plasmalogen PE (pPE) and identified interacting mitochondrial fission proteins such as Drp1 and Mff. To further validate the interacting partner, we pulled down the crude mitochondrial extract, which showed that the Drp1 and Mff interact with biotinylated pPE. Together, our findings suggest that the peroxisomal plasmalogen synthesis pathway plays an important role in maintaining normal mitochondrial health during animal aging.

140 **Defective phagocytosis leads to neurodegeneration through systemic increased innate immune signaling in *Drosophila*.** Guangmei Liu, Johnny Elguero, Shruthi Bandyadka, Zhenhao Yan, Cheng Yang Shi, Iqra Amin, Kim McCall Boston University

In nervous system development, disease, and injury, neurons undergo programmed cell death, leaving behind cell corpses that are removed by phagocytic glia. Altered glial phagocytosis has been implicated in several neurological diseases including Alzheimer's disease, Parkinson's disease, and traumatic brain injury. To untangle the links between glial phagocytosis and neurodegeneration, we investigated *Drosophila* mutants lacking the phagocytic receptor, Draper. Expressed on the membrane of phagocytes, Draper plays a crucial role in recognizing and engulfing dead cells and debris. Loss of Draper in glia leads to persistent neuronal cell corpses and age-dependent neurodegeneration. The presence of uncleared cell corpses and debris can act as activators to trigger increased immune signaling. We wondered whether neurodegeneration observed in *draper* mutants results from heightened immune activity. A major immune response in *Drosophila* is the activation of two NFκB signaling pathways that produce antimicrobial peptides, primarily in the fat body. In alignment with our hypothesis, we found that the antimicrobial peptide Attacin A is highly upregulated in the fat body of aged *draper* mutants and that inhibition of the Immune deficiency (Imd) pathway in the glia and fat body of *draper* mutants led to reduced neurodegeneration, indicating that immune activation promotes neurodegeneration in *draper* mutants. Immune activation in the central nervous system is characterized by the presence of activated, pro-inflammatory glia as well as infiltrating peripheral immune cells. Thus, we wondered if peripheral immune cells, hemocytes, react to glial phagocytic defects and invade into brain as flies age. We utilized hemocyte reporter line in *draper* mutants and found that hemocytes cluster at the pars intercerebralis in the central brain. To further dissect the role of immune signaling in peripheral (e.g., fat body and hemocytes) and local (e.g., glia) tissues in promoting age-dependent neurodegeneration in *draper* mutants, we performed snRNA-seq in fly heads to delineate differentially transcribed mRNAs in these tissues. snRNA-seq data will be presented in the conference. Taken together, these findings indicate that phagocytic defects lead to neurodegeneration via increased systemic and local immune signaling.

141 **Probing the mechanism of ROS-induced glial lipid droplet formation and implications for Alzheimer's disease** Matthew Moulton[1], Scott Barish[1], Isha Ralhan[2], Jinlan Chang[2], Lindsey Goodman[1], Jake Harland[1], Paul Marcogliese[3], Maria Ioannou[2], Hugo Bellen[1] [1]Molecular & Human Genetics, Baylor College of Medicine, [2]Physiology, University of Alberta, [3]Biochemistry and Medical Genetics, University of Manitoba

With an ever-growing list of Alzheimer's disease (AD) genetic risk factors, it is increasingly important to delineate the contribution of risk alleles on disease mechanisms. The apolipoprotein, APOE, is the highest known genetic risk factor for AD, implicating lipid dysregulation in AD pathogenesis. We have developed a model of reactive oxygen species (ROS)-induced glial lipid droplet (LD) formation and neurodegeneration in the fly. We have shown that elevated ROS in neurons triggers the production of lipids that become peroxidated by ROS. Peroxidated lipids are shuttled out of neurons and taken up by glia where they accumulate in LDs. Glial LD formation requires expression of an ortholog of APOE, *Glial Lazarillo* (*GLaz*). Targeted replacement of *GLaz* with expression of human variants of APOE demonstrates that the AD-associated allele, APOE4, reduces glial LD formation and promotes neuronal demise but APOE2 and APOE3 both facilitate LD formation and protect against neurodegeneration. We have identified additional genes required for glial LD formation that overlap with AD risk loci identified in genome wide association studies including *eato* (*ABCA1*), *ldd* (*ABCA7*), *LRP1* (*LRP1*), *VPS26* (VPS26A/B), *VPS35* (VPS35), *AP-2α* (AP2A2), *lap* (*PICALM*), and *cindr* (*CD2AP*). We now seek to understand the effects of variation in these AD risk genes on lipid transport between neurons and glia using novel humanized fly models.

Lipid dysregulation may also affect Aβ42-induced neurotoxicity. APOE4 carriers have higher rates of amyloid deposition and

lower rates of amyloid clearance than non-carriers, suggesting an interplay between lipid transport and Aβ42 clearance. Aβ42 is a lipophillic molecule that binds to APOE and an APOE receptor, LRP1. Thus, we hypothesize that LD formation in glia may contribute to the clearance of Aβ42 by promoting its cellular uptake and degradation. In the presence of ROS, however, we demonstrate that the neurotoxic effects of Aβ42 are enhanced in both fly and mouse models suggesting that efforts to mitigate Aβ-inducted neurotoxicity should be coupled with ROS mitigation strategies. We further demonstrate that ROS-mediated neurodegeneration can be abrogated by the use of a blood-brain-barrier penetrating antioxidant, N-acetylcysteine amide. Altogether, our data implicate a link between lipid uptake, ROS, Aβ production, and neurodegeneration and suggest that ROS mitigation could be an important therapeutic strategy for AD.

142 **Dissecting cutaneous wound healing in zebrafish** Leah Greenspan[1], Keith Ameyaw[2], Daniel Castranova[1], Van Pham[1], Gennady Margolin[3], Caleb Mertus[3], Brant Weinstein[1] [1]NICHD, National Institutes of Health, [2]Albert Einstein College of Medicine, [3]National Institutes of Health

Two percent of the US population is plagued by open chronic wounds, with a delay in vascular reperfusion being a major contributor to wound closure defects. This delay often occurs in aged or diabetic adults resulting in impaired healing, yet how and why this delay occurs remains unclear. Mammalian models have provided insight into the cell types and signals driving different phases of wound healing, but these models do not permit high-resolution imaging of the healing process in living animals, making it difficult to study transient events and cell-cell interactions. Zebrafish are ideal for visualization and experimental dissection of cutaneous wound healing in the context of an intact, living animal, with numerous transgenic lines available that mark relevant cell populations and powerful methods for high-resolution imaging of these lines. We have established a reproducible cutaneous wound model in zebrafish using a rotary tool combined with cellular-level long-term confocal imaging of wounds in living adult fish. We find that skin re-epithelialization and neutrophil recruitment initiates within hours after injury and peaks at one day, while macrophage activity and vessel regrowth increase between 1-4 days post injury, and vessel re-patterning takes many additional months. We are currently using our new model to study how wound healing is altered in aging and diabetic fish. We have also successfully established a method for *in vivo* profiling of endothelial cells using TRAP-RNAseq of “AngioTag” transgenic fish, demonstrating that this method can be used to uncover tissue- or organ-specific endothelial gene expression signatures. We are now using this technique to study the endothelial gene expression changes that occur during wound healing and how these are altered in the elderly and diabetics. Together, these studies will uncover the cellular and molecular mechanisms that restore vascular networks after cutaneous injury, providing potential new targets for therapeutic approaches.

143 **Tissue-specific temporal responses to aging in *Drosophila melanogaster* transcriptome** Maryam Nasiri Aghdam[1,2], Vijay Shankar[3], Maria E Adonay[3], Desireé Unselt[4], Robert Anholt[3], Trudy Frances Charlene Mackay[3] [1]Clemson University, [2]Departamento de Biología Molecular y Genómica, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, [3]Clemson University Center for Human Genetics, Clemson University, [4]Q² Solutions

The aging process encompasses intricate molecular dynamics across various tissues, exerting a significant influence on lifespan. *Drosophila melanogaster*, characterized by its swift generation cycles and controlled laboratory conditions, provides an optimal model for investigating these intricacies. Nonetheless, our understanding of tissue-specific molecular alterations during aging in this species remains limited. Employing longitudinal transcriptomic analysis on an advanced intercross population (AIP) of *D. melanogaster* across 11 time points and in diverse tissues (head, body, and reproductive), we discerned temporal trends in gene expression profiles. Time-dependent shifts from day 5 revealed a prevailing downward trend in male tissues and female body tissue, while female head and reproductive tissues exhibited an upward trend. A decline in key pathways, such as the tricarboxylic acid (TCA) cycle and amino acid biosynthesis, is consistently observed across both male and female tissues. An upregulation in xenobiotic metabolism through cytochrome P450, as well as galactose and glutathione metabolism, is shared across the sexes. In contrast, specific pathway modifications exhibit tissue-specific patterns. For instance, the sphingolipid metabolism pathway demonstrates an exclusive elevation in the female head tissue, while the DNA replication and repair pathways manifest an increase solely in the male head tissue. Furthermore, our analysis revealed differential regulation of pathway expression, with some tissues displaying an increase while others exhibit a decrease in overall pathway expression. Among the genes exhibiting the most substantial age-related variation, we identified alterations in the expression of *trbd*, *Mic26-27*, *SdhD*, *SERCA*, and *Ide*, which have previously been associated with lifespan. Additionally, we uncovered new age-related candidates with tissue-specific expression over time, including *Arc1*, *UQCR-C1*, *Apt1*, and *IBIN*. In summary, the aging process elicits distinct responses within various tissues. Notably, essential pathways like the TCA cycle and redox signaling continue to play crucial roles in determining lifespan in Drosophila. Finally, the emergence of novel age-related genes offers valuable insights into unexplored complexities associated with the aging process.

144 **Addressing Mendelian neurodegeneration: genome engineering of mouse models for X-linked dystonia-parkinsonism** Yu Jeremy Zhao[1], Weimin Zhang[1], Priya Prakash[2], Heather Appleby[1], Yinan Zhu[1], Ran Brosh[1], Shane Liddelow[2], Jef

D. Boeke[1] [1]Institute for Systems Genetics, NYU Langone Health, [2]NYU Langone Health

X-linked Dystonia-Parkinsonism (XDP) is a severe hereditary form of Parkinsonism endemic to the Philippines, caused by an SVA (SINE-VNTR-Alu) retroelement insertion in the *TAF1* gene that disrupts its normal splicing and expression. The specificity of XDP to human gene structure and the complexity of repetitive retroelement sequences present significant obstacles in creating accurate mouse models through direct genome editing.

Leveraging our expertise in large-scale DNA assembly, we aim to address this challenge with a genome writing approach. We engineered mouse embryonic stem cells (mESC) to include an XDP patient-derived *TAF1* gene downstream of the mouse *Taf1*. Upon Cre-mediated recombination, this locus converts by replacing exons 25-38 with a hybrid region that combines mouse protein-coding sequences and human gene structure. Our *in vitro* analyses confirm that the "humanized" *Taf1* gene undergoes proper splicing and preserved multiple known mouse and human splice isoforms. Utilizing these modified mESCs, we generated pre-converted TAF1/XDP mouse models and subsequently crossed them with Cre drivers to induce tissue-specific conversions. *In vivo* characterization revealed that neuronal-specific expression of the hybrid *Taf1* with the SVA insertion dramatically reduced brain size, enlarged lateral ventricles, and caused significant striatal and hippocampal pathology. Moreover, XDP male mice displayed irregular gait and reduced motor performance, similar to human XDP patients' symptoms.

We will introduce additional genetic variants, including age-related hexanucleotide repeats within the SVA element, to explore their inverse relationship with disease onset. Furthermore, this project represents our capability to design, construct, and deliver large DNA constructs (>100 kb) for genome writing in mammalian systems. Ultimately, our work sets the stage for addressing complex biological questions and genetic variations, establishing a foundation for collaborative exploration.

145 **Uncovering shared and neuron-specific targets across ALS and FTD relevant circuits in Drosophila models of TDP-43 proteinopathy** R. Keating Godfrey[1,2], Eric Alsop[3], Reed T Bjork[4], Lauren M Gittings[5], Rita Sattler[5], Kendall Van Keuren-Jensen[3], Daniela C Zarnescu[6,7] [1]University of Florida, [2]Department of Biological Sciences, Florida International University, [3]Translational Genomics Research Institute, [4]Department of Neuroscience, University of Arizona, [5]Dept. of Translational Neuroscience, Barrow Neurological Institute, [6]Cellular and Molecular Physiology, Penn State College of Medicine, [7]Department of Molecular and Cellular Biology, University of Arizona

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) comprise a spectrum of neurodegenerative diseases linked to TDP-43 proteinopathy, defined as the accumulation of cytoplasmic TDP-43 inclusions accompanied by loss of nuclear TDP-43. Proteinopathy ultimately causes RNA processing defects including dysregulation of splicing, mRNA transport and translation. Complementing our previous work in motor neurons, here we report a novel model of TDP-43 proteinopathy based on overexpression of TDP-43 in a subset of *Drosophila* Kenyon cells of the mushroom body (MB). This model recapitulates several aspects of dementia-relevant pathological features including age-dependent neuronal loss, nuclear depletion and cytoplasmic accumulation of TDP-43, and behavioral deficits in working memory and sleep that occur prior to axonal degeneration. Using RNA immunoprecipitations, we identify several candidate mRNA targets of TDP-43 in MBs, some of which are unique to the MB circuit and others that are shared with motor neurons that we have previously reported. Among the latter is the glypican Dally-like-protein (Dlp), which exhibits significant TDP-43 associated reduction in expression during aging. Bioinformatic analyses of candidate mRNA targets associated with TDP-43 in MBs highlight several signaling pathways including Hippo and wingless among others. Using genetic interaction approaches we show that overexpression of Dlp in MBs mitigates TDP-43 dependent working memory deficits, consistent with Dlp acting as a mediator of TDP-43 toxicity. Substantiating our findings in the fly model, we find that the expression of *GPC6* mRNA, a human ortholog of *dlp,* is specifically altered in neurons exhibiting the molecular signature of TDP-43 pathology in FTD patient brains. Furthermore, we identify several MB specific candidate targets of TDP-43 that are also altered in FTD patient brains and encode proteins associated with transcription, synaptic activity and proteasome mediated degradation. These findings suggest that circuit-specific *Drosophila* models provide a platform for uncovering shared or disease-specific molecular mechanisms and vulnerabilities across the spectrum of TDP-43 proteinopathies.

146 **Profiling Transcriptomics and Chromatin Accessibility Reveals Molecular Changes Associated with Protective Effects Induced by Priming** Hsin-Yun Chang, Siu Sylvia Lee Cornell University

Hormetic stress, where exposing the body to mild doses of stress, such as hot saunas and intermittent fasting, is thought to improve its resilience during later challenging times and have been popularized as health promoting regimens. While this phenomenon is well-documented across species, much remains to be learnt about the underlying molecular mechanisms, particularly regarding how priming can improve stress resilience and confer physiological benefits over a range of timescales. In this study, we developed a robust regimen where *C. elegans* were "primed" by transient exposure to mild heat stress, followed by recovery, and subsequent lethal heat shock challenge. We observed that the primed worms show consistently heightened

resistance to a later heat shock challenge, including better survival and motility, compared to naive worms. To investigate the possible gene regulatory mechanisms of this priming-induced protective effects, we performed ATAC-seq and RNA-seq at different timepoints, including immediately after priming, after recovery, and upon heat shock challenge. We hypothesized that changes in both chromatin accessibility and RNA expression would provide insights into possible molecular mechanisms of the protective effects. We found that mild heat stress priming and heat shock challenge both induce substantial changes in chromatin accessibility and RNA expression. Interestingly, the priming-induced changes are largely distinct from those induced by heat shock, suggesting that different levels of heat stress induce distinct molecular changes. Excitingly, while most priming-induced changes are restored after recovery, primed and naïve worms exhibited significant differential chromatin accessibility and RNA expression upon heat shock challenge. These differences likely point to candidate genes that contribute to the priming-induced beneficial effects. We have initially focused on the genes that showed correlated changes in chromatin accessibility and RNA expression in the primed worms, which include annotated transcription and chromatin factors, and lipid metabolism regulators. We are continuing with data comparison and functional testing of the identified candidate genes to gain better understanding of the temporal dynamics of gene regulatory mechanisms that contribute to priming-induced beneficial effects. In the long term, our study will likely provide important insights into how hormetic stress promotes stress resilience and health.

147 **Large Scale Analysis of Early Lethal Phenotypes** Jesse Mager University of Massachusetts

Early mammalian development requires that embryos accomplish specific milestones including implantation, axis specification and gastrulation. Since these events require precise timing of epigenetic regulation and complex morphogenetic movements for success, they are extremely vulnerable to genetic mutation and embryo lethality. Human data supports this idea with estimates as high as 80% of pregnancy losses occurring during the first trimester. Large scale projects designed to assess gene function in model organisms such as the Knock Out Mouse Project (KOMP) have also highlighted the stringent requirement of these early stages where ~12% of all null alleles result in lethality prior to E9.5. We have analyzed more than 200 novel early lethal single-gene knockouts produced by the KOMP. Assessment of such a large cohort of lethal alleles produced on the same genetic background, allows us to define specific phenotypic bottlenecks as well as predict essential gene networks. Rather than a distribution of phenotypes, we find the majority of homozygous mutant embryos have one of two specific phenotypes – a failure to implant or a failure to initiate gastrulation. Our data suggest that distinct mechanisms limit progression through each of these two stages. We propose that implantation failures occur due to molecular and/or transcriptional programing defects while gastrulation failures result from deficiencies in proliferation and/or cell number. Our findings serve as a guide for the analysis of early phenotypes and may inform the study of development of other eutherian mammals including humans.

148 **A cellular shearing mechanism important for dynamic tissue shape changes and cell differentiation** Liyuan Sui, Christian Dahmann TUD Dresden University of Technology

Dynamic changes in three-dimensional cell shape are important for tissue form and function. In the developing *Drosophila* eye, photoreceptor differentiation requires the progression across the tissue of an epithelial fold known as the morphogenetic furrow. Morphogenetic furrow progression involves apical cell constriction and movement of apical cell edges. Here we show that cells progressing through the morphogenetic furrow move their basal edges in opposite direction to their apical edges resulting in a cellular shearing movement. We further demonstrate that cells generate at their basal side oriented, force-generating protrusions. Knockdown of the protein kinase *Src42A* or photoactivation of a dominant-negative form of the small GTPase Rac decrease protrusion formation. Impaired protrusion formation stalls basal cell movement and slows down morphogenetic furrow progression and photoreceptor differentiation. This work reveals a cellular shearing mechanism important for the generation of dynamic tissue shape changes and cell differentiation.

149 **The Nucleus as a Barrier to Epithelial Cell Shape Changes** Rashmi Budhathoki[1], Noah deLeeuw[2], Liam J Russell[3], Dinah Loerke[2], James Todd Blankenship[1] [1]Department of Biological Sciences, University of Denver, [2]Department of Physics and Astronomy, University of Denver, [3]Department of Biological Sciences, Department of Physics and Astronomy, University of Denver

Planar polarized cell intercalation is a topology-driven event that brings tissue-scale changes for convergent extension movements during embryonic development in *Drosophila*. Here, we explore if the nucleus, as the largest organelle in a cell, poses a significant mechanical barrier to cells attempting to change shape and intercalate to achieve optimal body-axis elongation. We find that two central mechanisms allow nuclei to accommodate these stresses: 1) nuclear deformation and 2) the dispersion of nuclei to alternate planes along the apical-basal axis. We first tested the effects of restricting nuclear deformability with kugelkern disruptions. Embryos with “non-deformable” nuclei displayed a major shift towards the second mechanism; i.e., a more dynamic redistribution in apical-basal axis. Although this redistribution allowed cells to deform and still participate in cell intercalation, epithelial regularity was deeply compromised. We next tested embryos that possessed

"non-dispersible" nuclei by inhibiting microtubule polymerization. Interestingly, this caused a jamming phenotype in which nuclei became locked in the same apical-basal plane and cell intercalation was completely halted. Then, we asked what would happen in epithelia in which nuclei are both non-deformable and non-dispersible. In these circumstances, nuclei engaged in a tug-of-war to occupy the same z-plane in the absence of nuclear deformation and cell intercalation was again completely disrupted. These results suggest that the nuclear dispersion pathway is crucial for effective tissue elongation and guided by microtubules. To explore more on how this largest membranous organelle is being trafficked in apical-basal direction, we hypothesize three possible mechanisms: (a) motor protein-mediated transport, (b) microtubules pushing at actin cortex, and/or (c) nuclear translocation via microtubules of non-centrosomal origin. Our preliminary results suggest that dynein motors are necessary for centrosomal association with nuclei but are not the primary drivers of nuclear dispersion at this stage. Inhibiting CLASP, a microtubule plus end binding protein that has been known to interact with the actin cortex, caused loss of nuclear anchoring resulting in mispositioning of nuclei. These results suggest effective tissue elongation requires apical-basal trafficking of nuclei, which is promoted by microtubules that are anchored at the apical cortex.

150 **Positioning of the *Drosophila* hematopoietic niche** Kara Nelson, Stephen DiNardo University of Pennsylvania

Niches regulate stem cell behavior and are often found in specific locations within the tissues they support. How that position is established, and whether the specific positioning of a niche affects its function is unknown. I investigate formation of the *Drosophila* hematopoietic niche, the Posterior Signaling Center (PSC), which signals to hematopoietic progenitors to instruct their maintenance or differentiation into mature hemocytes. PSC positioning occurs during embryogenesis: PSC cells are specified laterally, then migrate to the dorsal surface of the embryo, where they ultimately reside, coalesced at the posterior of the hematopoietic gland. I live-imaged PSC migration which revealed that a muscle, visceral mesoderm (vm), moves dorsally alongside the PSC. We hypothesized that vm guides PSC positioning. Mutants that lack vm had mis-positioned PSCs, suggesting vm is required for PSC formation. Vm is known to express the secreted ligand, Slit, which is important for morphogenesis of other tissues. To test whether Slit is the vm signal that guides PSC positioning, I analyzed embryos where Slit signaling was eliminated only from vm. PSCs were mis-positioned, indicating vm-derived Slit signaling is required for PSC formation. To test whether Slit acts on the PSC as a directional guidance cue or a cue that allows it to be competent to migrate, I overexpressed Slit in a tissue nearby the forming PSC: the heart. These PSCs were mis-positioned, suggesting that Slit instructs PSC formation via directional guidance. Future experiments will test whether embryos with mis-positioned PSCs exhibit aberrant stem cell regulation.

151 ***C. elegans* Hedgehog-related Proteins are Apical Extracellular Matrix Components** Nicholas Serra, Chelsea Darwin, Meera V Sundaram University of Pennsylvania Perelman School of Medicine

C. elegans has no ortholog of Hedgehog or most of its canonical signaling partners. However, the *C. elegans* genome does encode 60 proteins thought to be evolutionarily related to Hedgehog (Hh-r) across four families: Warthog, Groundhog, Groundhog-like, and Quahog. The Patched related (PTR) gene family, the Hedgehog receptor in other systems, has undergone similar expansion in nematodes. Because most Hh-r genes lack obvious signaling roles or loss of function phenotypes, the purpose of these expansive protein families remain mysterious.

We report that endogenously tagged Hh-rs from the Groundhog-like and Warthog families are components of apical extracellular matrices (aECMs), specialized protective layers at the surface of all epithelial cells. Some of these proteins are continuously expressed, cell-specific components of cuticle. Other Hh-rs localize to the pre-cuticle, a transient aECM that precedes and patterns the cuticle proper. FRAP analysis indicates that these Hh-rs are stably incorporated into matrix. WRT-10, a newly identified pre-cuticle Hh-r, is required for normal formation of alae, acellular cuticle ridge structures, demonstrating a functional role in aECM organization. The lipocalin LPR-3 and patched related protein PTR-4 are each required for WRT-10's endocytosis during pre-cuticle clearance. Our emerging evidence suggests that Hh-rs are structural components of aECM, and that PTRs exert temporal control over Hh-r localization in a tissue specific manner. These findings suggest that *C. elegans* Hh-r proteins have diversified to meet the nuanced demands of aECM construction and function in diverse tissues. In addition, the aECM could serve as a reservoir for Hh-rs with proposed signaling roles, linking aECM remodeling and cell signaling.

152 **The Reissner's Fiber assembles downstream of local motile cilia activity to control body morphology** Elizabeth A Bearce[1], Sam Bertrand[2], Sophie Fisher[3], Zoe H Irons[2], Adamend Freda[3], Dan T. Grimes[3] [1]IMB, University of Oregoon, [2]Institute of Molecular Bio, University of Oregon, [3]University of Oregon

The linear body axis is a key feature of vertebrate life. It forms during embryogenesis based around the notochord and later the spine, a rigid but flexible column of vertebrae. We study the mechanisms that give rise to proper spine morphology. In zebrafish, generation and maintenance of the body and spine requires the function of motile cilia. Zebrafish embryos lacking cilia motility fail to undergo axial straightening and instead exhibit a curved early body axis and, later, scoliosis-like spinal

curves. Remarkably, we found that returning cilia motility to mutants allows the self-correction of body and spine morphology, suggesting a mechanism in which abnormalities are sensed and corrected. Motile cilia are required to assemble the Reissner Fiber (RF), an extracellular thread in the central canal composed of the protein Scospondin which we hypothesize to be important for the "sense-and-correct" mechanism. However, while Scospondin mutants do demonstrate morphological defects, we currently do not understand how RF forms downstream of motile cilia or how RF functions to promote a linear spine. To address this, we are performing live-imaging of cilia motility and RF in a variety of mutant backgrounds. This revealed that dynamic, rostral-caudal RF formation is dependent on local cilia motility in the central canal. When cilia are immobilized, knot-like RF structures form and eventually, the RF breaks down into diffuse monomers, something which correlates with the onset of spine dysmorphology. Our imaging has also revealed that central canal neurons uptake RF material in mutants that develop spinal curves. We propose that neuron-RF interactions, followed by endocytosis of RF material, function as a sensory system that allows the large-scale shape of the body and spine to be sensed, facilitating a path to maintain and correct organ morphology during growth, aging, and disease.

153 **Mechanosensitive live cell extrusions shrink the gut following food withdrawal** Aparna Sherlekar[1], Yu-Han Su[2], Samantha Thomas[1], Keerthana Yellapragada[2], Lucy E O'Brien[2], Emile G Magny[1] [1]MCP, Stanford University School of Medicine, [2]Stanford University School of Medicine

Many mature organs shrink when functional demand is reduced. This adaptive resizing response serves to optimize the organism's physiological fitness. However, the cellular processes that enable mature organs to shrink are largely unknown. Investigating the adult Drosophila gut, we discover that the gut's epithelial lining culls ~50% of its cells within two days of food withdrawal through massive cell extrusion. Live, in vivo imaging shows that during steady-state organ renewal, extrusions are slow and limited to late-stage apoptotic cells. By contrast, during starvation-induced shrinkage, extrusions are rapid and include both early-stage apoptotic cells and–strikingly–non-apoptotic cells. Comparative 4D analysis of single extrusion events suggests that the biophysical force required for cells to eject from the gut epithelium is weaker during shrinkage, which enables cells to readily exit. Screening mechanosensitive ion channels, we identify that the Pickpocket sodium channel may enforce the biophysical suppression of cell extrusions at steady-state and must be inhibited for starvation-triggered extrusions. Our results suggest that food withdrawal alters the mechanical state of the gut epithelium to permit low-energy extrusions, thus tuning cell number and organ size to fit functional demand. This work identifies a new role for cell extrusion in adaptive resizing of a mature epithelial organ and demonstrates that extrusions are a key mechanism for adaptive shrinkage.

154 **Control and Sensing of Spatially Patterned Embryonic Genome Activation Is Essential for Early Development** Wenchao Qian[1], Hui Chen[2], Matthew C Good[1] [1]Cell and Developmental Biology, University of Pennsylvania, [2]Biological Sciences, University of South Carolina

A watershed event in early development is the transition from maternal to zygotic control of embryogenesis, requiring awakening of the embryonic genome and widespread nascent transcription in a process termed zygotic genome activation (ZGA). In some embryonic models, ZGA onset is not spatially uniform, instead blastomeres display a temporally graded pattern of zygotic gene expression. How an embryo determines the precise timing of genome activation is an area of intense research investigation. Recently, we demonstrated in the *Xenopus laevis* model blastula that large-scale ZGA onset occurs in a spatiotemporal manner, contingent on embryonic blastomeres reaching a threshold cell size or DNA:cytoplasm ratio. Because amphibian embryos contain gradients of cell sizes along the animal-vegetal axis at the blastula stage, we wondered whether this cell size gradient specifies the pattern of ZGA and is essential for development. To address this question, we constructed a device to modulate the timing of cell division spatially within the blastula and reverse the gradient of blastomere sizes. Intriguingly, this manipulation is sufficient to reverse the graded patterning of ZGA onset. Functionally, alteration to the pattern of ZGA onset gradients causes embryo death, dose-dependent on the extent to which ZGA is delayed in the presumptive ectoderm. ZGA gradient reversal along the animal-vegetal activates an embryo quality control pathway, triggering apoptosis. Imposition of ZGA onset gradient along any other embryonic axes has no impact. Additionally, embryo death can be recapitulated by blocking ZGA in presumptive ectoderm. Co-injection with inhibitors of apoptosis prevent embryo death, and the data are consistent with a model in which embryos require spatially ordered expression of an anti-apoptotic program to fulfill the early quality control pathway. This work provides insights on mechanisms that regulate the timing of genome activation and how cell size is leveraged to coordinate tissue patterning and development.

155 **A genetic model for metazoan programmed DNA elimination** Thomas Dockendorff, Brandon Estrem, James Simmons, Maxim Zagoskin, Jansirani Srinivasan, Ryan Oldridge, Mehwish Iftikhar, Vincent Terta, Abigail West, Joe May, Jianbin Wang The University of Tennessee, Knoxville

Programmed DNA elimination (PDE) is a notable exception to the paradigm of genome integrity. In metazoa, PDE often occurs coincident with germline to somatic cell differentiation, resulting in reduced somatic genomes. Despite comprehensive

descriptions of the sequences lost in many metazoa, the mechanisms and consequences of PDE are still lacking due to the limited tools available in existing models. Recently, we established a functional and genetic model for PDE in the free-living Rhabditidae nematode *Oscheius tipulae*, a family that includes *Caenorhabditis elegans*. We identified a conserved motif, named Sequence For Elimination (SFE), for all 12 break sites on the six chromosomes at the junction of retained and eliminated DNA. CRISPR-edited SFE mutants exhibit a "fail-to-eliminate" phenotype only at the modified sites. To address the consequences of failure to eliminate and assess the fate of the inadvertently retained DNA, we are characterizing the SFE mutants to identify phenotypes and molecular changes in RNA expression, small RNAs, and histone modification marks. We will also present our data on the sequence determinants and genomic position required for the function of SFEs and our efforts to explore intraspecies variations of PDE by building and comparing telomere-to-telomere genomes for divergent strains of *O. tipulae*. This newly established PDE model is promising to provide insights into the mechanisms and functional significance of PDE in a metazoan.

156 **Regulation and function of non-canonical cell cycles in *C. elegans* and human hepatocyte organoids** Ramon Barrull Mascaró, Gabriella Darmasaputra, Christa Jordan Ortiz, Matilde Galli Hubrecht Institute

Many plant and animal cells transition from canonical to non-canonical cell cycles during development, resulting in the formation of polyploid cells. Two types of non-canonical cell cycles exist: endoreplication, where cells increase their DNA content without entering M phase, and endomitosis, where cells undergo all phases of the canonical cell cycle except cytokinesis, leading to a 4N or binucleate cell. Although endoreplication has been extensively studied in plants and insects, much less is known on the regulation and function of endomitosis, which is the most common mode of polyploidization in mammals. To study how cells transition to endomitosis, and what the consequences are of polyploidy for cells and tissues, our lab makes use of two experimental systems: the *C. elegans* intestine, which undergoes endomitosis and endoreplication cycles during larval development; and human 3D organoid cultures of primary hepatocytes (hep-Orgs), where cells can undergo both canonical or endomitosis cycles *in vitro*. Using live-imaging, single molecule fluorescence in situ hybridization (smFISH) and RNA-sequencing we find that *C. elegans* intestinal cells and human hepatocytes undergo endomitosis by inhibiting different aspects of cytokinesis signaling. Despite variations in the mechanisms leading to polyploidy, we observe remarkable similarities in the consequences of polyploidization. In both *C. elegans* and hep-Orgs, elevated ploidy levels are associated with increased transcription, protein translation, and cellular volume. Notably, not all functions scale proportionally to ploidy. In *C. elegans*, we find that mRNA transcription increases significantly during the first two intestinal polyploidization cycles, but does not substantially increase in the cycles thereafter, when cells reach ploidies of 16N and higher. Conversely, 26S rRNA transcription more closely follows DNA dosage, and continues to increase at higher ploidies. Also in polyploid hepatocytes, we find that ribosome biogenesis and protein sythesis scale with ploidy, unlike what has been reported in cells that are forced to become polyploid by induced cytokinesis failure. Thus, naturally occurring polyploid cells may have evolved mechanisms to specifically increase protein biosynthesis, which would explain why polyploidy is common in highly metabolically active tissues. Taken together, our work is shedding light into the regulation and function of somatic polyploidy, providing insights into how and why cells modify their cell cycles during multicellular development.

157 **Actin nucleator Arp2/3 promotes efficient DNA repair during *C. elegans* meiosis** Jordan E Brown, Diana E Libuda Biology, University of Oregon

Faithful genome inheritance in most sexually reproducing organisms requires meiosis, a specialized form of cell division that generates haploid gametes. To ensure accurate chromosome segregation, developing germ cells required the formation and repair of DNA double strand breaks (DSBs) using homologous recombination to generate crossovers. Chromosomes that fail to establish crossovers segregate incorrectly can lead to aneuploidy, a common cause of birth defects and miscarriages in humans. Recent work has found that the cytoskeletal protein actin is essential for the successful execution of meiosis in mammalian oocytes, and actin filament bundles can be detected in budding yeast nuclei during the specific stage of meiosis when active DSB repair is occurring. Notably, several studies established that actin facilitates DSB repair via homologous recombination in mitotic cells. While the presence and timing of nuclear actin in meiotic cells suggests a role for actin in meiotic DSB repair, a functional role for actin in meiotic DSB repair has not been established. Using a combination of live imaging, high-resolution deconvolution microscopy, and genetics, our data indicate that the presence of actin and actin nucleation by the Arp2/3 protein complex facilitates efficient DSB repair during meiotic prophase I in *Caenorhabditis elegans* oocytes. Using a conditional loss of Arp2/3 in the germline, we find that efficient meiotic DSB repair requires actin nucleation by the Arp2/3 protein complex. Specifically, our data indicate loss of Arp2/3 leads to an increase in the number of DSBs and a delay in DSB repair in the germ line. Coinciding with the impact on meiotic DSB repair, the conditional loss of Arp2/3 in the germline also causes a drop in fertility, which suggests Arp2/3 assists in the formation of viable oocytes. Further, we find the timing of chromosome pairing is altered upon loss of Arp2/3, thereby indicating that stable and accurate homologous chromosome associations that are critical for meiotic DNA repair via homologous recombination may require actin. Overall, this study is illuminating the specific role of actin and the cytoskeleton during meiotic prophase I of germ cell

development to protect the genome from instability.

158 **Transcriptional regulators modulate DNA damage response** Gonen Memisoglu[1], Nevan Krogan[2], James E Haber[3], Alexander J Ruthenburg[4] [1]Molecular Genetics and Cell Biology, The University of Chicago, [2]Department of Cellular and Molecular Pharmacology, University of California San Francisco, [3]Department of Biology and Rosenstiel Basic Medical Sciences Center, Brandeis University, [4]Department of Molecular Genetics and Cell Biology, The University of Chicago

We performed an unbiased genetic screen to identify novel factors that modulate the DNA damage response in budding yeast. This analysis revealed a previously uncharacterized genetic interaction between the essential DNA damage kinases and the cyclin kinase module (CKM) of the Mediator of transcription; a large protein complex that functions as a general transcriptional factor. We find that all subunits of the CKM, as well as CKM's kinase activity are critical for cell cycle re-entry following a DNA break, whereas the rest of the Mediator is largely dispensable. CKM mutants do not significantly impair DNA repair by homologous recombination; however, confer sensitivity exclusively to double strand break inducing reagents, suggesting that CKM specifically impinges on DNA damage response to double strand breaks.

We also discovered that a single DNA break is sufficient to significantly downregulate global transcription in a CKM-dependent manner. Our ChIP analyses show that in response to DNA damage, CKM downregulates global transcription by antagonizing general transcription machinery. Notably, akin to CKM mutants, RNA polymerase II mutants with faster elongation rates are also defective in cell cycle re-entry following a DNA break. Conversely, slowing down the RNA polymerase II elongation rescues the mitotic re-entry defect of CKM mutants, illustrating that CKM-dependent transcriptional regulation is essential for proper DNA damage signaling and mitotic re-entry.

Our preliminary data illustrate that the pharmacological inhibition of CKM in mammalian cells also lead to a hyperactive DNA damage signaling. Taken together, our results point to an evolutionary conserved role for CKM in DNA damage signaling and mitotic re-entry.

159 **Defective crossover homeostasis compromises chromosome segregation in aged mouse spermatocytes** Lakshmi Paniker[1], Vindhya Kilaru[1], Rhea Kang[1], Melissa Frasca[1], Suhani Bhakta[1], Isabella Ferranti[1], Ericka Humphrey[1], Francesca Cole[2] [1]The University of Texas MD Anderson Cancer Center, [2]University of Texas MD Anderson Cancer Center

Homologous recombination during meiosis generates crossovers, which are required to connect homologous chromosomes for their accurate segregation into gametes. Meiotic recombination is initiated by double-strand breaks (DSBs) generated by the SPO11 transesterase. In multiple organisms, a critical buffering mechanism, crossover homeostasis, maintains crossover numbers despite variation in DSB numbers. In mouse spermatocytes, both natural and genetic variation of early recombination intermediates on the order of ±25% is efficiently buffered to maintain crossovers at the expense or profit of an alternative repair product, noncrossovers. We have found in aged mouse spermatocytes, that DSB numbers are reduced by ~20%. However, unlike adult or juvenile mouse spermatocytes, crossovers in aged spermatocytes bear the brunt of reduced DSBs with 40% of spermatocytes lacking connection between homologs, in particular the sex chromosomes. Further reducing meiotic DSBs by removing a single copy of *Spo11* leads to 60% of aged spermatocytes lacking crossovers between homologs. We also show that there are two noncrossover pathways, an early acting pathway that likely contributes to chromosome pairing and a later acting pathway that likely serves as a reservoir for crossover control. Consistent with this model, in adult mouse spermatocytes, only the latter noncrossover pathway is utilized as a buffering reservoir when DSB numbers are reduced. In aged mouse spermatocytes, crossover homeostasis is compromised and cannot favor crossovers at the expense of this later noncrossover pathway. As a consequence, chromosomes frequently mis-segregate in aged mouse spermatocytes. Intriguingly, studies to determine whether older human spermatocytes have higher risk of chromosome mis-segregation have been controversial. What these studies lack is an investigation of the frequency of meiotic DSBs in the individuals tested for chromosome segregation. The frequency of DSBs is highly variable both between cells, but also between individuals. We will present our latest investigations into the mechanisms of crossover homeostasis and how this process is compromised with age in spermatocytes.

160 **Recombination rate plasticity depends not only on environmental stressors, but also genomic context and genetic background** Laurie S Stevison[1], Natalia Rivera-Rincon[2], Ulku Huma Altindag[1], Taylor Novak[2] [1]Auburn University, [2]Biological Sciences, Auburn University

For over a century, scientists have known that meiotic recombination rates are plastic, thus varying considerably among individuals depending on environmental and/or physiological stress. Through an examination of genome wide variation in recombination rate plasticity in ~3k progeny, we identified a global signature of increased recombination rate across the genome in *D. pseudoobscura* (p=0.02). Despite this global signal, we found variation in the degree of plasticity across chromosomes, with the strongest plasticity on chr4 and the least on chrX. Further, we found variation in the direction of

change at a fine scale (~100kb resolution), with many regions significantly reduced under heat stress. The distribution of crossovers was also significantly altered with increases in crossover number per chromosome (p=0.007) and the proximity of double crossovers (p=0.0023), suggesting that heat stress breaks down both crossover assurance and interference. Comparing these short-term changes to long term changes in recombination rate in close relatives, we showed that intervals with greater divergence in their recombination rates, both within and between species, had greater plasticity than intervals with conserved recombination rate over evolutionary time. In addition to recombination rate, we investigated individual stress response measures such as physiology and reproductive output, which vary by stock, sex and among individuals. Based on these results, we have begun to investigate the role of genetic background on recombination rate plasticity. Specifically, using the DGRP and a visible marker stock of *D. melanogaster*, we have shown recombination rate to be significantly reduced due to increased caloric density (p=3.6e-5) and low oxygen environments (p=1.9e-4), particularly in stocks that show increased physiological sensitivity to these stressors. In combinations of stress factors, we found an increased recombination rate regardless of genetic background (p=3.2e-3). Interestingly, we found that underlying differences among stocks in recombination rate under control conditions significantly impacted plasticity across treatments. Together, this work in different Drosophila species reveals recombination rate to be variable due to both differential exposure and susceptibility to environmental stress with complicated interactions. This outcome has important implications for how changes in the environment can interplay with genetic background to alter the landscape of genetic variation in natural populations.

161 **Aneuploidies of Specific Chromosomes upon Loss of the Spindle Checkpoint Protein Bub3 in Budding Yeast** Pallavi Gadgil[1], Olivia Ballew[2], Soni Lacefield[1] [1]Geisel School of Medicine at Dartmouth, [2]Indiana University

Aneuploidy generally has deleterious effects to growth rates of cells. However, studies have shown that cells with mutations in certain regulatory genes can gain specific chromosomes to provide survival and growth benefits. We found that loss of spindle checkpoint protein Bub3 results in cells that are aneuploid for specific chromosomes. In budding yeast, the spindle checkpoint is not essential, but loss of the checkpoint genes *BUB3* and *BUB1*, have a higher probability of chromosome mis-segregation than loss of *MAD1, MAD2,* and *MAD3*. This difference is likely due to the role of Bub3 and Bub1 in helping recruit the chromosome passenger complex to the inner centromere, which is involved in correction of improper kinetochore-microtubule attachments. The prior assumption was that these aneuploid cells would eventually be lost in the population since they have growth defects. However, we observed that although all chromosomes had an equal probability of mis-segregation initially, the *BUB3*-deleted (*bub3*Δ) haploid cells only maintained specific chromosomes and these chromosomes persist through many generations. Thus, we tested two types of survival advantages. First, we asked if evolved cells had a growth advantage compared to the non-evolved cells. We found that some evolved strains did have an advantage, but most did not. Next, we asked whether the *bub3*Δ cells gain and maintain specific chromosomes because the elevated expression levels of a subset of genes from the gained chromosomes can compensate for the loss of Bub3 or because the gain of these chromosomes is tolerated. We tested individual genes on each chromosome and performed a scan of all the genes on one of the upregulated chromosomes to determine if their increased expression would prevent aneuploidy of that chromosome. We found that the increased expression of multiple genes can help prevent aneuploidy of one of the specific chromosomes. Overall, our results suggest that the increased expression of certain genes, by maintaining aneuploidy of specific chromosomes, may be advantageous to cells lacking Bub3.

163 **Genetic basis of lethal mutations and how they persist in nature** Sarah Marion, Mohamed Noor Duke University

For nearly a century, evolutionary biologists have observed chromosomes which cause lethality when made homozygous persisting at surprisingly high frequencies (>25%) in natural populations of many species. These curious findings provide a challenging question fundamental to understanding natural fitness variation: given the extreme deleterious nature of lethal mutations, why do they appear at such high frequencies? Although most research on this question dates to the 1930's, we still know remarkably little about the genetic basis of naturally occurring lethal mutations or what evolutionary forces create their frequencies. Before even attempting to explain why lethal alleles are so common in nature, it is crucial to understand their genetic underpinnings. Decades of research has assumed lethal chromosomes are due to single locus, loss-of-function mutations, but this *has never been directly tested*. Even less is known about the classes of genes in which lethal mutations occur or their distribution throughout the genome.

We are using wild *Drosophila melanogaster* to determine the genetic basis of lethal mutations. *D. melanogaster* were collected from a natural population in Durham, North Carolina, and balancers were used to isolate ~300 independent samples in which chromosome 2 is homozygous lethal. By crossing a set of deficiency lines (that span over 70% of the second chromosome) to each lethal line, we have mapped hundreds of lethal lesions to defined regions of chromosome 2. Fine scale mapping and sequencing results provide novel characterization of naturally occurring lethals, including a nonsense mutation in the *drosha* gene. While this is evidence that at least some lethal alleles are single locus, we also provide novel evidence that most or all lethal alleles are single locus using Poisson-based mapping expectations.

We present the most extensive mapping study of naturally occurring lethal alleles ever conducted. Our results are the first direct demonstration for a single locus, loss-of-function mode of action of lethal mutations and provide sequence-level characterization of naturally occurring lethal alleles. Beyond underlying genetics, we discuss potential evolutionary force(s) responsible for the maintenance of lethal mutations and future analyses of our mapping and sequence data that will provide modern insight to a century-old question.

164 **Comparison of mutation rate in different ploidy states of the fission yeast *Schizosaccharomyces pombe* as a test of the drift-barrier hypothesis** Kevin Bao, Rutuja M Gupte, Nathaniel Sharp Genetics, University of Wisconsin, Madison

Why is there variation in mutation rate between organisms? Organisms have all evolved accurate DNA replication and repair and yet mutations still occur and at different rates. One theory is that selection has limited ability to eliminate weak mutator alleles which are maintained by drift. This is termed the drift-barrier hypothesis. Tests of this hypothesis have largely relied on comparing measurements of effective population size (N_e) and mutation rate, but getting accurate measurements of N_e is difficult. Alternatively, we propose that measuring cell-type specific mutation rates can be used as a test of the drift-barrier hypothesis. If a given organism rarely undergoes cell division in one cell context, then selection will have less opportunity to optimize the replicative machinery that applies only to this context. One example of such a context is ploidy. Thus, yeast species offer an excellent opportunity to test this hypothesis because they can grow as either haploid or diploid cells. Prior work in the diplontic budding yeast *S. cerevisiae* corroborates this idea. Using mutation accumulation (MA) – a method using repeated bottlenecks to render selection ineffective and allow spontaneous mutations to accumulate – the per site mutation rate was found to be 40% higher in haploids than in diploids for single nucleotide mutations (SNMs). The higher mutation rate in the rare ploidy state is consistent with our prediction, but could alternatively be explained if haploidy is inherently mutagenic. To separate the effect of ploidy versus evolutionary history, we performed MA for over 1700 generations in the haplontic fission yeast *Schizosaccharomyces pombe*. After sequencing, we found that the SNM rate was 45% lower and the insertion/deletion (indel) rate was 40% lower in haploids than in diploids. This is consistent with the drift-barrier hypothesis because mutation rate was significantly higher in diploid *Sc. pombe* – the historically uncommon and theoretically less optimized cell state. Not only is this the first time that the diploid mutation rate of *Sc. pombe* has been measured, but also this lends support to the idea that cell environment matters for the evolution of mutation rate. This presents a novel approach to testing the drift-barrier hypothesis and will help resolve the controversy over the role of genetic drift in mutation rate evolution

165 **Selection can locally reduce deleterious germline mutation rates via the deposition of H3K36me3 and DNA methylation** Leandros Boukas[1], Afrooz Razi[2], Hans T. Bjornsson[3], Kasper D. Hansen[2] [1]Johns Hopkins University/Children's National Hospital, [2]Johns Hopkins University, [3]Johns Hopkins University/University of Iceland

Understanding whether selection on regional mutation rate modifiers has led to reduced mutation rates at regions where mutations are more likely to be deleterious is a long-standing problem in molecular population genetics. In recent years, the drift-barrier hypothesis has been proposed as a simple yet powerful argument which states that selection on local mutation rate modifiers is too weak to overcome drift in finite populations.

Here we revisit this question. We focus on characterizing trans-acting mutation rate modifiers that: a) preferentially affect the mutation rate of regions most important for fitness; b) affect the mutation rate of many such regions at once. Such modifiers occupy an intermediate place between global mechanisms (such as DNA repair variants) and entirely local effects, raising the intriguing possibility that selection on them could be effective in the face of drift. First, we show - using a dataset of 18,365 de novo synonymous mutations - that genes that are more intolerant to loss-of-function mutations in humans have lower coding mutation rates. We confirm this result by examining the synonymous substitution rate from a human-chimp comparative analysis, and further show that the relationship between loss-of-function intolerance and coding mutation rate disappears if one includes intronic mutations; this explains why it has been missed in previous studies. We then show that a histone modification, H3K36me3, is preferentially deposited at coding exons of loss-of-function intolerant genes, and is associated with a lower mutation rate at these exons.

To examine the effect of drift, we perform simulations in finite populations. Our simulations are based on the same model underlying the theoretical foundation of the drift barrier. We modify this model with a parameter that explicitly reflects the number of sites whose mutation rate is simultaneously affected. Using empirically estimated mutation rates and selection coefficients, we find that coding mutation rate modification via selection in favor of exonic H3K36me3 can overcome the drift barrier. We also establish a similar result for DNA methylation at promoters, showing that selection can act against promoter DNA methylation to reduce the mutation rate at CpG sites and thereby preserve promoter CpG islands. Of note, our simulations incorporate empirical estimates of the rate at which DNA methylation and H3K36me3 patterns change in the germline, via a human-chimp-rhesus comparative analysis which shows that these marks are extremely stable over time.

In summary, we find that mutation rate modification of coding sites and promoter CpG sites via selection in favor of exonic H3K36me3 and against promoter DNA methylation, respectively, is evolutionarily plausible. Our results provide insights into the evolution of germline mutation rates, and the interaction between mutation rates and gene regulatory systems.

166 **Natural selection causes association studies to prioritize variant specificity over variant impact** Hakhamanesh Mostafavi, Jeffrey Spence, Mineto Ota, Nikhil Milind, Tami Gjorgjieva, Jonathan Pritchard Genetics, Stanford University

Genome-wide association studies (GWAS) have long been used in an attempt to find variants and genes that strongly impact a phenotype of interest. Yet, GWAS hits can be difficult to interpret, and a large amount of phenotypic variance is often explained by variants with no obvious trait relevance. This raises the question of what variants are prioritized by GWAS. Here, we argue that association studies prioritize variants that are most specific to the trait under study --- not necessarily the variants with the largest effects. We show that this prioritization of specificity is a consequence of natural selection acting on several independent axes of phenotypic variation and variants having differing degrees of pleiotropy. We use this insight to compare the types of genes discovered by GWAS and rare variant burden tests. We also show how this view explains the observation that heritability is often strongly enriched in genomic regions that are specifically active in the trait-relevant cell-type even if the variants are not acting through obviously trait-relevant genes.

167 **The impact of sample design on the observed site frequency spectra and its relevance for the discovery of rare deleterious variants in natural populations and associations with phenotypic variation** Margaret C Steiner[1], Daniel P Rice[2], Arjun Biddanda[3], Marida Ianni-Ravn[1], Christian Porras[4], John Novembre[5] [1]Human Genetics, University of Chicago, [2]University of Chicago, [3]Johns Hopkins University, [4]Ichan School of Medicine, [5]Human Genetics, Ecology and Evolution, University of Chicago

A key question in any study design is whether it is advantageous to sequence as many individuals as possible in one geographic location (“narrow sampling”) or to sequence individuals from as many geographic locations as possible (“broad sampling”). Here we consider this question in the context of efforts to discover variants that affect phenotypic traits under stabilizing selection, such that rare variants are selected against. We ask: how does the spatial breadth of sampling impact the observed site frequency spectrum, and how does that in turn affect one’s power to make association with phenotypic trait variation? With such questions in mind, we introduce a novel theoretical framework to study the impact of spatial sampling design on the discovery of rare variants. In particular, we develop a population genetic model for the distribution of carriers of deleterious alleles in a structured population – accounting for dispersal, drift, selection, mutation, and uneven spatial sampling simultaneously. Analysis of our model suggests that, for a fixed sample size, broader sampling will result in the capturing of a greater number of deleterious variants, but each variant will be at reduced frequency within the sample; in contrast, narrow sampling yields fewer variants but each is found at higher frequency within the sample. To investigate how these different discovery profiles impact the power to discover associations to phenotypes, we then integrate our work with statistical genetic models to identify trade-offs for genome-wide association studies (GWAS) and burden test studies. We find that under our model, power to detect a single-variant association typically decreases for broader sampling – plausibly due to the dilution of allele frequencies in broad samples – unless variant effect size is above a critical value. However, power to detect gene-level associations using a burden test, which combines signals across many loci, increases for broader sampling. We validate the theory results using simulations and then explore whether the predictions of the theory are borne out in human whole-genome-sequencing data from gnomAD and the UK Biobank and using an example from *Arabidopsis thalania*. Overall, the results imply that, for samples with increased breadth, burden tests will be key to identifying phenotypic associations. We expect our analyses will help to inform a broader discussion regarding best practices for study design in the sequencing era, both in humans and a broader set of organisms. They also have relevance for understanding the site frequency spectra and biases introduced by sample design more generally.

168 **Background selection landscape in human genomes: insights from Ancestral Recombination Graph** Yun Deng[1], Rasmus Nielsen[2], Yun Song[2] [1]Computational biology, UC Berkeley, [2]UC Berkeley

Background Selection (BGS) has shaped the diversity patterns along human genomes with the effects of linkage. With development in BGS theory, people have been able to predict diversity level in human genome matching real data accurately. However, the prediction has worked mainly for large scale, often for 1Mb windows. Also, the region-specific background selection coefficients have not been explicitly inferred, because previously only diversity patterns on large scale were leveraged and the dimensionality is much lower than the number of selection parameters for conserved regions. Here we show that with Ancestral Recombination Graph (ARG) inference, we can look into much finer-scale diversity variations, which provides more information for learning the genome-wide selection landscape. Our results shed new lights on BGS analysis, which

provides a much-finer scale B-map and estimation of background selection in a region specific way along the genome, instead of summarizing as Distribution of Fitness Effects (DFE). The regions with inferred strong background selection align well with CADD tracts (inferred from cross-species conservation), while only using human population level data. We believe that applying this new method to different species will greatly benefit the understanding the sharing and variation of background selection along evolutionary history.

169 **The relationship between the mutation spectrum and the distribution of fitness effects across species** David Castellano, Justin Conover, Ryan Gutenkunst University of Arizona

Understanding the interplay between DNA mutation rates and fitness effects is a fundamental question in evolutionary biology. In this study, we investigate this relationship in three model organisms: humans, *Mus musculus*, and *Arabidopsis thaliana*, using polymorphism data from natural populations and germline mutations from several sources. Our analysis in *Arabidopsis* shows that the 3mer mutations with the highest mutation rates are more deleterious. In contrast, in humans and mice, we find that the most mutable nonsynonymous 3mer mutations have less deleterious effects. This pattern is particularly pronounced within non-CpG transitions in both humans and mice, and within non-CpG transversions in mice, suggesting that the mutation spectra in these two mammalian species tend to be less disruptive to fitness than the mutation spectrum in *Arabidopsis*. We suggest that the differences observed between *Arabidopsis* and mammals are likely due to sequence-dependent DNA repair enzymes. Without these enzymes, highly mutable nonsynonymous 3mer mutations are quickly removed due to their high mutation rates, unless they are kept by strong negative selection, resulting in the correlation we observed in *Arabidopsis*. In contrast, in humans and mice, these enzymes may exist and be under natural selection to reduce the impact of highly mutable 3mer mutations imposing a greater genomic deleterious burden, resulting in a distinct mutation spectrum. Our work highlights the contrasting relationship between mutation rates and fitness effects between these species and suggests the singular role of repair mechanisms in mammals.

170 **Environment-independent distribution of mutational effects emerges from microscopic global epistasis** Sarah Ardell[1], Alena Martsul[1,2], Milo S Johnson[3,4], Sergey Kryazhimskiy[1] [1]Ecology, Behavior and Evolution, University of California San Diego, [2]Platform Reagent Development Group, Illumia, Inc, [3]Integrative Biology, University of California Berkeley, [4]Biological Systems and Engineering Division, Lawrence Berkeley National Laboratory

Adaptive evolution can lead to profound changes in the phenotypes and behaviors of biological systems, sometimes with adverse and sometimes with beneficial consequences for human health, agriculture and industry. However, predicting these changes remains difficult. One major challenge is that how new mutations alter phenotypes and fitness of organisms often depends on the genetic background in which they arise (G×G interactions or “epistasis”), the environment (G×E interactions), or both (G×G×E interactions). Phenotypic predictions rely on coarse-grained “macroscopic” descriptions of these interactions, typically captured by the distributions of mutational effects. Several recent studies reported that the effects of many mutations on fitness scale with the fitness of the background genotype, a phenomenon termed “global epistasis”. However, how the patterns of global epistasis vary across environments is unknown and how global epistasis shapes the distributions of mutational effects is unclear.

To address these questions, we measured the effects of ~100 barcoded insertion mutations on growth rate in 42 strains of *Saccharomyces cerevisiae* in six laboratory environments. We find that the slopes of the relationship between the effects of mutations and background growth rate remain nearly invariant across environments, despite substantial variation in both the effects of individual mutations and background-strain growth rates. Instead, the environment tunes one global parameter, the background fitness at which most mutations switch sign, which we term “the pivot growth rate”. As a result, the distribution of mutational effects is remarkably predictable across genotypes and environments.

This apparent simplicity in how the effects of individual mutations and their distributions vary across genotypes and environments has potential implications for our understanding of evolutionary dynamics, phenotypic prediction and conservation biology. At a more fundamental level, it suggests that organism’s architecture imposes some as of yet uncharacterized constraints on the effects of mutations.

171 **Increasing undergraduate access to research with *C. elegans*** Joslyn Mills Biology, Bridgewater State University

Hands-on learning is essential for students to fully grasp complicated concepts, but a single exposure to a technique or idea during a semester is usually not enough to achieve long-term retention of understanding. Students must be engaged in interactive learning in order for them to more successfully retain the concepts, increase attention, and have meaningful experiences which leads to significant learning[1,2]. Further, success in the STEM fields correlates with exposure to research experiences before the period of attrition from the STEM majors[3,4]. With this approach in mind, I designed a Course-based

Undergraduate Research Experience (CURE) course to be offered to all Biology students that only need introductory biology to register. This course brings discovery-based research into the classroom to foster technical and conceptual learning, either as an introduction to or to increase retention of students in STEM[5] fields. It provides the hands-on laboratory and project design experience students need to become more competitive to join a research lab for their eventual thesis work; particularly for those students that have not had the advantage of working in a lab before (minorities, females, etc[6]). Students with prior experience in high school are typically favored, thereby limiting inclusivity and diversity. Therefore, the long-term goal of this course is to expose many students from a variety of backgrounds to research and help them meet curriculum requirements in support of the academic programs and associated labs to prepare them for future exciting STEM careers.

In the course, the students take on the role of a scientist, where they perform a reverse genetics screen in C. elegans to select a gene to explore for the rest of the semester. After selecting their gene, as a small group, they develop their own hypothesis and write and execute a proposal to test it using published literature to support their ideas, ending with a written report and oral presentation of their findings. This approach allows us to gather clues to what the function of a gene is, and we can further determine if this gene would be a potential target to design therapeutics to treat diseases. This CURE course is easily adaptable to be offered at other institutions, and has been executed in traditional (fully in-person), fully online, and hybrid formats with great success.

172 **Melanogaster: Catch The Fly!: A Citizen Science Network in Adaptation Genomics** Josefa González[1], Miriam Merenciano[2], Marta Coronado-Zamora[1], Ewan Harney[1], Irene González[2], Sònia Casillas[3], Roberto Torres[2] [1]Institut de Biologia Evolutiva (CSIC-UPF), [2]La Ciència Al Teu Món, [3]Universitat Autònoma de Barcelona

The citizen science project *Melanogaster: Catch The Fly!* (*MCTF!*) brings together high school teachers and students, from rural areas of Spain, Germany, Ukraine, Serbia, and Colombia, and their local communities, with scientists from all across Europe (and beyond), and communication experts to collaborate towards the advancement of frontier science. *MCTF!* offers citizens the possibility of actively participating in several research activities, thus providing them with a unique opportunity to learn about the scientific process, while they contribute to facilitate and expedite scientific research. *MCTF!* Also provides the participants the opportunity to increase their scientific, technological, and 4C capacities (collaboration, communication, creativity, critical thinking), through a hands-on project that empowers them as agents and enablers of a necessary global change.

In *MCTF!,* school teachers and students participate in collecting and classifying *Drosophila* species (fruit flies) that are then sequenced and analyzed to understand how organisms adapt to the environment. The data generated is shared through the European Drosophila Population Genomics Consortium (DrosEU). The activities of the *MCTF!* citizen science project also include: teacher training courses in genomics and science communication; the experimental validation of genetic variants using the PCR technique; bioinformatic analysis modules that introduce high-school and university students in big data analysis; and an activity based on the service and learning methodology that allow citizens to monitore the effects of climate change on local biodiversity.

173 **Mini-CURE molecular genetics lab exercises using *C. elegans* and toxicology** Julie Hall Biology, Lincoln Memorial University

Course-based undergraduate research experiences (CUREs) give students the opportunity to explore and investigate scientific topics within the structure of a classroom. Students are led through the development of research statements, execution of experiments, and analysis of data to foster an understanding of the scientific process. These mini-CURE lab exercises differ from traditional CUREs because they are only a few weeks in length. They bring in the learning objectives of the CURE without having to be invested in an entire semester or part of a bigger project allowing other topics to be covered within the lab course. These exercises are part of a 300-level molecular genetics lab course in which students choose a toxicant to investigate for two experiments using *C. elegans*. These can be adapted for a variety of courses and may be conducted with other model organisms. Lab 1 focuses on utilizing reverse transcription and PCR to analyze gene expression. Lab 2 is a design your own experiment where students pick an outcome (movement, growth, reproduction, or death) to observe after exposure to their toxicant or stressor of choice. Students work in pairs and begin by performing a literature search to pick a toxicant or stressor for the study and determine two concentrations to test for the experiments along with an outcome to test in Lab 2. Lab 1 allows students to learn RNA isolation, PCR, and gel electrophoresis while testing a hypothesis related to gene expression. Lab 2 provides more opportunities for students to have choice in which they explore an effect of the toxicant or stressor that interests them. Students present their research through the writing of an introduction, results, and discussion sections in the form of a journal style paper. Student choice with these two labs provides them with the opportunity to have ownership of the experiments. Students also practice skills of developing research statements and hypothesis through literature research and investigation. Although the design of this lab lasts a total of 6 weeks within a semester, modifications can be made to lengthen the time to focus more on student directed design or shorten the lab depending on the structure and time of the course.

These labs are reported as being a favorite within the course and students become invested in conducting the experiments because they got to choose what was being tested (toxicant) and what they wanted to test (outcome).

174 **A virtual lab meeting training program benefits both mentees and host labs** Katie Lotterhos[1], Moisés Bernal[2], Megan Phifer-Rixey[3], Torrance Hanley[4] [1]Northeastern University, [2]Auburn University, [3]Drexel University, [4]Sacred Heart University

Professional networks are critical for early career scientists. However, access to these networks is variable and inequitable, with greater barriers for students from systemically-marginalized groups, first generation college students, and students that attend institutions without extensive research programs. To help expand networks in evolution and marine sciences, the Research Coordination Network for Evolution in Changing Seas developed and ran a Virtual Lab Meeting Training Program. This program matched "Mentees," students at the undergraduate or graduate level, with "Mentors," postdoctoral researchers, research scientists, or professors, that shared their interests. Mentees then attended lab meetings virtually, with at least two meetings devoted to the Mentees professional development, and received a stipend after completing the program. After running for two academic years, Mentees and Mentors were surveyed to evaluate the program. Results indicated that the program was largely effective. Mentees reported that they gained knowledge of the hidden curriculum of research science and expanded their professional networks. Mentors found that Mentees brought new perspectives and knowledge and that participating required only a few extra hours of time over the course of the program. Greater diversity among Mentees than Mentors also suggests that this type of program has the potential to help increase participation of early career scientists from marginalized groups. Importantly, Mentee responses suggest that stipends are a crucial part of the program and should be considered for future programs. Overall, we found that this type of program can help support trainee development with little additional investment from Mentors, translating to benefits to the field.

175 **An undergraduate course at the intersections of genetics, disability studies, and gender and sexuality studies** Karen G Hales Biology, Davidson College

Undergraduate genetics courses and textbooks often use language frameworks that invalidate or "other" disabled people and LGBTQIA+ people, including those with differences of sexual development. Shifting to more inclusive paradigms within undergraduate biology education may improve retention in STEM of people with these identities, and may contribute to a future medical workforce better equipped to empower disabled and LGBTQIA+ people and treat them with empathy and dignity. After previously making incremental relevant shifts in my longstanding genetics courses, I report here the development and implementation of a novel undergraduate seminar course entitled "Genetics, Disability, and Gender Identities" that explores intersections of genetics with the scholarly fields of Disability Studies and Gender and Sexuality Studies. An initial focus on the eugenics movement sets the historical background, showing how concepts of normality and fitness intertwined with ableist, hetero- and cis-normative, and white supremacist social systems. The first half of the semester then weaves biological analysis of deafness, Down syndrome, autism, and psychiatric conditions with disability studies frameworks such as the medical vs. social models of disability, also incorporating first person perspectives from people with those identities. Using such frameworks, students critically assess assumptions in the biomedical literature about molecular treatments as well as assistive reproductive technologies. In the second half of the course, students explore ongoing research on the biology of sexual development, sexual orientation, and gender identity, from work on a variety of organisms to recent genome-wide association studies in humans. In parallel, students analyze public conversations about whether or not such research is helpful or harmful to the LGBTQIA+ rights movement, views on gender from sociological angles, implementation of sex testing in sports, and impacts on health care and public policy. Strongly positive student feedback on the course indicated that building bridges across scholarly areas is important for establishing a complete and inclusive view of biological topics that connect with marginalized identities.

176 **Development and Retention of Female Academics Via a Peer-led Book Club Intervention** Amanda L Zacharias[1,2], Deborah Y Kwon[2,3] [1]Cincinnati Children's, [2]Genetics, University of Pennsylvania Perelman School of Medicine, [3]Neuromuscular & Movement Disorders, Biogen

Purpose: In response to concerns from fellow postdocs that there was insufficient institutional and individual support to encourage women to remain in the academic "pipeline", we created a peer-led book club intervention for female graduate students and postdocs. This intervention has operated successfully for over 4 years with support from the Department of Genetics at the Perelman School of Medicine at the University of Pennsylvania.

Design: Membership expands widely beyond the Department of Genetics to anyone on the department seminar listserv and is composed of 56% postdocs, with a sizable international contingent. Books are nominated and ranked in preference by the membership; selections have ranged from self-help titles aimed at women in business targeting common issues (negotiation, Imposter syndrome), the history of women in science, to new research on biological gender differences. Meetings are

held monthly in several small groups that meet over lunch or dinner at a consistent time to foster group cohesion and accommodate different schedules. These meetings not only provide education and awareness on gender-related issues in science, but also offer a safe environment where female scientists are able to share personal and professional issues. Once a semester, a joint session is held to hear a female faculty describe their career path, which serves to provide relatable examples and opportunities for trainees to network with faculty. Experts from across the Penn campus have also been brought to lead interactive workshops on relevant topics.

Results: Based on Likert scale surveys of 52 participants over 4 years, 94% reported the group helped them feel part of the university community, 80% reported increased confidence, 75% reported the group had helped them identify solutions to problems in their professional life, and 98% would recommend participating in the group to other women. All women departing the group thus far (n=14) have continued their scientific careers in academia, pursuing graduate education, postdoctoral fellowships, and faculty positions, or have attained other academic positions of scientific leadership. These results indicate that an intervention of only 12 hours per year may have significant impact on retaining women in academic science. We believe a peer-led book club could be a valuable intervention for other under-represented groups because it provides community while teaching soft-skills.

177 **Nematode Hunters: an integrated approach combining science outreach, course-based undergraduate research, and mentored research to identify novel nematode viruses** Jessica N Sowa[1], Katherine Przeworski[2] [1]Biology, West Chester University of Pennsylvania, [2]Pennsylvania Leadership Charter School

C. elegans and other related free-living nematodes are a popular and powerful model system for studying the cell biology and evolution of host-pathogen interactions. However, only four viruses capable of naturally infecting *Caenorhabditis* nematodes have been identified, and of those only one (Orsay virus) infects *C. elegans.* This severely limits *C. elegans* as a model system for studying host-virus interactions specifically.

To search for novel nematode viruses capable of infecting *C. elegans*, we have taken a community-science approach to obtain a diverse sampling of wild-caught nematodes. The Nematode Hunters outreach program partners with 4th grade classrooms, allowing teachers to implement a week-long classroom module with all supplies provided by WCU. In this module, students learn about nematodes, collect samples from their local environment, identify samples containing wild nematodes, and ultimately submit the nematodes to WCU to be screened for intracellular infections. Data collected from pre and post surveys indicates that participation in Nematode Hunters leads to both an increased knowledge of how science is conducted and recognition that they have participated in the scientific process for 4th graders in the program.

Once received, samples are screened via co-culturing of wild nematodes with *C. elegans* expressing intracellular infection reporters. This screening is conducted by students enrolled in a course-based undergraduate research class. Using this approach we have evaluated over 500 wild nematode isolates sent in from both the Nematode Hunters program and other collaborators, identifying more than 200 potential intracellular infections. To prioritize potential viral infections, students in the course homogenized reporter-activated populations and passed the homogenate through a 0.22uM filter to size-exclude other pathogen types. Follow up testing is then conducted by students in the Sowa lab, including FISH staining to detect Orsay or other known nematode viruses and collection of samples for RNA sequencing.

178 **Enhancing biology education in Nigeria: use of Drosophila as an effective teaching and learning aid** Rashidatu Abdulazeez[1], Monsurat Titi Gbadamosi[2], Hammed Badmos[3], Muhammad Oyale Akhadelor[4], Dawoud Usman[5], Salisu Muhammad[1], Nurudeen Aliyu[6], Abubakar Ibrahim Mukhtar[7], Hassan Sani[8], Saadatu Idris[9], Racheal Henry[10], Usman Liman Gambo[11], Jamila Musa[12], Emmanuel Kayode Ajibulu[1], Felix Faruq Uduimoh[1], Dalhatu Mukhtar Shehu[1], Nuhu Muhammad Danjuma[13] [1]Zoology, Ahmadu Bello University, Zaria, [2]Vivian Therapeutics, [3]Cagan Lab, University of Glasgow, [4]Federal College of Forestry Mechanization, Afaka, Kaduna State, [5]Biomedical Research and Training Centre, Damaturu, [6]Steamledge Limited, Kano, [7]Anatomy, Ahmadu Bello University, Zaria, [8]Biochemistry, Federal University of Lafia, Nassarawa, [9]Biology, Ahmadu Bello University, Zaria, [10]Anatomy, Federal University Wukari, Taraba, [11]Microbiology, Ahmadu Bello University, [12]Intergrated science, Federal college of education, [13]Pharmacology and Therapeutics, Ahmadu Bello University Zaria

Conducted as a precursor to a three-day workshop for biology teachers-in-training (B.Sc. (Ed)/ B.Ed. college students), this survey featured participants selected from seven universities nationwide. This diverse cohort primarily consisted of females (54.5%), originating from underrepresented regions of the country, while males constituted the remaining 45.5%. Notably, a significant portion of the participants had previously attended privately owned secondary schools. The survey's outcomes unveiled resounding support for practical teaching methods as the most effective approach to imparting biology knowledge. An impressive 68.2% of participants concurred that hands-on activities significantly augment students' understanding of biology. Furthermore, participants expressed a strong inclination towards conducting practical classes, particularly on subjects

such as genetics and DNA extraction from cheek cells, contingent on the availability of requisite resources. A striking revelation was that a substantial 72.7% of the participants could not recollect encountering Drosophila, commonly known as the fruit fly, in their secondary school biology textbooks. Similarly, a discernible knowledge deficit was apparent concerning Drosophila melanogaster, with 22.7% of participants acknowledging limited familiarity, and the highest proportion (54.5%) admitting to having very little knowledge about the fruit fly's nervous system. Nonetheless, a remarkable 72.7% of the participants demonstrated a keen interest in integrating Drosophila into their science teaching, signifying the considerable potential of this model organism in shaping the future of biology education. These findings cast light on the preferences and preparedness of biology teachers-in-training, offering valuable insights into how practical and hands-on teaching methods can be leveraged to enhance the biology education experience.

179 **Investigating the mechanisms by which hunger modulates an animal's olfactory behavior** Roshni Jain[1,2], Eryn Slankster[3], Yihe Zeng[3], Kelsie Dreelan[3], Jingmin Lin[3], Juli Petereit[4], Dennis Mathew[2,3] [1]Biology, University of Nevada, Reno, [2]Molecular Biosciences Program, University of Nevada, Reno, [3]Biology, University of Nevada, Reno., [4]Nevada Bioinformatics Center, University of Nevada, Reno.

An animal's olfactory behavior is modulated by its hunger. In insects and mammals, hunger modulates the function of first-order olfactory sensory neurons (OSNs). Previous research from our lab and others have suggested that hunger-dependent modulation of OSN function is mainly mediated by insulin, an anorexigenic hormone. However, the mechanisms by which insulin modulates OSN function are unclear. This research aims to understand the molecular mechanisms by which insulin mediates the hunger-dependent modulation of OSN function and, thereby, the animal's olfactory behavior. The experimental plan takes advantage of the *Drosophila* larva as a model system. The premise is that cell-surface insulin receptors translocate to the nucleus, associate with promoters, and regulate gene expression. First, RNA sequencing analyses of larval OSNs revealed that OSNs with low insulin signaling (mimicking a hunger state) had lower expression levels of several genes involved in vesicular transport, including *Rab5*. Rab5 protein is found on synaptic vesicles and regulates protein transport. Next, immunocytochemistry analyses confirmed that insulin signaling regulates the Rab5-dependent transport of several synaptic proteins, including Domeless (Leptin homolog), to the OSN terminals. Finally, behavior analyses showed that disrupting Domeless expression at OSN terminals affected the larva's olfactory and feeding behaviors. Overall, these results reveal a previously undescribed insulin signaling mechanism in OSNs—vesicular protein transport. Our work provides a foundation for further analyzing the mechanisms by which insulin mediates the hunger-dependent modulation of an animal's olfactory behavior.

180 **Type 3 iodothyronine deiodinase (DIO3) controls the timing and stability of cone development in human retinal organoids** Christina McNerney[1], Robert J Johnston[2] [1]Biology, Johns Hopkins University, [2]Johns Hopkins University

How neuronal subtypes are generated at distinct times during human retinal development is poorly understood. To understand how developmental timing is regulated, we investigated the choice between blue and red/green cone photoreceptor fates in human retinal organoids. Blue cones are specified before red/green cones and thyroid hormone (TH) signaling promotes red/green cone fate. How this signaling mechanism is temporally regulated is not understood. Here, we find that DIO3, an enzyme that degrades TH, is a master regulator of cone developmental timing. The ratio of DIO3-expressing cells decreases over time to control the timing, quantity, and stability of S and M/L cone generation. Negative feedback at the cellular level ensures homeostatic levels of TH signaling. These mechanisms control the timing of cone development and the stability of cell fates, which ultimately yield reproducible ratios of cone subtypes in the human retina.

181 **Velvet Ant venom activates both insect and mammalian pain sensors through distinct mechanisms** Lydia J Borjon[1,2], Luana C de Assis Ferreira[2,3], Andrea G Hohmann[2,3], W Daniel Tracey[1,2] [1]Biology, Indiana University, [2]Gill Center for Biomolecular Science, Indiana University, [3]Psychological and Brain Sciences, Indiana University

The Scarlet Velvet Ant (*Dasymutilla occidentalis*) has an extremely painful sting which has been described as "Explosive and long-lasting, you sound insane as you scream. Hot oil from the deep fryer spilling over your entire hand." Prior studies have shown that the defensive venom is effective across vertebrates including mammals, birds, amphibians, and reptiles. This leads to the hypothesis that the venom may target an evolutionarily conserved pain pathway. To test this, and to determine the venom's pain-causing mechanism of action, we applied venom to *Drosophila* larvae in a fillet preparation, and quantified neuronal activity using calcium-imaging with genetically encoded GCaMP6f. We found that velvet ant venom specifically activates larval nociceptors (cIV da neurons), without activating other sensory neurons (such as cIII da neurons). We tested candidate target channels whose expression is specific to nociceptors. Pickpocket (Ppk) and Balboa (Bba) are members of the DEG/ENaC and ASIC channel superfamily and are necessary for mechano-nociception in fly larvae (Zhong et al., 2010). RNAi against *ppk* or *bba* in cIV da neurons prevents activation by venom. The presence of both Ppk and Bba subunits are required for proper localization to sensory dendrites and the channel subunits likely form heterotrimers (Mauthner et al., 2014). We found that co-expression of Ppk and Bba in cIII da neurons is sufficient to cause these neurons to be strongly activated by

venom. However, expression of Ppk or Bba alone does not cause activation, providing evidence for the first time that Ppk/Bba heteromers form functional channels. *Dasymutilla occidentalis* venom is composed of 24 peptides whose amino acid sequences have been determined (Jensen et al. 2021). Testing each of these chemically synthesized peptides, we have identified noxious components of the velvet ant venom proteome. A single peptide is responsible for fast-acting nociceptor activation through Ppk/Bba channels. 5 other peptides activate neurons more generally, at a slower time scale and at higher concentrations. Behavioral experiments in mice indicate that the latter non-specific peptides trigger robust pain behaviors, but the peptide targeting the fly channels does not. This suggests a potent insect-specific component of the wasp venom, and we found that velvet ants can successfully defend against predation by praying mantis (*Tenodera sinensis*) using its venomous sting. Combined, our results suggest that the venom cocktail of velvet ants has diverse peptides that act across phyla to activate pain sensing neurons.

182 **Identifying cellular and molecular regulators of acoustic startle sensitivity** Kimberly Scofield[1], David Christopher Cole[2], Sruti Bontala[2], Sureni Sumathipala[2], Jacob Deslauriers[2], Kurt Marsden[2] [1]Biological Sciences, North Carolina State University, [2]North Carolina State University

Sensory over-responsiveness occurs when an individual is unable to ignore irrelevant stimuli, and it is often a debilitating component of neuropsychiatric disorders. To understand the mechanisms that enable appropriate sensory filtering, we study the acoustic startle response in larval zebrafish, a conserved defensive response that allows organisms to quickly escape from danger. If this response threshold is too low, however, the organism will overreact to innocuous stimuli. Through a forward genetic screen, previous work found that nonsense mutations in *Cytoplasmic FMRP Interacting Protein 2* (*cyfip2*) cause acoustic startle hyperresponsiveness. It is not known, though, whether this is due to enhanced detection of auditory stimuli or reduced filtering of sensory input. To address this, we measured the activity of hair cells using vital dyes and found no difference in activity of either otic vesicle or lateral line hair cells between *cyfip2* mutants and siblings. We also established a transgenic line that expresses the excitatory opsin CoChR in the auditory nerve, enabling us to directly activate the auditory nerve. If the hyper-responsiveness in *cyfip2* mutants is driven by enhanced detection, then directly exciting the auditory nerve will abolish it. Our data show that we can reliably elicit kinematically stereotyped startle responses with blue light that are distinct from light-driven behavioral responses. CoChR-expressing *cyfip2* mutants were not hyperresponsive to optical stimuli, but they were also not hyperresponsive to acoustic stimuli. Instead, we found that CoChR-expressing wildtype larvae were hypersensitive to acoustic stimuli compared to non-transgenic siblings, indicating that CoChR expression likely alters auditory nerve function. Startle responsiveness of *cyfip2* mutants was unaffected by auditory nerve CoChR expression, however, suggesting that auditory nerve neurons may already be hyperexcitable and could thus be a site of *cyfip2*-mediated startle threshold regulation. We will complement this optogenetic approach by measuring auditory nerve activity using the calcium indicator jGCaMP8m. We are also developing a transgenic line to allow us to express Cyfip2 in specific cell populations to determine where it is acting in the acoustic startle circuit. In total, these experiments will allow us to better understand the genetic and neural circuit mechanisms that control sensory filtering, providing key insight into sensory processing disorders.

183 **How flies and vector mosquitoes sense heat and humidity (and you)** Paul Garrity[1], Rachel Busby[1], Willem Laursen[1], Tatevik Sarkissian[2], Shruti Shankar[1], Ruocong Tang[1] [1]Biology, Brandeis Univ, [2]Biology, Brandeis University

Temperature and humidity are ubiquitous environmental variables with major effects on the survival and reproduction of insects like flies and mosquitoes. Temperature is a fundamental property of matter that affects all aspects of animal physiology, and animals must sense and respond to temperature to maintain body temperatures compatible with survival. Humidity reflects the concentration of water vapor in the air, and monitoring humidity helps insects avoid dehydration. In addition to supporting homeostasis, temperature and humidity sensation also play critical roles in helping disease-spreading vector mosquitoes (which transmit devastating diseases like malaria, dengue and zika) locate and bite humans based on the heat and humidity we emit. In addition, humidity sensation helps female vector mosquitoes locate water sources for egg laying --- this is a critical step in their reproduction, as mosquito larvae are aquatic. Thus, identifying and characterizing the molecular and cellular mechanisms by which insects sense and respond to temperature and humidity has potential relevance for understanding insect physiology as well as for vector control efforts.

In prior work in *Drosophila*, we have found that several classes of molecular receptors participate in mediating responses to temperature and humidity. These receptors include the Transient Receptor Potential (TRP) channel TrpA1, the Gustatory Receptor Gr28bD, and several Ionotropic Receptors (IRs), including Ir21a, Ir25a, Ir40a, Ir68a and Ir93a. Here we will present recent work in *Drosophila* that combines molecular genetics, physiology and behavior to identify a class of molecular receptor (and a set of neurons that express this receptor) that acts as a previously unappreciated mediator of temperature sensation and thermosensory behavior in the adult fly. In addition, we have previously found that IR family members initially identified in *Drosophila* have key roles in heat and humidity sensing in the malaria vector *Anopheles gambiae* and the arbovirus vector *Aedes aegypti*. Here we present recent work in *Aedes aegypti*, establishing that different IR family members make

distinct, but overlapping contributions to host seeking, blood feeding and oviposition site seeking behavior. Together, these IRs, and the neural circuits that rely on them, combine to allow mosquitoes to respond to a wide variety of host-derived cues, allowing them to hunt for blood meals effectively under a wide variety of environmental conditions.

184 **Neurexin (*nrx-1*) isoforms differentially mediate multiple foraging circuits and behaviors in *C. elegans*** Michael P Hart, Mara H Cowen, Brandon L Bastien Genetics, University of Pennsylvania

Some of the most conserved behaviors across animal phylogeny are feeding-related and involve responses to food and nutrients. Foraging behaviors range from searching for food to more complex social strategies (social vs. solitary foraging). The nematode *C. elegans* has robust behavioral responses to food, including multiple foraging behaviors and strategies, many with well-defined neurons, circuits, and signaling pathways involved. We used automated imaging platforms to assay multiple foraging behaviors in individual or populations of young adult *C. elegans*. Using longitudinal and unbiased quantification of behavior, we identified that the conserved synaptic adhesion molecule neurexin/*nrx-1* is required for *C. elegans* food search and social foraging strategies. Food search requires the cooperative function of both the short and long isoforms of *nrx-1* to regulate octopamine signaling, response, and octopamine neuron synaptic connectivity. Social feeding behavior requires the long isoform of neurexin in two pairs of glutamatergic sensory neurons (ADL and ASH), where it regulates connectivity of just the ASH neurons. Glutamate signaling from both ADL and ASH neurons is required for social foraging behavior, where we observe increased synaptic glutamate synaptic release in social animals compared to their solitary counterparts (which is independent of *nrx-1*). We report independent roles for the canonical partner of neurexin, neuroligin/*nlg-1*, in both food search and social foraging behaviors. These studies uncover molecular and circuit mechanisms that contribute to multiple foraging behaviors, including highly conserved genes.

185 **Defining neuronal extracellular vesicle (EV) subtypes by single-EV molecular analysis** Inna Nikonorova[1], Elizabeth A. desRanleu[1], Joshua Saul[2], Jonathon Walsh[2], Katherine A. Jacobs[2], Juan A. Wang[2], Maureen Barr[2] [1]Genetics, Rutgers University, [2]Rutgers University

Cilia are present in most cells in the human body, including the brain. Ciliopathies often present with neurological manifestations, such as intellectual disability, agenesis of the corpus callosum, hydrocephalus, intracerebellar cysts, and polymicrogyria. The underlying mechanisms through which cilia dysfunction leads to these profound defects in neurodevelopment remain enigmatic.

Polycystins are ubiquitous and essential ciliary proteins. Organ-specific knockout of polycystins leads to major dysfunctions via yet unidentified molecular cascades. Polycystins are highly expressed in the brain, and their role in the nervous system is beginning to be understood. In zebrafish, polycystins function in the cilia of CSF-contacting neurons of dorsolateral and ventral origin that regulate spine posture. Globally, loss of polycystin function in vertebrates leads to randomization of left-right body plan during embryogenesis with polycystins acting through EVs shed from the nodal cilium. Whether polycystins act via EVs in the nervous system of vertebrates remains to be discovered. Emerging evidence suggests that abnormal EV signaling within the brain may contribute to neuronal degeneration.

In *C. elegans*, polycystins function in the cilia of male-specific sensory neurons that direct mating behavior. These conserved polycystins are shed from the ciliary tip into the environment for animal-to-animal communication. The signaling mechanism and cargo of the neuronal polycystin-carrying EVs remain unknown.

Here, we use proximity labeling, super-resolution microscopy, and genetic perturbations in *C. elegans* to define polycystin-associated EV cargo. We have identified and validated TRAFs (tumor necrosis factor TNF receptor-associated factors), three transmembrane lectins with dorsoventral specialization, and a novel transmembrane protein that resembles an ion channel as cargo of polycystin-carrying EVs. We discovered that all newly identified partners of the polycystin complex required polycystin-1 for their loading to ciliary EVs. Disruption of polycystin-1 lead to the ciliary release of polycystin-2 EVs, which lack polycystin-associated transmembrane components and TRAF signaling adaptors. These findings suggest that the loading of cargo to ciliary EVs follows a regulated hierarchical process and demonstrates how a single genetic perturbation can profoundly affect the composition of a specific type of EV, impacting neuronal communication mediated by these vesicles.

186 **Neuromodulation of serotonin drives presynaptic plasticity underlying reward learning** aaron stahl[1], Valentina Botero[1], Seth Tomchik[1,2,3] [1]Neuroscience and Pharmacology, University of Iowa, [2]Pediatrics, University of Iowa, [3]Iowa Neuroscience Institute, University of Iowa

Associative learning involves temporally-specific actions of multiple monoaminergic neurotransmitters including serotonin (5-HT). Olfactory associative learning drives presynaptic plasticity in the release of acetylcholine (ACh) from mushroom body Kenyon cells (KCs). These changes in ACh release systematically vary across the longitudinal axonal compartments of the

KCs. Each of these compartments innervates unique downstream mushroom body output neurons (MBONs). In addition, each compartment receives heterosynaptic input from different sets/combinations of monoaminergic neurons. These monoaminergic neurons modulate the synaptic plasticity between KCs and MBONs. Serotonergic neurons innervate the KC compartments, and KCs express multiple serotonin receptors. Serotonergic neurons exert strong behavioral effects on olfactory classical conditioning, though their role in modulating the compartmentalized synaptic plasticity driven by reward learning is not known. Here we investigate the role of 5-HT in driving reward-associated presynaptic plasticity in KC compartments. We paired *in vivo* imaging of ACh release across the MB γ lobe with appetitive conditioning and conditional RNAi-mediated knockdown of 5-HT receptors in the KCs. Conditional knockdown of two different 5-HT receptors in adult mushroom body Kenyon cells altered the odor-evoked release of ACh across γ lobe compartments following appetitive conditioning, systematically shifting baseline odor-evoked ACh release and abolishing the conditioning-induced changes in ACh release across compartments. This loss of plasticity correlated with loss of behavioral learning – appetitive conditioning was impaired following the knockdown of different 5-HT receptor subtypes. These data suggest that layered signaling via monoaminergic pathways modulates baseline ACh release and drives plasticity underlying learning.

187 **A Notch signal required for a morphological novelty in *Drosophila* has antecedent functions in genital disc eversion** Donya N Shodja[1], William J Glassford[2], Sarah J Smith[3], Mark Rebeiz[4] [1]Biological Sciences, George Washington University, [2]Columbia University, [3]Yale, [4]University of Pittsburgh

A fulfilling explanation for the origin of morphological novelties requires a concrete understanding of the developmental program controlling the novelty as well as the pre-existing molecular foundation it was built upon. We therefore must uncover how key regulators of the program evolved expression associated with the novelty, how new genetic programs emerged downstream, and how these circuits relate to any ancestral roles that predated the new structure's emergence. Developmental signaling pathways that are conserved throughout animal development have been frequently implicated in the evolution of novelties. Here, we demonstrate that a Notch signaling center required for the posterior lobe, a morphological novelty on the male genitalia of *Drosophila melanogaster,* had ancestral roles fundamental to the proper formation of the entire adult male genitalia. We identified transcriptional enhancers of the ligand *Delta*, which allowed us to track the evolutionary history of this signaling center. Surprisingly, our analysis reveals that the signaling center becomes active days before the posterior lobe forms, serving an early-acting role necessary for genital disc eversion (Epper, 1983) – the process in which the epithelium underlying genital structures turns inside out. We provide a likely mechanism by which Delta contributes to genital eversion through a network of apical extracellular matrix, which also became integrated into the novel posterior lobe program. This work demonstrates that novelties may be formed in the context of already complex developmental processes, by appending new roles to pre-existing signals.

188 **Decoding developmental signaling using molecular optogenetics in zebrafish** Catherine E Rogers[1], Allison J Saul[2], Leanne E Iannucci[2], William K Anderson[2], Selvaraj Velanganni[2], Patrick Müller[3], Katherine W Rogers[2] [1]Cell, Molecular, Developmental Biology, and Biophysics, Johns Hopkins University - NIH partnership, [2]NICHD, National Institutes of Health, [3]Universität Konstanz

Cell fate decisions during embryogenesis are influenced by signaling levels, dynamics, and combinations. To experimentally manipulate these signaling features and determine how they are decoded in zebrafish embryos, we are developing a suite of orthogonal optogenetic tools that activate BMP, Nodal, and FGF signaling in response to blue or red light. We demonstrate that the blue light-responsive optogenetic tools activate specific pathways with blue, but not red, light exposure. In addition, we are quantifying the tools' on/off kinetics and light intensity-dependence and working to generate transgenic zebrafish harboring optogenetic activators. To create orthogonal tools to simultaneously activate two pathways independently, we are systematically testing different red light-responsive construct designs in zebrafish embryos. In ongoing experiments, we are applying these tools together with RNAseq to identify transcriptome-wide changes in gene expression in response to acute, optogenetically delivered signaling pulses during early development. These optogenetic tools provide a powerful platform to investigate how embryonic cells decode signaling levels, dynamics, and combinations. Funding: NIH Intramural ZIAHD009002-01 to KWR.

189 **WheresWally: a bioinformatic pipeline for rapid mutation mapping using whole genome sequencing** McKenna Feltes[1], Sofia Angel[1], Aleksey Zimin[2], Steven Salzberg[2], Steven Farber[1] [1]Biology, Johns Hopkins University, [2]Biomedical Engineering, Johns Hopkins University

Forward genetic screening is a powerful, unbiased approach that has led to numerous discoveries across many fields of biology. Historically, identification of the causative mutation was achieved by recombinant mapping, a time consuming process which relies on a mapping outcross. More recently, the development of affordable and rapid sequencing platforms has enabled "mapping-by-sequencing" approaches that utilize RNA or DNA sequencing datasets to generate lists of candidate mutations located in genomic intervals linked to the phenotype. Gene candidates can be tested using reverse genetic approaches such as

CRISPR editing. “Mapping-by-sequencing” represents a massive leap forward in mutation mapping, however, when genomic intervals and candidate lists are large, gene testing becomes intractable. To address this limitation, we have developed an analysis pipeline, WheresWally, which combines modern bioinformatic tools with classical recombinant mapping to rapidly identify causative mutations generated by forward genetic screening. We have designed WheresWally using ENU mutagenized zebrafish, but it can be adapted to suit other organisms and/or mutagens. The pipeline defines the linkage block by identifying regions of high SNP homozygosity in the mutant genomic sequence which is generated by whole genome sequencing (WGS) of a pooled mutant bulk. The linkage block is compared to the wildtype block to identify segregating small nucleotide polymorphisms (SNPs) and insertions and deletions (indels). Indels serve as markers which can be used to identify recombinants which further narrow the linkage block and candidate gene list. Compared to traditional recombinant mapping markers, these indels are present at a higher density and are specific to the bulk analyzed, allowing for better mapping resolution without an outcross. Using this approach we have mapped 6 novel alleles generated from an ongoing zebrafish mutagenesis screen designed to identify genes controlling lipid flux. In the era of CRISPR knockout reverse genetics, WheresWally aids in the identification of hypomorphic point mutants generated by forward genetic mutagenesis screens which remain powerful tools for the study of gene function and mechanism.

190 **Ecolocator: A supervised machine learning model for location and climate-of-origin prediction** Jordan Rodriguez[1], Andrew Kern[1], Richard Cronn[2] [1]Biology, University of Oregon, [2]United States Forest Service

As the Earth’s climate changes, nearly every organism on the planet will shift its geographical range in response. For ecologically and economically important species, it is vital that scientists and managers be able to make informed decisions about future suitable environments for populations. In previous work we have shown that supervised machine learning methods are capable of predicting location of origin from genomic variation using georeferenced training data. However, the spatial genetic variation signal that we are capturing may be the result of both neutral processes (e.g. drift) and local adaptation. Reasoning that the connection between genotype and environment mediated by local adaptation might be discernable from neutral variation, we introduce Ecolocator, a deep learning method that jointly predicts location of origin as well as environmental variables of that location. Ecolocator trains on a dataset of genotypes with known geographic location and associated climate variables such that it can predict the climate-of-origin and geographic location based on the genotype of an unlabeled sample. To validate our approach, we applied our method to the coastal variety of the most important timber species in the world, *Pseudotsuga menziesii var. menziesii* (Douglas fir), which previously has been shown to have strong local adaptation. Using a preliminary dataset of ~340 georeferenced genotypes and associated climate variables for those locations from ClimateNA, we are able to predict where an individual genotype might be best suited to given environmental conditions throughout the range. Our open-source tool clarifies the biological implications of the connection between environmental variation and genetic variation so that informed conclusions regarding the conservation, adaptation, and resiliency of this species can be made.

191 **ProteinCartography: Comparing proteins with structure-based maps for interactive exploration** Prachee Avasthi, Brae M Bigge, Mert Celebi, Jase Gehring, Erin McGeever, Atanas Radkov, Dennis A Sun Arcadia Science

Proteins are a fundamental building block of all organisms. Comparing proteins across different organisms can allow us to identify conserved functions, as well as instances of evolutionary innovation. Historically, such analysis was performed by comparing protein sequences. However, recent advances in protein structure prediction (AlphaFold, ESMFold) and comparison (Foldseek) have also enabled the systematic comparison of protein structures between organisms. Building on these tools, we developed “ProteinCartography,” a pipeline which generates interactive visualizations of protein structure comparisons. ProteinCartography searches available sequence and structure databases for matches to user input proteins, compares all hits, and clusters proteins based on their structural similarity. It reports results through interactive visualizations that summarize protein metadata including functional annotations, taxonomy, structure prediction quality, and other metrics, allowing users to rapidly explore protein space. Using ProteinCartography, scientists are able to develop specific hypotheses about their proteins of interest using a comparative framework with greater ease, clarity, and depth than conventional search approaches.

192 **Leveraging genome-scale molecular networks from multiple species using machine learning to translate gene-level data and knowledge across species** Christopher A Mancuso[1], Kayla A Johnson[2], Alexander McKim[3], Keenan Manpearl[2], Renming Liu[3], Hao Yuan[4], Julia Ganz[4], Ingo Braasch[4], Arjun Krishnan[2] [1]Biostatistics and Informatics, University of Colorado Anschutz Medical Campus, [2]Biomedical Informatics, University of Colorado Anschutz Medical Campus, [3]Computational Mathematics, Science and Engineering, Michigan State University, [4]Integrative Biology, Michigan State University

Research organisms are critical for studying complex mechanisms underlying human biology and disease. Nevertheless, thousands of genes in humans and model organisms remain experimentally un(der)-characterized in terms of their roles in cellular pathways, cell type/tissue function, phenotypes, and diseases. This significant gap in knowledge is a major barrier to

delineating, in an unbiased manner, the best genes in different model systems to study multifactorial biomedical phenomena and translate the findings back to human biology. Varying evolutionary distances and lineage-specific genetic and functional changes further compound this barrier.

To overcome this barrier, we are developing advanced machine learning (ML) approaches that take advantage of millions of biomolecular interactions in the form of genome-scale gene/protein networks spanning multiple species (e.g., human, mouse, zebrafish, fruit fly, roundworm, and yeast). Specifically, we have developed a new ML framework called GenePlexusZoo that casts molecular networks from multiple species into a single "functional" space where genes in similar network neighborhoods, within and across species, are close to each other. Multiple rigorous evaluations demonstrate that this multi-species network representation improves the ability to predict novel genes associated with pathways, traits, and diseases within a single species and across species, even in cases where the inter-species correspondence is undetectable based on shared orthologous genes.

Now, we have expanded the capabilities of GenePlexusZoo to handle highly multifactorial, polygenic conditions (e.g., Autism Spectrum Disorder) with the goal of identifying a collection of model phenotypes (even from different organisms) that can together recapitulate the complexity of each condition. After such phenotypic deconvolution of a complex disorder, our approach prioritizes specific genes in each model system pertinent to each phenotype, which can be followed-up experimentally.

Our framework is a significant improvement over existing methods because it has desirable properties that are lacking in existing methods: the ability to handle networks from multiple species, incorporate many-to-many orthology information, and generate a network representation that is reusable across different types of and newly-defined prediction tasks. GenePlexusZoo is available as an open-source software and an interactive webserver for all researchers to use and build on.

193 **Biomarker Curation, Integration, and Data Model Development** Daniall Masood[1], Raja Mazumder[2], Jeet Vora[2], Sean Kim[2], Karina Martinez[2] [1]Department of Biochemistry and Molecular Medicine, George Washington University, [2]Department of Biochemistry and Molecular Medicine, George Washington Univeristy

In the pursuit of evaluating disease and medical intervention outcomes, biomarkers emerge as pivotal tools for researchers and clinicians. Biomarker data is extensive, but disorganized over a vast number of papers and resources. This project endeavors to establish a standardized biomarker definition and consolidate diverse biomarker data under a unified data model.

Our biomarker definitions and model follow the FDA-NIH Biomarker Working Group's definition: "a characteristic measured as an indicator of normal biological processes, pathogenic processes, or responses to an exposure or intervention". Ongoing efforts are underway to develop a biomarker-centric view of data within the Biomarker Partnership, funded by the Common Fund Data Ecosystem, an NIH initiative. The data model currently encompasses 'core' and 'contextual' biomarker data, forming the foundation for biomarker definition.

Core data is essential to the model and must be fulfilled for a biomarker to be added to the data model (e.g. biomarker, assessed_biomarker_entity, condition). Contextual data (any extra data related to a biomarker) originates from various partner resources within the Biomarker Partnership, integrated into the data model framework. Any absent data is addressed through inference, guided by biomarker-centric rules. Biomarker curation follows this standardized data model, drawing from both manual curation of biomarker-related papers and automated extraction from public resources that have biomarker or biomarker-related data. The curated data includes essential biomarker information (e.g., biomarker entity, change, disease), ensuring accessibility for incorporation into the data model. Contextual data, curated from diverse partner resources, is integrated into the data model, and supplemented through inference if necessary. This approach solidifies the groundwork for an expansive biomarker knowledge graph.

GlyGen (glygen.org), a glycoscience knowledgebase, is a current example of how biomarker data is harmonized, integrated, and represented. These biomarkers are associated with glycan and protein identifiers. While currently focusing on glycan and protein biomarkers, GlyGen lays the framework for how biomarker data can become integral part of biological knowledgebases.

The culmination of biomarker data curation and the standardized data model promises unprecedented accessibility and search efficiency for biomarkers thereby improving their findability, accessibility, interoperability, and reuse.

194 **A genome-wide genetic screen uncovers determinants of human melanogenesis** Vivek K Bajpai Chemical, Biological & Materials Engineering, University at Oklahoma

Melanin, an inert biopolymer, is responsible for skin, hair and eye pigmentation. Consequently, genetic variants affecting melanogenesis underlie diversification of human species into distinctly pigmented subpopulations. Melanin production also contributes to the natural homeostasis of tissues that produce it, and dysregulation of these pathways can lead to slew of human pathological conditions affecting the skin (e.g., vitiligo and melasma), eyes (age related macular degeneration) and ear (sensorineural deafness). Melanin is typically produced by melanocytes, which originate from the neural crest and reside in the epidermis, where they transport melanin filled vesicles (a.k.a. melanosomes) to the surrounding keratinocytes, resulting in skin pigmentation. Importantly, the number of melanocytes and their anatomical location do not vary among humans, only varying melanogenesis determines the human pigmentation diversity. The core biochemical machinery that regulates melanin synthesis has been known for a long time and further key insights have come from mapping genes involved in hypo- and hyper-pigmentation diseases and from genome-wide association studies (GWAS) of normal-range skin and hair color variation in human populations. However, current candidate GWAS variants can explain only a fraction of skin color variation in humans, suggesting that many loci controlling pigmentation remain undiscovered. To fill this knowledge gap, we leveraged the light scattering properties of melanin and performed a genome-wide CRISPR-Cas9 screen to systematically discover genes driving human melanogenesis. We first demonstrated a tight correlation between melanin content of pigment cells and their light scattering properties as measured as side scatter parameter (SSC) by flow cytometry using pigment cell lines and human pluripotent stem cell derived model of melanogenesis. We next exploited this relationship to directly survey genes involved in melanogenesis through a genome-wide CRISPR screen. We uncovered 169 functionally diverse genes converging on melanosome biogenesis, endosomal transport and gene regulation, of which 135 represent novel associations with pigmentation. In agreement with their melanin-promoting function, the majority of screen hits are upregulated in melanocytes from darkly pigmented individuals. We further unravel functions of KLF6 as a transcription factor regulating melanosome maturation and pigmentation in vivo and of the endosomal trafficking protein COMMD3 in modulating melanosomal pH. Our study reveals a plethora of melanogenesis regulators, with broad implications for human variation, cell biology, and medicine.

195 **Update on the Alliance of Genome Resources** Paul W Sternberg[1], Carol Bult[2], Alliance of Genome Resources[1] [1]California Institute of Technology, [2]The Jackson Laboratory

The Alliance of Genome Resources (aka, the Alliance) is a consortium of model organism knowledgebases (MODs) and the Gene Ontology Consortium (GOC). The mission of the Alliance is to support comparative genomics as a means to investigate the genetic and genomic basis of human biology, health, and disease. To promote sustainability of the core community data resources that make up the Alliance, we have implemented and maintain an extensible “knowledge commons” platform for comparative genomics built with modular, re-usable infrastructure components that can support informatics resource needs across a wide range of species. These include JBrowse, InterMine, BLAST, Textpresso, a common Community Forum, and other features we are developing. We will briefly describe our progress towards harmonizing information from SGD, WormBase, FlyBase, ZFIN, Xenbase, MGD, RGD and the GO Consortium resources, storing that information in a useful form available by software, download, or via our web portal at www.AllianceGenome.org. Our goal is to provide the Union of the data and features of these resources (as opposed to the Intersection), and we fully expect to provide better service to all our communities. The individual MODs will continue to exist and in addition to continuing to curate information from the scientific literature, large scale experiments, and submissions from individual investigators , they will innovate methods for data analysis and display and interact with their respective communities. In 2022, the Alliance was recognized as a Core Global Biodata Resource by the Global Biodata Coalition, a step that we hope will allow us to engage international funding to further enhance this resource.

196 **Investigating differences in mitotic checkpoint strength in the early *C. elegans* embryo** Priscila A Medrano Gonzalez, Imge Ozugergin, Abigail R Gerhold Department of Biology, McGill University

The mitotic checkpoint preserves genome stability by inhibiting the anaphase-promoting complex and delaying mitotic exit until all chromosomes are attached to the mitotic spindle via kinetochore-microtubule attachments. Despite its central role in preventing chromosome segregation errors, checkpoint strength (i.e., the ability to block mitotic exit in the presence of unattached kinetochores) varies between species, cell types, and developmental stages. The reasons for this variation are poorly understood. In *C. elegans* embryos, checkpoint strength correlates with cell size. Checkpoint strength increases as cell size decreases during early embryonic cleavage divisions and when cell size is reduced experimentally in 2-cell stage embryos, using RNAi treatments that affect embryo size. We have found that cells from small 2-cell stage embryos tend to have a stronger checkpoint than similarly sized cells produced during cleavage, suggesting that cell size is not the sole determinant of checkpoint strength in *C. elegans* embryos. To better understand what underlies this difference, we characterized the expression levels, localization, and dynamics of endogenous, GFP-tagged mitotic proteins, including the core checkpoint proteins MDF-1/Mad1, MDF-2/Mad2, BUB-3, SAN-1/Mad3, over the first 5 rounds of embryonic cleavage divisions. We found

that expression of MDF-2/Mad2 increases during this window of development, likely via *de novo* translation of maternally supplied transcripts, such that smaller cells later in development have a higher concentration of MDF-2/Mad2 than larger cells at earlier embryonic stages. While the expression of MAT-2/Apc1, an essential scaffolding subunit of the anaphase-promoting complex, also increases, the rate of increase is significantly outpaced by that of MDF-2/Mad2. As activated MDF-2/Mad2 is a rate-limiting factor in anaphase-promoting complex inhibition and checkpoint activity, we predict that increased MDF-2/Mad2 expression contributes to increased checkpoint strength as cell size decreases during development. We are currently testing this prediction, as well as assessing whether similar differences affect checkpoint strength in small 2-cell stage embryos. These results suggest that developmental factors act in parallel to cell size to determine checkpoint strength in *C. elegans* embryos, and that checkpoint protein expression may be a general determinant of checkpoint strength.

197 **Developmental phenotypes caused by the inappropriate inheritance of histone methylation require Polycomb Repressive Complex 2** Zaynab A Massenburg, Sydney Morgan-Benitez, Brandon Carpenter Kennesaw State University

Histone methylation is a post-transcriptional modification to the N-terminal tails of histone core proteins that regulates DNA accessibility, and consequently, gene expression. At fertilization, histone methylation must undergo maternal reprogramming to reset the epigenetic landscape in the new zygote. During maternal reprogramming of histone methylation in *C. elegans*, H3K4me is removed by the H3K4 demethylase, SPR-5, and H3K9me is subsequently added by the histone methyltransferase, MET-2. Recently, we demonstrated that SPR- 5; MET-2 maternal reprogramming antagonizes the H3K36 methyltransferase, MES-4, which maintains a transcriptional memory of a subset of germline genes between generations. Maternal loss of SPR-5 and MET-2 results in ectopic expression of MES-4 germline genes in somatic tissues and a severe developmental delay. Recent work from the Strome Lab shows that MES-4 repels the activity of the Polycomb Repressive Complex 2 (PRC2), which includes the H3K27 methyltransferase, MES-2, at germline gene loci in the germline. These findings prompted us to examine whether PRC2 complex-dependent H3K27me3 may contribute to the developmental delay in *spr-5; met-2* mutants by concentrating ectopic H3K36me3 at germline gene loci in the soma. To test this possibility, we knocked down MES-2 using RNAi and found that the developmental delay in *spr-5; met-2* mutants is completely rescued. By performing RNA-seq and ChIP-seq, we further demonstrate that knocking down MES-2 rescued the ectopic transcription of MES-4 germline genes and reduced the ectopic H3K36me3 at these loci in *spr-5; met-2* mutant somas. Together, these data suggest that the PRC2 Complex contributes to a soma-to-germline transition and developmental delay in *spr-5; met-2* mutants and provides mechanistic insight into how highly conserved histone modifying enzymes cooperate during development to establish germline versus somatic cell fates.

198 **The CYK4 GAP domain controls contractile ring assembly and dissolution by regulating the cortical targeting of centralspindlin** Aleesa Schlientz[1], Sebastian Gomez-Cavazos[2], Kian-Yong Lee[2], Pablo Lara-Gonzalez[2,3], Arshad Desai[2], Karen Oegema[2] [1]School of Biological Sciences, University of California, San Diego, [2]University of California, San Diego, [3]University of California, Irvine

During cytokinesis, an equatorial contractile ring constricts to partition the cell contents. Contractile ring assembly requires active GTP-bound RhoA generated by the guanine nucleotide exchange factor ECT2. The centralspindlin complex, composed of two molecules of kinesin-6 and two molecules of CYK4, is the major ECT2 activator during cytokinesis. Centralspindlin is phosphorylated by Polo-like Kinase 1 (PLK1) at the central spindle during anaphase and diffuses to the adjacent plasma membrane where it activates ECT2. The N-terminal half of CYK4 is the primary target of PLK1 and engages with ECT2 to activate it, likely by relieving ECT2 autoinhibition, whereas the C-terminal half of CYK4 contains a C1 domain, which contributes to plasma membrane targeting, and a GTPase-activating protein (GAP) domain predicted to interact with a Rho family GTPase. The function of the CYK4 GAP domain has been unclear. Here, we show that the CYK4 GAP domain functions with the adjacent C1 domain to target centralspindlin to the cell cortex. Using an assay we developed to monitor cortical recruitment of centralspindlin during cytokinesis in the one-cell *C. elegans* embryo, we show that RhoA and the GTPase-binding interface of the CYK4 GAP domain are both essential to recruit centralspindlin to the equatorial cortex. Comparison of a CYK4 mutant that disrupts the RhoA binding interface of the GAP domain to a catalytic mutant (R459A) that selectively disrupts the ability of the GAP domain to convert bound RhoA-GTP to Rho-GDP revealed striking differences. In a mutant background partially compromised for RhoA activation, preventing RhoA binding inhibited furrowing, whereas the catalytic mutant was largely able to complete cytokinesis. In addition, whereas the RhoA-binding mutant reduced centralspindlin recruitment to the equatorial cortex, the catalytic mutant did not. The catalytic mutant additionally seemed to prevent the normal dissolution of cortical centralspindlin and contractile ring components at the end of cytokinesis. These results lead us to propose a model in which cortical recruitment of centralspindlin by the CYK4 GAP domain is central to a feedback loop in which generation of active RhoA at the cell cortex drives further centralspindlin recruitment and RhoA activation to drive rapid contractile ring assembly. As the contractile ring disassembles, conversion of RhoA-GTP to RhoA-GDP by the CYK4 GAP domain is important to ensure timely dissolution of the contractile ring.

199 **The transgenerational accumulation of repressive chromatin extends lifespan via DAF-12 signaling in *C.***

elegans Scott Roques[1], Jaime Croft[2], Alex Beaudoin[1], Teresa Lee[1] [1]Biological Sciences, University of Massachusetts Lowell, [2]University of Massachusetts Lowell

Longevity is a complex phenotype that integrates genetic information with environmental cues. Recent work has shown that epigenetic components, like histone modifications, also play an important role in regulating lifespan. We discovered that *C. elegans* populations with higher levels of repressive H3K9me2 acquire longevity in a transgenerational manner: mutations in WDR-5, a component of the H3K9me-modifying COMPASS/MLL complex, or in JHDM-1, a putative H3K9me demethylase, both cause a gradual increase in lifespan over 10-20 generations. Longevity in both mutants requires germline H3K9me2 deposition, which specifically accumulates at genes expressed in the germline. In *C. elegans*, several longevity pathways convene at DAF-12, the nuclear hormone receptor involved in signaling between somatic and germline tissues. DAF-12 also acts as a key regulator of entry into the alternative L3-stage called dauer in response to environmental stress. Here, we investigate the involvement of DAF-12 in our transgenerational longevity mutants. We find that *daf-12* is necessary for both *wdr-5* and *jhdm-1* mutant populations to acquire longevity. Interestingly, a mutation in *daf-12* also suppresses the maintenance of longevity in transgenerational *wdr-5* mutant populations, but not in *jhdm-1* mutants, indicating that the lifespan extension in each mutant may occur via different downstream pathways. Finally, mutations in either *wdr-5* or *jhdm-1* partially rescued the dauer-defective phenotype of *daf-12* mutants, suggesting that chromatin landscapes may also influence entry into dauer. Taken together, these findings highlight the complex relationship between chromatin state and germline-to-soma signaling during important life history decisions.

200 **DROSHA forms distinct nuclear condensates in *C. elegans*** Bing Yang[1], Brian Galleta[2], Nasser Rusan[2], Katherine McJunkin[1] [1]National Institute of Diabetes and Digestive and Kidney Diseases, [2]National Heart, Lung and Blood Institute

Precise and specific control of miRNAs both temporally and spatially is of extreme importance, since mis-regulation of miRNAs could result in numerous abnormal phenotypes, like heart diseases and cancer. miRNA biogenesis employs a two-step mechanism. The first step is the cleavage of primary miRNA transcripts (pri-miRNA) into precursor miRNAs (pre-miRNA) by the Drosha/DGCR8 Microprocessor complex. The second step involves the Dicer nuclease, which processes the pre-miRNA into mature miRNA products. Efforts to understand the structural and biochemical properties of Microprocessor have been mostly restricted to the carboxyl domains of Drosha and DGCR8, and the function of the less conserved N-terminal regions containing the IDR (Intrinsic Disorder Region) domains in Microprocessor is poorly understood. We constructed fluorescence tagged DROSHA protein via CRISPR in *C. elegans* and observed granule-like localization in the nuclei, which suggested a phase-separated distribution of the Microprocessor. Preliminary FLIP experiments on DROSHA::GFP suggested that the granule-like structures are highly dynamic. Through co-localization analysis, we learnt that DROSHA granules are distinct from other known subnuclear organelles in *C. elegans*. To further understand the function of IDR domains in Microprocessor, we generated mutants of Microprocessor lacking the IDR domains and observed phenotypes associated with one of the IDR deletion mutants, which also showed reduction in microRNA processing activity. Taken together, we discovered that DROSHA forms distinct nuclear condensates and one of the predicted IDRs plays a critical role in mediating DROSHA activity.

201 **Mechanical force of uterine occupation enables large vesicle extrusion from proteostressed maternal neurons** Guoqiang Wang[1], Ryan Guasp[1], Sangeena Salam[1], Edward Chuang[1], Andrés Morera[1], Anna J Smart[1], David Jimenez[1], Sahana Shekhar[1], Ilija Melentijevic[1], Ken C Nguyen[2], David H Hall[2], Barth Grant[1], Monica Driscoll[1] [1]Molecular Biology and Biochemistry, Rutgers University, [2]Neuroscience, Albert Einstein College of Medicine

Large vesicle extrusion from neurons may contribute to spreading pathogenic protein aggregates and promoting inflammatory responses--two prospective mechanisms leading to neurodegenerative disease. Factors that regulate extrusion of large vesicles, such as exophers produced by proteostressed *C. elegans* touch neurons, are poorly understood. Here we document that mechanical force can significantly potentiate exopher extrusion from proteostressed neurons.

Exopher production from the *C. elegans* ALMR neuron peaks at adult day 2 or 3 under lab conditions, coinciding with the *C. elegans* reproductive peak. Genetic disruption of *C. elegans* germline, sperm, oocytes, or egg/early embryo production can strongly suppress exopher extrusion from the ALMR neurons during the peak period. Conversely, restoring egg production at the late reproductive phase through mating with males, or inducing egg retention with genetic interventions that block egg-laying, can strongly increase ALMR exopher production.

The ALMR neuron is the most active touch receptor neuron (TRN) for exopher production as compared to the other five TRNs. Interestingly ALMR is the TRN most proximal to the uterus, with the exopher-producing ALMRs mostly (~95%) located in the vicinity of the uterine egg zone. Additionally, genetically maneuvering ALM neurons away from the egg zone can strongly suppress ALMR exopher production. Moreover, over-filling the uterus with eggs can strongly promote exopher extrusion from the ALMs, AVM, PVM neurons near the egg zone, but not from the two tail-located PLM neurons. Genetic interventions

that promote ALMR exopher production are associated with expanded uterine length. In contrast, genetic interventions that suppress ALMR exopher production are associated with shorter uterine lengths. Overall TRNs close to an egg-distended uterus, show increased exopher production.

A simple hypothesis for neuronal exopher production could be that eggs produce chemical factors that stimulate exophergenesis. Our data rule out this model because filling the uterus with oocytes, dead eggs, or even injected fluid can all strongly induce ALMR exopher production. Thus, we favor a model in which the mechanical force of uterine occupation triggers exopher extrusion from the proximal proteostressed maternal neurons.

Our observations draw attention to the potential importance of mechanical signaling in extracellular vesicle production and in aggregate spreading mechanisms, and make a case for enhanced attention to mechanobiology in neurodegenerative disease.

202 **Emerging high-content methods for aging research in *C. elegans*** George L. Sutphin, Samuel Freitas, Emily A. Gardea, Vanessa Silbar Molecular & Cellular Biology, University of Arizona

This seminar will present a new robotic imaging platform for high-content data collection in the *Caenorhabditis elegans*. *C. elegans* are a long-standing model for human aging due to their short lifespan, ease of culture in the laboratory, and the availability of powerful molecule tools. The standard approach to measuring *C. elegans* lifespan involves the labor-intensive process of manually examining animals cultured in groups on petri plates to determine whether they are still alive every 1-3 days throughout their lifespan. Advancement in automated image collection, image processing, and machine learning over the past decade has led to the development of several systems that enable automated collection of *C. elegans* lifespan data, increasing throughput while limiting subjective scoring bias. In addition to being short-lived, *C. elegans* are transparent, allowing fluorescent biomarkers reporting activity in many molecular processes to be monitored. As with lifespan, standard methods for quantifying fluorescent biomarkers are labor-intensive and involve paralyzing animals and manually capturing fluorescent images. We developed an robotic imaging platform that combines automated lifespan and healthspan data collection with simultaneous collection of fluorescent imaging data across lifespan in free-crawling *C. elegans* cultured on solid media. Our system is designed for use with single-worm culture systems, enabling dynamic changes in up to three co-expressed biomarkers to be tracked in individual animals across lifespan. The specific set of biomarkers used can be tailored to the distinct goals of each experiment. Our platform can monitor ~20,000 animals in parallel (~150,000 animals per year) and is compatible with genetic (RNAi, deletion mutants, transgenics) and pharmacological interventions. The ability to capture multiple physiological—lifespan, activity, health, body size/shape—and molecular—up to three fluorescent biomarkers—over time in the same individual animals represents a shift from high-throughput lifespan screening to high-content data collection with applications across the *C. elegans* research community.

203 **Sex-specific mechanisms of temperature-induced transposon mobilization in spermatocytes** Diana E Libuda Biology, University of Oregon

Sexually-reproducing organisms generate haploid gametes, such as sperm and eggs, to transmit their genome to the next generation. All tissues are susceptible to dramatic increases in temperature, however, developing sperm are unusually sensitive to small temperature fluctuations. In contrast to oogenesis, spermatogenesis requires a narrow isotherm of 2-7°C below core body temperature to ensure fertility. One of the research focuses of my group is to elucidate the sexually dimorphic mechanisms that cause temperature-induced male infertility and genomic instability. In my talk, I will discuss our recent work with the nematode *C. elegans* and the zebrafish *Danio rerio* that has identified how small RNA pathways and meiotic chromosome structures contribute to temperature-induced transposon mobilization specifically in spermatogenesis.

204 **Modeling the fitness cost of chromosomal duplication identifies determinants of aneuploidy toxicity in budding yeast** Julie CM Rojas[1], James Hose[2], H Auguste Dutcher[2], Michael Place[2], Audrey P Gasch[2] [1]Genetics-Biotechnology Center, University of Wisconsin-Madison, [2]Genetics, University of Wisconsin - Madison

Whole-chromosome aneuploidy, characterized by an abnormal number of chromosomes, affects growth and fitness across most eukaryotes. Although generally thought of as deleterious, aneuploidy often underlies adaptation to hostile environments and is prevalent in 80% of human tumors. The reason for this discordance is not clear, in part because the cellular consequences of chromosome imbalance remain unknown. To understand the molecular determinants of aneuploidy effects, we generated a panel of wild-isolate S. cerevisiae strains in which each of the 16 chromosomes is duplicated and then used comparative mathematical modeling of the strains' fitness costs to test specific biological hypotheses. The distribution of measured fitness costs is relatively well explained by simply summing the number of genes per chromosome, explaining 62% of the variance in growth rates, consistent with the hypothesis that genetic burden affects fitness. However, this simple model does not consider the specific properties of genes amplified on those chromosomes or non-genic features. To explore the impact of specific chromosomal features, we used a low-copy plasmid library to measure the fitness effects of duplicating

genes individually and then performed lasso regression to define the determinants of aneuploidy fitness effects. We outline a multi-factorial model in which the impacts of aneuploidy are explained by the additive effect of individual-gene fitness costs along with specific classes of non-coding RNAs present on each chromosome. We confirmed the model experimentally by showing that the duplication of snoRNAs is detrimental while amplification of tRNAs improves strain growth, especially in a sensitized mutant background lacking RNA binding protein Ssd1. In all, our model explains 75-94% of the variance in aneuploid growth rates and reveals important new insights into the mechanisms of aneuploidy toxicity.

205 **SUMO modifies Hop1^{HORMAD1} at distinct sites to facilitate checkpoint signaling and inter-homolog crossing over** Sara Hariri[1], Marry Wallace Corrigan[2], Regina Bohn[2], Nikhil Bhagwat[2] [1]Microbiology and Molecular genetics, UC Davis, [2]UC Davis

Protein modification by the ubiquitin-related modifier, SUMO, helps orchestrate the complex events of meiotic prophase I, including chromosome pairing, synapsis, and recombination. Our recent proteomics analysis identified cohorts of SUMO-modified proteins involved in each step of meiotic recombination in budding yeast. One SUMO target is the conserved HORMA-domain protein, Hop1^{HORMAD1}, a dynamic component of chromosome axes that mediates interactions between homologous chromosomes. Hop1 facilitates the initiation of recombination by DNA double-strand breaks, promotes recombination between homologous chromosomes rather than sister chromatids, and mediates DNA damage checkpoint signaling by activating the effector kinase, Mek1^{CHK2}. Our recent analysis points to roles of SUMOylation in the inter-homolog bias and checkpoint signaling functions of Hop1. We show that a SUMOylation-deficient mutation (*hop1-15KR*) causes reduced levels of inter-homolog recombination (crossing over) and bypasses the meiotic prophase-I arrest phenotypes of mutants defective for recombination and chromosome synapsis. Moreover, the activity of the apical kinase Mek1 is decreased in *hop1-15KR* mutant cells, further confirming a defect in checkpoint signaling. To understand how SUMOylation facilitates Hop1 function, I will analyze the SUMO-deficient hop1-15KR protein for: (i) protein stability; (ii) phosphorylation by the DSB sensor kinases Mec1^{ATR} and Tel1^{ATM}; nuclear and chromosomal localization dynamics; and interaction with its partner proteins. Together, this analysis will provide insights into how SUMOylation regulates key aspects of meiotic prophase-I via modification of Hop1.

206 **Strategic targeting of Cas9 nickase induces large segmental duplications** Yuki Sugiyama, Satoshi Okada, Takashi Ito Kyushu University

The genesis of genomic structural variations (SVs) is critical in genome evolution. A method to induce specific SVs at the targeted genomic region is essential to understand how genomes evolve via SVs. However, such a method is yet to be established. In this study, we attempted to develop a method to induce specific segmental duplications in the genome using paired-nicking by nCas9.

We constructed a genetic reporter system to detect a segmental duplication in the genome of the budding yeast *Saccharomyces cerevisiae*. We made a strain in which chromosome IV carries two fragments derived from the *URA3* gene (*RA3* and *UR,* harboring a 391-bp overlapping sequence) at the interval of 47-kb containing replication origin. A recombinational repair event between the overlapping sequences duplicates the 47-kb segment between *RA3* and *UR* to reconstitute the *URA3* gene. The cells harboring the segmental duplication are Ura$^+$ or can grow on the medium lacking uracil. When two single-strand breaks were induced simultaneously at an upstream position of *RA3* and a downstream position of *UR* using Cas9(D10A) nickase with two guide RNAs designed at the two positions, ~15 % of surviving colonies were Ura$^+$. Long-read sequencing confirmed the tandem duplication of the 47-kb segment. We named this method “Paired-Nicking-induced Amplification (PNAmp).”

We investigated the maximum size of segments that PNAmp can duplicate. We made a series of strains harboring various intervals between *RA3* and *UR.* Surprisingly, even when the interval was ~1 Mb (covering ~90% of the right arm of chromosome IV), 10% of the surviving colonies were Ura$^+$.

To verify that PNAmp can induce SD in a natural genomic context, we targeted a 117-kb region bounded by the Ty1 retrotransposable elements, which share ~96% homology, on chromosome IV. After inducing paired nicks upstream of one Ty1 element and downstream of the other, we performed whole-genome sequencing to demonstrate not only a 1.15-fold increase in normalized read counts of the target region, but also the presence of reads covering the junction of the intended SD. These results indicated that PNAmp can use naturally occurring homologous, but not identical, sequences to induce SDs.

In addition, we showed that PNAmp using an appropriate splint sequence (termed “splinted PNAmp”) allows efficient duplication of genomic segments even when they lack flanking homologous sequences.

In summary, we established a method to induce specific large-scale segmental duplication at high efficiency using paired-nicking by nCas9.

207 **Expanded CCTG tetranucleotide DNA repeat tracts associated with Myotonic Dystrophy Type-2 elevate DNA fragility *in vivo* in a length-dependent manner** Jane C. Kim, Zaid M. Salah, Madison B. Atchley, Clarissa I. Garcia, Luis A. Hernandez California State University San Marcos

An expanded tract of CCTG tetranucleotide DNA repeats in the *CNBP* gene is the mutation responsible for the genetic disorder Myotonic Dystrophy Type 2 (DM2). Strikingly, affected individuals can have 75-11,000 CCTG repeats at the locus. The molecular mechanisms and genetic control responsible for CCTG repeat expansions and contractions is not well understood. We used a direct duplication recombination assay (DDRA) to study DNA fragility of these repeats and investigate how this fragility is affected by repeat orientation, length, and persistence of single stranded DNA. We found that 100 repeats of either CCTG or reverse complementary CAGG repeats elevate DNA fragility above a no repeat control, though there was no significant difference between the two orientations. Investigating repeat length in one orientation, we found that DNA fragility was elevated upon exceeding 60 repeats with a non-linear increase for 138 repeats. DNA fragility was elevated in strains with point mutations in *RFA1*, which encodes the largest subunit of the heterotrimeric Replication Protein A. Thus, we propose that greater persistence of single-stranded DNA elevates CAGG/CCTG fragility, and repair of these double strand breaks contributes to the massive DNA expansions and contractions observed in DM2 patients and their offspring.

208 **Determining the role of a major microtubule binding pathway in the regulation and function of kinetochore** Nairita Maitra, Devin Edwards, Sue Biggins Fred Hutch Cancer Center

A cell must ensure equal partitioning of its duplicated chromosomes each time it divides. Error in this process can result in either gain or loss of genetic material, leading to abnormalities found in cancer and birth defects. Cells utilize the force generated by the microtubule-based spindle to pull the chromosomes apart. A megadalton protein complex called kinetochore assembles at the centromere of each chromosome, recognizes these pulling forces, and eventually transmits them to the DNA, facilitating the separation of the genetic material. The tension on the kinetochore-microtubule attachments keeps changing throughout the cell cycle. During metaphase, the attachments are under high tension, as the pulling force of the microtubules is opposed by the linkage between the duplicated chromosomes. However, cells often make improper attachments that lack tension. Error correction pathway detects such attachments, destabilizes the kinetochore-microtubule binding, giving the cells another chance to build proper attachments. While these activities during the metaphase are necessary, during anaphase, the tension between the kinetochore and microtubule drops as the cohesion between the duplicated chromosome is gone, and the microtubules also start shortening. Hence, asking how the kinetochores remain attached to the microtubules during anaphase when the tension is low is important. Two competitive pathways recruit the major microtubule-binding protein Ndc80c to the kinetochore- Mis12c and Cnn1 pathway. The Cnn1 pathway gets enriched at the kinetochore during anaphase, making it a potential pathway that could stabilize the low-tension attachment during anaphase. Using budding yeast as my model organism, I aim to study how the Cnn1 pathway regulates kinetochore assembly and function during the cell cycle, especially in anaphase. Recent studies show that SUMOylation is critical in kinetochore assembly and function. Cnn1 protein has a conserved SUMO interacting motif (SIM) that can interact with another kinetochore protein via SUMOylation. Purifying Cnn1 from wild-type and $Cnn1^{SIM}$ mutant showed that the level of Stu2, a microtubule polymerase, decreases in the $Cnn1^{SIM}$ mutant, which is cell cycle-independent and unique to the Cnn1 pathway. Moreover, our biophysical assay shows that the $Cnn1^{SIM}$ mutant has weak kinetochore-microtubule attachments during anaphase compared to the wild type cells. Hence, currently, I am investigating how the interaction is happening and how it affects the kinetochore-microtubule attachments. The exclusive interaction of a microtubule polymerase like Stu2 with the Mis12c and Cnn1 pathway could demonstrate how the Cnn1 pathway might maintain kinetochore-microtubule attachments under low tension.

209 **Elevated and skewed dNTP pools alter multiple activities at the replisome** Jennifer A Surtees, Natalie Lamb, Luke Hess Biochemistry, University at Buffalo

The fidelity of DNA replication is critical in ensuring the stability of the genome from cell division to the next. Accurate DNA synthesis by replicative DNA requires appropriate levels and ratios of deoxyribonucleotide triphosphates (dNTPs), the building blocks of DNA, and is enhanced by the polymerase proofreading exonuclease function. The mismatch repair (MMR) system functions as a spell-check for DNA replication, detecting and directing repair of replication errors that evade proofreading. When dNTP pools are dysregulated, it interferes with the normal functioning of the replisome. Elevated dNTP pools lead to an increased rate of nucleotide misincorporation, increase the rate of DNA replication and alter the number of replication origins that are activated. We previously used deep sequencing to demonstrate that altering the dNTP pools in different ways (elevated, skewed) leads to distinct mutation profiles. These misincorporation events are substrates for MMR, but as the mutation rates increase, MMR can become saturated. Thus, altered dNTPs can promote mutagenesis that can lead to cancer. At the same time, cancer cells have elevated dNTP pools to maintain rapid proliferation. This can, in turn, lead to further mutagenesis and promote the molecular evolution of the cancer, providing a selective advantage.

In a previous synthetic lethal (SGA) screen in *Saccharomyces cerevisiae,* utilizing *rnr1Y285A,* which resulted in 20-fold excess dCTP and dTTP, we identified almost all of the genes involved in the mismatch repair (MMR) pathway. The contribution of the MMR system to maintaining replication fidelity is well established, but our results highlight an essential role of the pathway in the presence of skewed dNTP pools. Deleting MMR genes in combination with *rnr1Y285A* resulted in compromised cellular fitness and a defect in cell cycle progression. Our data suggest that the errors accumulated under elevated dNTP pools is sufficient to activate the DNA damage response.

We were also intrigued by the observation that altered levels/ratios of dNTP pools lead to increased frameshift slippage events and the possibility that this might affect the rate of trinucleotide repeat (TNR) expansions. TNR expansions occur in the presence of *CNG* repeat sequences in the DNA and promote neurodegenerative diseases such as Huntington's Disease or myotonic dystrophy type I. To test this, we used our yeast *in vivo* TNR reporter system to determine the rate of expansions in genetic backgrounds that alter dNTP pools. Our preliminary data indicate that in *rnr1D57N* (2-fold increase in all 4 dNTPs) resulted in decreased $(CAG)_{25}$ expansions compared to wild type. We propose that alterations at the replication fork can modify the probability of generating a slipped strand TNR structure that can be expanded.

These data are consistent with our hypothesis that elevated dNTP pools fundamentally change the activity of the replisome.

210 **Evolution in action: extreme genomic and phenotypic variation in RNAi/meiotic drive systems** Garima Setia[1], Bernard Kim[2], Holly Mudgett[3], Taiya Jarva[1], Patricia Foley[3], Dmitri Petrov[2], Colin Meiklejohn[3], Eric C. Lai[1] [1]MSKCC, [2]Stanford, [3]University of Nebraska

Selfish meiotic drive systems can distort progeny sex-ratio and/or induce sterility. Although widespread in nature, the molecular mechanisms of meiotic drive, and how they are silenced to restore Mendelian segregation, remain largely mysterious. Importantly, their rapid evolution means that classic model organisms are often not suited to reveal their fundamental features, breadth and impact. Using *Drosophila simulans* (*Dsim*), we uncovered critical roles for hpRNA-class RNAi substrates to suppress incipient sex chromosome conflicts. These arose in the *simulans*-clade ancestor, and are not found in their close relative *D. melanogaster*. Knockouts of *Dsim* hpRNA-siRNA loci (Nmy and Tmy) exhibit profound defects in the male germline, leading to loss of male progeny or outright sterility. These phenotypes are due to de-repression of recently-emerged members of the «Dox» family, which derive in part from protamine, which condenses the paternal genome. Strikingly, analysis of nanopore genomes from a panel (~20) of wild *Dsim* strains indicates that nearly all individual lines examined harbor different numbers of Dox family genes on their X chromosomes. Notably, these include many *de novo* insertions that were not present in the initial PacBio *Dsim* genome available for study. Moreover, numerous wild X chromosomes exhibit highly variable drive activities when assayed in *nmy* or *tmy* mutants, in that several X chromosomes can partially or completely suppress sex ratio or sterility defects, but some can enhance these hpRNA mutant phenotypes. We hope to gain mechanistic insights into sex ratio and sterility drive from these long-read genomes and genetic interactions. Overall, they uncover broad, unanticipated complexity in rapidly-evolving sex chromosome conflicts and may potentially foment speciation.

211 **Unveiling a novel exonuclease driving paternal mitochondrial DNA elimination in *Drosophila* spermatogenesis** Zhe Chen[1], Zong-heng Wang[2], Fan Zhang[2], Michaela Yamine[2], Christian Combs[2], Hong Xu[2] [1]NHLBI, National Institutes of Health, [2]National Institutes of Health

The exclusive maternal transmission of mitochondrial DNA (mtDNA) in animals was traditionally attributed to passive differences in cytoplasmic contents between eggs and sperm. However, recent studies have revealed active mechanisms involved in the elimination of mtDNA during spermatogenesis in various species. Despite this progress, the factors driving this process and the physiological significance of mtDNA clearance remain largely unknown. In our investigation, we identified POLDIP2 as a novel mtDNA exonuclease that plays a central role in this elimination process. POLDIP2, encoded by the CG12162 locus, exhibits specific enrichment in the late stages of spermatogenesis when mtDNA clearance occurs. Although *Poldip2* mutant flies exhibited normal spermatogenesis progression, they produced fewer mature sperms that frequently contained multiple copies of mtDNA, indicating the essential role of POLDIP2 in mtDNA clearance. Notably, we discovered that POLDIP2 is an exonuclease with a preference for degrading single-stranded DNA and double-stranded DNA with breaks. Intriguingly, ectopic expression of a mitochondrially targeted *E.coli* exonuclease III in *Poldip2* mutant flies effectively mitigated residual mtDNA and substantially restored male fertility and nuDNA fragmentation, highlighting the detrimental consequences of persisting mtDNA in mature sperm cells. To our knowledge, POLDIP2 represents the first factor identified to specifically enforce maternal inheritance of mitochondrial genomes. This discovery opens avenues for future investigations into the physiological significance and underlying mechanisms of this highly conserved yet enigmatic uniparental inheritance of mtDNA.

212 **Specialized translational machinery is required for spermatogenesis in *Drosophila melanogaster*** Brook L Falk[1,2], Yonit Tsatskis[2], Celine Salhab[2,3], Kirsten Arnold[4], Sarah C Hughes[4], Julie A Brill[1,2] [1]Department of Molecular Genetics, University of

Toronto, [2]Cell Biology Program, The Hospital for Sick Children, [3]Human Biology Program, University of Toronto, [4]Department of Medical Genetics, University of Alberta

Drosophila melanogaster sperm development relies on extensive post-transcriptional regulation as thousands of transcripts are preserved to be translated at later stages when they are required. A key step in translation initiation is binding of eukaryotic initiation factor 4E (eIF4E) to the 5' mRNA cap. *D. melanogaster* has multiple paralogues of eIF4E, including four testis-enriched paralogues (eIF4E-3, -4, -5 and -7). We and our collaborators previously discovered that eIF4E-3 and -5 are both needed for male fertility and formation of mature sperm. Their roles, however, are stage specific as eIF4E-3 first appears pre-meiotically and is required for meiotic chromosome segregation and cytokinesis whereas eIF4E-5 is required for the final stage of spermiogenesis called individualization. During individualization, organelles and cytoplasmic components not needed in mature sperm are stripped away by non-apoptotic caspase activity. In flies lacking eIF4E-5, the gradient of the caspase regulatory protein, Soti*,* is disrupted and caspase activity is dysregulated, resulting in the absence of mature sperm. The specific functions of the testis eIF4Es are likely conferred by differences in gene expression, mRNA localization and translation, or protein sequence. Therefore, we generated transgenes to define the gene-specific sequences that are required for eIF4E-3 and -5 function. We found that fertility of *eIF4E-3* mutants is rescued by expression of a 3xFLAG-tagged genomic eIF4E-3 transgene that includes its introns and upstream and downstream regulatory regions, whereas fertility of *eIF4E-5* mutants is restored by expression of 3xFLAG-tagged eIF4E-5 transgenes containing either the endogenous genomic region or a cDNA under control of a spermatocyte-specific promoter (*b2-tubulin).* We have also generated domain swap transgenes to test the requirement for the non-conserved portions of eIF4E-3 and -5. To further the mechanistic understanding of the testis eIF4Es, I will use the tagged constructs in affinity purification coupled with mass spectrometry and RNA-immunoprecipitation experiments. In addition, I generated eIF4E-5 transgenes tagged with the promiscuous biotin ligase miniTurbo to aid in the identification of transiernt protein interactors. Overall, eIF4E-3 and -5 are stage specific translational regulators required to ensure correct spatiotemporal synthesis of proteins during different stages of spermatogenesis, and our results will provide insight into how these testis eIF4Es function and are regulated during spermatogenesis.

213 **Mating induces ecdysone signaling in the *Drosophila* testis niche disrupts soma-germline contacts and stem cell cytokinesis** Tiffany V. Roach, Kari F. Lenhart Biology, Drexel University

Germline maintenance relies on adult stem cells to continually replenish lost gametes over a lifetime and respond to external cues altering the demands on the tissue. Mating worsens germline homeostasis over time, yet a negative impact on stem cell behavior has not been explored. Using extended live imaging of the *Drosophila* testis stem cell niche, we find that short periods of mating in young males disrupts cytokinesis in germline stem cells (GSCs). This defect leads to failure of abscission, preventing release of differentiating cells from the niche. We find that GSC abscission failure is caused by increased ecdysone hormone signaling induced upon mating, which leads to disrupted somatic encystment of the germline. Abscission failure is rescued by isolating males from females but recurs with resumption of mating. Importantly, reiterative mating also leads to increased GSC loss, requiring increased restoration of stem cells via symmetric renewal and de-differentiation. Together, these results suggest a model whereby acute mating results in hormonal changes that negatively impact GSC cytokinesis but preserves the stem cell population. Future work will focus on directly visualizing somatic stem cells and their immediate daughters to observe encystment behaviors in real time under homeostatic as well as stressful conditions.

214 **Close encounters with Oskar: proteomic profiling of germ granule interactions and beyond** Kwan Yin Lee[1], Harathi Jonnagaddala[2], Marian Kalocsay[2], Elizabeth R Gavis[1] [1]Molecular Biology, Princeton University, [2]Experimental Radiation Oncology, The University of Texas MD Anderson Cancer Center

A conserved feature of germline development in animals is the formation of cytoplasmic ribonucleoprotein bodies called germ granules. Germ granules are phase transitioned condensates comprising a protein scaffold into which numerous mRNAs encoding proteins required for germline specification, proliferation, and maintenance are incorporated. In *Drosophila melanogaster,* recent work has shown that germ granules are remodeled during primordial germ cell (PGC) development so that they can be repurposed for distinct functions. Remodeling occurs by the recruitment of protein factors, perhaps leveraging the properties of germ granules as phase transitioned entities that can exchange protein content with the environment over time. Is this a general strategy to generate different outcomes in the post-transcriptional regulation of mRNAs within germ granules? A dedicated mechanism is necessary because a germ granule can contain up to hundreds of different mRNAs. Differences in the regulation of several germ granule mRNAs have been known for over a decade, but mechanisms underlying these observations remain unknown. Oskar is a core germ granule protein in *Drosophila melanogaster* that is present throughout the lifecycle of the germ granule. Granule assembly is driven by Oskar which nucleates the recruitment of other germ granule scaffold proteins through both protein-protein and multivalent interactions. As part of the germ granule, Oskar also binds and post-transcriptionally regulates specific mRNAs. To expand our understanding of how germ granules contribute to post-transcriptional regulation, we used a proximity dependent biotinylation approach to capture the protein milieu that

Oskar is immersed in from oogenesis to embryogenesis. Oskar was conjugated to TurboID, an engineered biotin ligase that catalyzes promiscuous biotinylation of proteins within a radius of several nanometers. Using multiplexed TMT quantitative mass spectrometry, we generated Oskar-TurboID datasets in ovary samples and in samples at multiple timepoints during embryogenesis. Our experiments reveal dramatic changes in the proteins biotinylated by Oskar-TurboID in embryogenesis compared to oogenesis. Oskar-TurboID biotinylates hundreds of additional factors at the onset of embryogenesis suggesting widespread remodeling of the germ granules and their environment upon fertilization. We hypothesize that these dramatic changes represent a developmental program driving post-transcriptional regulation of germ granule mRNAs to prepare the *Drosophila* embryo for PGC formation. Live imaging and antibody staining confirmed the dynamic localization of protein candidates from our Oskar-TurboID time course. Therefore, our Oskar-TurboID approach comprehensively records molecular encounters of Oskar *in vivo*.

215 **Drosophila H2A.Z regulates developmental timing and the global transcriptome** Pakinee Phromsiri, Noah Reger, Fanju Meng, Claire Makowski, Patrick Murphy, Michael Welte University of Rochester

In early Drosophila embryos, the variant histone H2Av is necessary for the upregulation of numerous genes during zygotic gene activation (ZGA) and is already present at many transcription start sites before ZGA. We discovered that nuclear H2Av levels increase gradually with each nuclear cycle (NC), from NC9 to NC14. To determine whether this stepwise increase is functionally important, we compared embryos from mothers with one (*1X H2Av*), two (*2X H2Av*; wild type) and four (*4X H2Av*) copies of the *H2Av* gene. Even though these three genotypes develop grossly normal, they display consistent differences in the length of NC13, compared to wild type. NC13 is slowed down in *1X H2Av* and accelerated in *4X H2Av* embryos. We also observed a similar acceleration of NC13 in *Jabba* mutant embryos in which H2Av is not properly sequestered in the cytoplasm and over accumulates in nuclei (similar to *4X H2Av*). These observations suggest that the nuclear levels of H2Av control the timing of certain developmental events around ZGA. H2Av is the sole H2A variant in Drosophila, combining H2A.X and H2A.Z functions. H2A.X is phosphorylated upon DNA damage and promotes DNA repair; H2A.Z functions in transcription and chromatin structure. Using transgenes encoding a mutant H2Av unable to be phosphorylated, we found that H2Av's H2A.X function is dispensable for the NC13 speed up. Since H2A.Z is involved in transcriptional regulation, we compared wild type and *4X H2Av* embryos by RNA-seq. In NC13 and early NC14, we found significant differences in abundance for hundreds of transcripts. These differences appear during zygote development as the global transcriptome of freshly laid embryos was largely identical between the two genotypes. At the later timepoints, most of the changes reflect premature degradation of maternally provided transcripts; in NC13 *4x H2Av* embryos, these messages are already reduced to levels that in the wild type are reached only in NC14. We also find that a small fraction of zygotic transcripts (46 out of 6231 detected) display altered expression levels, possibly reflecting premature or delayed activation of their transcription. We are currently testing whether such changes to transcriptional regulation drive NC13 acceleration and premature degradation of maternal messages.

216 **Cuticle nanopatterning in the *Drosophila* olfactory organs is controlled by the ER-resident *Osiris* family protein Gore-tex.** Shigeo Hayashi, Sachi Inagaki, Takeshi Itabashi, Atsuko Iwane RIKEN Center for Biosystems Dynamic Research

Insect cuticle structures are extensively modified to meet various physiological demands, such as decorating the surface with structural color and superhydrophobicity in the ocular lens. The biological mechanism of insect cuticle nanopatterning is totally unknown. Small pores of ~30 nm diameter in the cuticle of olfactory organs permit access of chemical signals to sensory neurons inside the cuticle. We previously reported that nanopore formation and olfactory response fail in the mutant of the *gore-tex (gox)/Osiris23 (Osi23)* gene (Ando et al., 2019). *Osi* family genes are expressed in various cuticle-secreting cells and encode endosome-associated transmembrane proteins. Their sequences are highly conserved in insects but absent in the genome of other arthropods, suggesting that *Osi* genes are involved in insect-specific cuticle morphogenesis. To understand the role of the *gox/Osi23* gene, we performed ultrastructural analyses of olfactory hair cells in the early stage of cuticle formation at 42 to 52 hours after puparium formation. Reconstruction of membrane structures from 3D stacked images of the focused ion beam SEM revealed interconnected networks of endoplasmic reticulum spanning the entire length of olfactory hair cells. Gox-labeled endosomes were found to span the position connecting the ER network to the cell surface. We show that Gox restricts subcortical ER by promoting ER phagy, which is essential for nanopore formation. We will present the identification of the molecule linking Gox to ER-phagy and the downstream cellular events linking the membrane dynamics to the nano-level cuticle assembly.

217 **Combinatorial role of signaling factors in the maintenance of Drosophila germline stem cell fate** Amelie Raz, Hafidh Hassan, Yukiko Yamashita Whitehead Institute for Biomedical Research

In the Drosophila testis, GSCs divide asymmetrically to simultaneously self-renew and generate differentiating spermatogonia which, in turn, will undergo multiple symmetric divisions before entering meiosis. Such divergent cell behaviors – asymmetric division and self-renewal by GSCs vs. symmetric division and differentiation by their daughters – suggests that the GSC-

to-spermatogonia transition is a strict step-wise cell identity shift. However, contrary to this model, spermatogonia can spontaneously **de**differentiate back into GSCs; this behavior is required to reestablish GSCs after loss (e.g., after starvation). We determine that GSCs endow their daughter cells with most-to-all of the GSC transcriptome, maintaining spermatogonia in a protected, uncommitted, and dedifferentiation-competent state. However, spermatogonial dedifferentiation is typically suppressed by a lack *active* GSC-like transcription requiring reception of niche signals. We find that after GSC loss, longer-range niche factors can diffuse to spermatogonia, activating a subset of the GSC transcriptional program and triggering dedifferentiation. Upon engraftment into the niche, short-range signaling factors activate transcription of a separate set of GSC targets, returning these cells to normal GSC behavior, including self-renewing divisions. Such combinatorial behavior of two separate signaling ligands, in which reception of one, neither, or both each yields a unique and required cellular behavior (dedifferentiation, differentiation, or self-renewal, respectively) reveals for the first time why more than one ligand is required to maintain germline stem cell homeostasis. Together, this model identifies a gene regulatory path for programming germline stem cell identity during both self-renewal and dedifferentiation.

218 **Investigating the generation of asymmetric cell migration during heart development** Vanessa Gonzalez, Rebecca Burdine Molecular Biology, Princeton University

Asymmetric collective cell migration of cardiac progenitor cells (CPCs) is necessary for proper asymmetric development, left-sided placement, and function of the vertebrate heart. Errors in heart development can result in congenital heart defects, the most common structural birth defect in the United States. Patterning of the vertebrate embryo along the left-right (LR) axis is required for proper positioning and asymmetric development of the heart. The first left-right asymmetry in zebrafish heart development is produced by “jogging”: the asymmetric migration of CPCs to produce a left-lateralized heart tube. We and others have shown that the jogging of CPCs is required for proper LR positioning of the heart and dependent on left-sided Nodal signaling. Asymmetric Nodal signaling results in transcription factor FoxH1-mediated gene expression changes that produce faster CPC migration rates in left-sided CPCs, suggesting that transcriptional changes are critical for establishing the heart’s asymmetry. To identify how Nodal influences gene expression to increase left-sided CPC migration rates, I utilized single-cell RNA sequencing to characterize asymmetric transcriptional events during CPC migration. With this data, I have identified a set of genes that are differentially expressed between left-sided and right-sided CPCs; these candidate genes are all components or regulators of the cytoskeleton and potential novel Nodal signaling targets that are important for proper LR asymmetry of the heart. More specifically, I find that several actin genes and F-actin regulator genes are upregulated in left-sided CPCs. We then find that the F-actin cytoskeleton itself is asymmetrically present and increased in left-sided CPCs in response to Nodal signaling; loss of Nodal signaling in *southpaw* mutants results in symmetric F-actin. Additionally, I am currently characterizing a promising candidate gene, *bves*, to determine its function in jogging. *bves* is known to promote tight junction (TJ) formation, which enables faster collective cell migration. I hypothesize that *bves* upregulation by Nodal increases TJ formation and function in left-sided CPCs, and that this is critical for maintaining epithelial integrity and cell migration rates during jogging. *bves* mutants demonstrate LR cardiac laterality issues and immunofluorescence demonstrates that *bves* and *ZO-1*, a canonical TJ protein, co-localize in the jogging heart, suggesting a role for *bves* and TJs in LR cardiac asymmetry. Ongoing experiments will continue to characterize the genes and cytoskeletal components necessary for asymmetric CPC migration and proper jogging to establish asymmetry in the vertebrate heart. My work is advancing our understanding of the genetic and cellular basis of asymmetric heart development, thus shedding light on the processes that may be affected in congenital heart defects.

219 **Dissecting the cell type-specific roles of Hand2 during zebrafish cardiac development** Yanli Xu[1], Rupal Gehlot[1], Samuel Capon[1], Marga Albu[1], Jonas Gretz[1], Joshua Bloomekatz[2], Kenny Mattonet[1], Dubravka Vucicevic[3], Sweta Talyan[4], Stefan Günther[4], Mario Looso[5], Beth Firulli[6], Anthony Firulli[6], Scott Lacadie[3], Deborah Yelon[7], Didier Stainier[1] [1]Developmental Genetics (Dept. III), Max Planck Institute for Heart and Lung Research, [2]The University of Mississippi University, [3]Max-Delbrück-Center for Molecular Medicine in the Helmholtz Association (MDC), Berlin Institute for Medical Systems Biology (BIMSB), [4]Max Planck Institute for Heart and Lung Research, [5]Bioinformatics Core Unit (BCU), Max Planck Institute for Heart and Lung Research, [6]Indiana Medical School, [7]University of California

The bHLH transcription factor Hand2 plays multiple roles during vertebrate organogenesis including cardiogenesis. Cardiogenesis requires the integration of diverse cell types including the myocardial and endocardial cells that form the initial layers of the heart; it also requires the orchestration of several morphogenetic processes, including trabeculation and cardiac valve formation. Despite the importance of Hand2 during cardiogenesis, much remains to be uncovered about its mechanism of action. Here we utilized advanced genetic and imaging tools in zebrafish and first observed that *hand2* is expressed in the anterior lateral plate mesoderm which gives rise to the myocardium and endocardium from the heart tube stage to the valvulogenesis and trabeculation stages. We generated several *hand2* mutant alleles and found that dimerization-deficient mutants display the null phenotype (cardia bifida) while DNA binding-deficient mutants do not. Mechanistically, we found that *Pdgfra* is a conserved Hand2 target and effector during early cardiac development. Due to the early embryonic

lethality of *hand2*-null zebrafish, we generated a floxed allele to further investigate its function in specific lineages. Knocking out *hand2* in *myl7* expressing cells (*i.e.,* cardiomyocytes) led to a late phenotype whereby the mature trabecular ridges mostly fail to form, which is correlated with a decrease in Notch signaling in the myocardial cells. Interestingly, knocking out *hand2* in *kdrl* expressing cells (*i.e.,* endothelial cells) resulted in a loss of valve interstitial cell and a hypo-trabeculated ventricle. Altogether, these results further our understanding of Hand2 function across time and space during cardiogenesis.

220 **The role of neural crest-derived cardiomyocytes in zebrafish heart development and regeneration** Julia Whittle[1], Chelsea Herdman[2], Sarah Abdul-Wajid[2], Leonard Almero[2], H. Joseph Yost[2] [1]Molecular Medicine, University of Utah, [2]University of Utah

The neural crest (NC) is a highly migratory embryonic stem cell population unique to vertebrates. It forms at the dorsal side of the neural tube, subsequently undergoing an epithelial-mesenchymal transition to migrate throughout the embryo and differentiate into a diverse population of cell types. A subpopulation of the NC migrates to the heart and differentiates into functional cardiomyocytes (NC-Cms). In zebrafish, NC-Cms make up about 12% of cardiac cells in the embryonic ventricle and are virtually indistinguishable from other cardiomyocytes in adulthood. However, NC-Cms play important roles both in zebrafish heart development and in regeneration. In development, these cells express the Notch ligand *jag2b*, postulated to guide heart trabeculation through Notch signaling. Ablation of NC-Cms during development causes mild trabeculation defects in embryos as well as adult-onset hypertrophic cardiomyopathy and reduced heart function. We observe a phenocopy of adult hypertrophic cardiomyopathy in *jag2b* knockout mutants despite successful migration of NC-Cms to the heart, suggesting that *jag2b*-driven Notch signaling from NC-Cms is also necessary for adult heart function. In addition to their role in development, NC-Cms appear to activate during injury repair of the adult heart. The NC transcription factor *sox10* is expressed in zebrafish hearts 7 days post injury, enriched in proliferating cells. In contrast, NC-Cm ablated fish display a noticeable reduction in heart regeneration markers such as *nppb* and *raldh2*, and lack *sox10* expression at the site of injury. It appears that NC-Cms may revert to an embryonic NC-like state during heart regeneration to proliferate and rebuild missing tissue. We are also currently investigating the expression of *jag2b* at the site of injury, to determine if it reprises its role in heart development during regeneration. The neural crest guides development by differentiating into a broad array of unique cell types throughout the animal- however it appears that this NC-Cm population, after differentiation into functional cardiomyocytes, maintains some degree of elasticity and specialization well into adulthood, perhaps by maintaining a distinct epigenetic memory and the ability to re-activate embryonic capabilities of cell signaling and tissue building. To address this, we are currently exploring the chromatin structure of these cells, as well as their expression profiles and behaviors during regeneration.

221 **A regulatory network of Sox and Six transcription factors initiate a cell fate transformation during hearing regeneration in adult zebrafish** Erin Jimenez[1], Claire C Slevin[2], Wei Song[3], Zelin Chen[4], Stephen Frederickson[2], Derek Gildea[2], Weiwei Wu[2], Abdel G Elkahloun[2], Ivan Ovcharenko[3], Shawn M Burgess[2] [1]Biology, Johns Hopkins University, [2]National Human Genome Research Institute, [3]NCBI, [4]Southern Marine Science and Engineering Guangdong Laboratory

Using adult zebrafish inner ears as a model for sensorineural regeneration, we performed a targeted ablation of the mechanosensory receptors in the utricle and saccule and characterized the single-cell epigenome and transcriptome at consecutive time-points following hair cell ablation. Using deep learning on the regeneration-induced open chromatin sequences, we were able to identify unique, cell-specific transcription factor (TF) motif patterns enriched in the raw data. We correlated enhancer activity with gene expression to identify gene regulatory networks. A clear pattern of overlapping Sox- and Six-family transcription factor gene expression and binding motifs was detected, suggesting a combinatorial program of TFs driving regeneration and cell identity. Pseudo-time analysis of single-cell transcriptomic data demonstrated that the support cells within the sensory epithelium changed cell identity to a more pluripotent “progenitor” cell population that could either differentiate into hair cells or return to a support cell identity. We showed that sox2 becomes enriched in the progenitor cells and is reduced again when the cells differentiate in either direction. Analysis of the scATAC-seq data identified a 2.6 kb DNA sequence element upstream of the sox2 promoter that dynamically changed in accessibility during hair cell regeneration. When deleted, the upstream regulator of sox2 showed a dominant phenotype that resulted in a hair cell regeneration specific deficit in both the lateral line and adult inner ear.

222 **Neutrophils facilitate the epicardial regenerative response after heart injury** Elizabeth Peterson, Jisheng Sun, Xin Chen, Jinhu Wang School of Medicine, Emory University

Title: Neutrophils facilitate the epicardial regenerative response after heart injury

Introduction: As neutrophils are the first responders to tissue damage and effective heart restoration requires the systematic control of inflammation induction and resolution, we speculated that neutrophils play a critical role in the transition to heart

regeneration in zebrafish.

Methods: We utilized reporters and immunofluorescence staining to visualize neutrophils, cardiac cells, and activation markers after cardiac injury. To limit neutrophils, we incubated fish with the drug AT7519 from 4-6 hours post-amputation (hpa). For scRNA-seq of 1 day post-amputation (dpa) cardiac neutrophils, we isolated $EGFP^+$ cells by FACS from amputated *lyz:*EGFP fish hearts for 10x Genomics' scRNA-seq. We used SU5402 from 27-32 hpa to limit FGF signaling.

Results: Neutrophils mobilized to the injury site, peaking at 1 dpa and resolving by 3 dpa. Remarkably, these 1 dpa neutrophils localized near activated/proliferating epicardial cells in the wound. To further analyze this cell-cell interaction, we employed drug treatment to limit neutrophil infiltration and detected impaired cardiac regeneration. Neutrophil depletion also significantly reduced epicardial cell expansion, proliferation, and activation. scRNA-seq of 1 dpa neutrophils identified a cell cluster enriched with cell proliferation signaling pathways, including the FGF, MAPK, and ERK signaling pathways. Pharmacological inhibition of FGF indicated a requirement for FGF activity for efficient epicardial cell proliferation. Further, neutrophil depletion limited ERK signaling activation, suggesting a supportive role for neutrophils in the activation of epicardial cell proliferation.

Conclusion: Altogether, our studies revealed that neutrophils facilitate the expansion of the epicardium at the injury site to support heart regeneration.

223 **ptx3a+ fibroblast/epicardial cells provide a transient macrophage niche to promote heart regeneration** Jisheng Sun, Elizabeth Anne Peterson, Xin Chen, Jinhu Wang Emory University

Macrophages conduct critical roles in heart repair, but the cardiac tissue niche required to nurture and anchor them is poorly studied. Here, we investigated macrophage niche components in the regenerating heart. First, we analyzed cell-cell interactions through scRNA-seq datasets derived from damaged zebrafish and neonatal murine hearts. We identified a strong interaction between fibroblast/epicardial (Fb/Epi) cells and macrophages, in which outgoing signals were predominantly sent by Fb/Epi cells and incoming signals were mainly received by macrophages. Then, we visualized the association of macrophages with Fb/Epi cells and the blockage of the macrophage response after depleting Fb/Epi cells in the regenerating zebrafish heart. Moreover, we found that Fb/Epi cells with pentraxin 3 long a (ptx3a) expression displayed immune regulatory functions and ptx3a+ cell-associated macrophages exhibited M2 characteristics. Experimentally depleting ptx3a+ cells resulted in lower M2 macrophage numbers and enhanced scar formation in the wound. Further, we identified expression of multiple signaling pathways in ptx3a+ cells, including CSF pathway components, and determined that pharmacological inhibition of the csf1a pathway or csf1a knockout blocked the M2 macrophage response. Moreover, we found that genetic overexpression of csf1a enhanced the M2 macrophage response with or without heart injury, and reduced collagen in the regenerating area. Altogether, our studies illuminate a new cardiac Fb/Epi niche which mediates a beneficial macrophage response after heart injury, a process facilitated by upregulating the csf1a gene.

224 **The role of cilia genes in the development, survival and regeneration of hair cells** Hope Boldizar[1], Amanda Friedman[1], Jennifer Galdieri[1], Tess Stanley[1], María Padilla[2], Arielle Sclar[1], Tamara Stawicki[1] [1]Neuroscience, Lafayette College, [2]Biology, Lafayette College

Primary cilia play key roles in the proliferation, survival and signaling of cells throughout our body. Sensory hair cells, the cells we use for hearing and balance, have a single primary cilium known as the kinocilium. We wished to further investigate the role of the kinocilium in hair cell development and regeneration using the zebrafish lateral line. The lateral line contains a number of neuromasts which consist of both supporting cells, some of which will proliferate and develop into hair cells, and the hair cells themselves. Mutations in cilia intraflagellar transport (IFT) genes cause a loss of the kinocilium and have previously been shown to cause decreased numbers of hair cells in both the inner ear and lateral line of zebrafish. We focused specifically on mutations in the genes *ift88* and *dync2h1* which should impact both anterograde and retrograde IFT respectively. We found that similar to what had previously been shown in the inner ear of *ift88* mutants there were a small number of cells undergoing apoptosis in the lateral line of both IFT gene mutants. *ift88* mutants additionally show a reduction in mitochondria activity. In *atp6v1f* mutants which also have these reductions it has been shown that treatment with Ru360, a mitochondria calcium uniporter inhibitor, can rescue hair cell number losses. However, we failed to see this in either IFT gene mutant. Additionally, we found that cell proliferation was normal in neuromasts of these mutants during hair cell development. This suggests that cilia may be more important for the survival than the initial development of hair cells in the zebrafish lateral line. Though we cannot rule out a role for cilia in hair cell development after proliferation has happened. However, unlike in development, preliminary data suggests cilia gene mutants may have alterations in cell proliferation during hair cell regeneration. We are in the process of further analyzing hair cell regeneration in these mutants.

225 **Genetic analysis of CNS autoimmunity using the diversity of the Collaborative Cross reveals unique phenotypes**

and mechanisms Emily A Holt[1], Anna Tyler[2], Taylor Lakusta-Wong[3,4], Karolyn G Lahue[1], Katherine Hanks[1], Cory Teuscher[5], Martin T Ferris[6], J. Matthew Mahoney[2,3], Dimitry N. Krementsov[1] [1]Department of Biomedical Health Sciences, University of Vermont, [2]The Jackson Laboratory, [3]Department of Neurological Sciences, University of Vermont Larner College of Medicine, [4]Department of Neurology, University of Vermont Medical Center, [5]Department of Medicine, University of Vermont Larner College of Medicine, [6]Department of Genetics, University of North Carolina

Multiple Sclerosis (MS) is a complex disease with significant heterogeneity in disease course and progression. Genome-wide association studies (GWAS) have identified 232 loci associated with MS. However, these loci are only associated with MS incidence and not disease course, the genetic basis of which remains obscure. Here we leveraged the Collaborative Cross (CC) - a genetically diverse mouse strain panel - and myelin oligodendrocyte glycoprotein peptide 35-55 (MOG_{35-55}) induced experimental autoimmune encephalomyelitis (EAE), to model genetics of MS disease course. Thirty-three CC strains were selected based on compatible MHC haplotypes ($H2^b$ and $H2^{g7}$) and EAE was monitored for 50 days. CC strains captured a wide spectrum of distinct EAE phenotypes, compared with typical chronic EAE in C57BL/6 mice, ranging from highly resistant (CC011/Unc) to severely progressive (CC028/GeniUnc). Strains also showed wide variation in disease trajectory, including monophasic disease (CC068/TauUnc and others) and relapsing remitting EAE, with ≥60% incidence in 3 strains, including CC002/Unc. In addition to classical EAE symptoms (ascending paralysis), we identified CC004/TauUnc as having a high incidence (~79%) of axial rotary (AR)-EAE, manifesting as profound ataxia and axial rotation. Sex differences in EAE course, were observed in 4 strains, including CC042/GeniUnc and CC018/Unc. Quantitative trait locus (QTL) analysis revealed distinct linkage patterns for EAE incidence and severity, with peaks on Chromosome (Chr) 4 and 14 respectively, passing genome wide significance. Machine learning-based functional candidate gene prioritization using gene network data and MS-GWAS genes as training input, ranked top candidate genes for QTL Chr4 (*Tox, Sdcbp, Chd7*) and Chr14 (*Abcc4, Gpc5, Gpc6*). Profiling of CNS infiltrating cells and histology revealed distinct pathology associated with EAE profiles, including cerebellar lesions with neutrophil infiltration in AR-EAE (CC004/TauUnc) and diffuse spinal cord lesions with reduced lymphocyte infiltration in progressive EAE (CC028/GeniUnc). Taken together, this work has led to the development of an easily implementable EAE model in CC strains, thereby expanding the EAE mouse model phenotypic repertoire and has demonstrated that high-resolution mapping can be achieved using the selected 33 CC strains. Importantly, our findings strongly support the hypothesis that heterogeneity in MS disease course is driven by natural genetic variation.

226 **A cross-species approach using an *in vivo* evaluation platform in mice demonstrates that sequence variation in human *RABEP2* modulates ischemic stroke outcomes** Han Kyu Lee, Douglas A Marchuk Molecular Genetics and Microbiology, Duke University School of Medicine

Ischemic stroke, caused by vessel blockage, results in cerebral infarction; the death of brain tissue. Previously, quantitative trait locus mapping (QTL) of cerebral infarct volume and collateral vessel number identified a single, strong genetic locus regulating both phenotypes. Additional studies identified the causative gene, encoding rabaptin, RAB GTPase binding effector protein 2 (*Rabep2*). However, there is yet no evidence that variation in the human ortholog of this gene plays any role in ischemic stroke outcomes. We established an *in vivo* evaluation platform in mice using adeno-associated virus (AAV) gene replacement and verified that both mouse and human RABEP2 rescue the mouse *Rabep2* KO ischemic stroke volume and collateral vessel phenotypes. Importantly, this cross-species complementation enabled us to experimentally investigate the functional effects of coding sequence variation in the human *RABEP2* gene. We chose four coding variants from the human population that are predicted by multiple *in silico* algorithms to be damaging to RABEP2 function. *In vitro* and *in vivo* analyses verify that all four led to decreased collateral vessel connections and increased infarct volume. Thus, there are naturally occurring loss-of-function alleles. This cross-species approach will expand the number of targets for therapeutics development for ischemic stroke.

227 **Mapping cell death and expression QTL using a barcoded library of genetically diverse macrophages** Gavin F Fujimori[1], Michael Kiritsy[2], Megan Proulx[1], Audrey Lord[3], Colton Linnertz[4], Martin Ferris[4], Clare Smith[5], Richard Baker[1], Christopher Sassetti[1] [1]Microbiology and Physiological Systems, UMass Chan Medical School, [2]Department of Medicine, Duke, [3]Boston University, [4]Genetics, UNC School of Medicine, [5]Molecular Genetics and Microbiology, Duke

Macrophages play an important role in maintaining tissue homeostasis and regulating immune responses. As innate immune cells, macrophages integrate an array of signals from cytokine, chemokine, and pattern recognition receptors. This complex network of molecular signals informs macrophage responses in any given situation. Furthermore, immune genes are under continuous adaptation due to the constant pressure of evolving pathogens. We developed a resource to take advantage of the resulting genetic diversity to study macrophages and innate immune processes. We produced a pool of DNA barcoded bone marrow progenitors derived from 59 Collaborative Cross strains. These cells can be differentiated into macrophages to study various aspects of macrophage biology. We have performed two proof-of-concept screens to confirm that we can map QTL using selection by either surface marker expression or sensitivity to a cell death inducer as phenotypes. The change in

relative abundance of each strain in the pool after selection is used to map for QTL. When mapping on Anthrax Lethal Factor (LF) induced cell death we identified a striking peak on Chromosome 11 at the well described *Nlrp1b* locus. The allele effects for susceptibility to LF induced cell death at the *Nlrp1b* locus matched those described in the literature. In addition, we identified a significant peak on chromosome 9. The allele effects at this locus explained the variance observed in strains that harbored a susceptible *Nlrp1b* allele. We performed single cell sequencing on the pool stimulated with IFNγ, Pam3CSK4, both IFNγ and Pam3CSK4, or unstimulated. Using normalized counts as a metric we were able to map several significant cis-eQTL. These include one underneath the chromosome 9 LF toxicity-associated peak that corresponds to the *Pkm* gene and matches the *Nlrp1b* allele effects. Thus, in a proof-of-concept cell death screen we identified both the expected and an unexpected peak reaching genome-wide significance. Additionally, we were able to leverage single cell sequencing to identify a cis-eQTL that we hypothesize to modify LF-mediated cell death. These results demonstrate the power of this new tool in leveraging Collaborative Cross strains to rapidly decipher the genetic basis of macrophage phenotypes in a pooled system.

228 **Genetics of Susceptibility to Mouse Myeloma leads to Co-targeting of Oncogenes and Tumor Suppressors** Beverly A Mock Lab of Cancer Biology & Genetics, CCR, NCI, NIH

Multiple Myeloma (MM) is a clonal proliferation of neoplastic plasma cells in the bone marrow. Despite recent therapeutic advances, drug resistance and MM progression is common. Mouse plasma cell tumors model certain aspects of these antibody producing neoplasms. Long-term genetic studies utilizing backcross, and congenic strain analyses coupled with positional cloning strategies and functional studies identified *Cdkn2a* (p16)*,* and *Mtor* as plasmacytoma susceptibility genes. Tumor incidence data in congenic strains carrying resistance alleles of *Cdkn2a* and *Mtor* led us to *hypothesize* that drug combinations affecting these pathways are likely to have an additive, if not synergistic effect in inhibiting tumor cell growth. When drug combinations targeting these pathways were evaluated, MYC protein degradation was found to be a common mechanism of action. Following these studies, high throughput screening of 1900 small molecule compounds identified several drug combinations that could simultaneously inhibit oncogenic MYC expression and simultaneously increase expression of the tumor suppressor, p16. Candidate combinations were evaluated for cooperative reductions in MYC protein expression in MM cells treated at IC50 doses of each drug. Cooperative reductions in viability were observed with top combinations in proteasome inhibitor-resistant and sensitive MM cell lines but did not limit normal fibroblast viability. The combinations cooperatively increased p16 and RB activity, while also enhancing cleaved caspase 3, leading to increased apoptosis. Combination-associated survival was evaluated in a transplantable Ras-driven allograft model of advanced MM which closely recapitulates myeloma in humans. Several combinations significantly prolonged survival in sublethally-irradiated C57BL/6 mice injected intracardiac with donor MM cells compared to control mice. Furthermore, and most importantly, the combination prolonged survival compared to single agents and control in three mouse models. These data identify potentially useful drug combinations for preclinical evaluation in drug-resistant MM and may ultimately reveal novel mechanisms of combined drug sensitivity.

229 **Generative adversarial networks, transfer learning, and interpretability for evolutionary inference** Sara Mathieson Computer Science, Haverford College

The broad field of generative AI has captured a worldwide audience with novel text, image, audio, and video. In evolutionary biology we have used synthetic data for decades, but created using custom simulations from evolutionary models. However, it is often challenging to create realistic simulations for populations with unique histories, which compromises the results of downstream analyses. Recently, new methods inspired by the generative AI literature have emerged as ways to automatically adapt simulations to mirror the real genomic data of any population or species.

Here I will focus specifically on a generative adversarial network (GAN) method for inferring demographic and natural selection parameters. Our method, called pg-gan, works by training a parametric generator and CNN (convolutional neural network) discriminator in concert, until there is a close match between real and simulated data. The main training algorithm requires only fast neutral simulations, which allows us to fit a demographic model. Then, we save the resulting discriminator and fine-tuned it with minimal simulations of selection, which are often computationally expensive. The final CNN allows us to predict selected regions for held aside genomic data. We demonstrate the effectiveness of our approach in simulation and with human and mosquito populations. Additionally, we show how to interpret the trained networks by clustering discriminator features based on their correlation with known summary statistics. Discriminator features include the convolutional filters themselves, the last hidden layer (where high-level information is distilled), and the final network output. Overall pg-gan has proven useful in evaluating and strengthening simulated data, especially for understudied populations that deviate from broad geographic groups.

230 **Population genetics meets ecology: a guide to simulations in continuous geography** Elizabeth T Chevy[1], Jiseon Min[2], Victoria Caudill[2], Samual Champer[3], Benjamin C Haller[3], Andrew D Kern[2], Sohini Ramachandran[1,4], Clara Rehmann[2], Chris C R

Smith[2], Silas Tittes[2], Peter L Ralph[2,5] [1]Center for Computational Molecular Biology, Brown University, [2]Institute of Ecology and Evolution, University of Oregon, [3]Department of Computational Biology, Cornell University, [4]Ecology, Evolution, and Organismal Biology, Brown University, [5]Department of Mathematics, University of Oregon

Nearly all populations we study exist in geographic space, yet demographic models, and their useful population genetic expectations, rarely accommodate continuous space. Interactions between individuals—and therefore genetic relatedness—are constrained by physical space and geographic context, and the most flexible, realistic model must capture this. However, continuous spatial modeling has its quirks. Without careful attention to the consequences of modeling choices, it can be difficult to even simulate a stable population. Population size, for example, cannot simply be "set": it is an emergent property of the simulation. Implementing complexities such as competition, sex, or environmental heterogeneity can have unintended consequences that render the simulation unrealistic or no longer useful for the modeling task.

Here, we describe a robust framework for continuous-space demographic simulations. We present some fundamental relationships, such as how genetic distance changes with geographic distance depending on how individuals migrate during their lifetimes. We also show that subtle modeling choices can have dramatic effects on properties of the simulation. For example, two models of natural selection achieve very different equilibria when selection acts on fecundity vs. mortality, and the speed at which they obtain equilibrium depends on the spatial scale.

In addition to our results, we provide practical material for researchers designing their own spatial simulations. Template code demonstrates how properties such as population density, sex, or selection can be implemented in the simulation engine SLiM. Finally, we demonstrate how to use our framework to model real systems. We provide four vignettes that explore how climate change affects geographic range, how precipitation affects an invasive species, how biogeography determines larval vs. adult abundance, and how patchy resources can drive competition.

231 **A genealogy-based framework to estimate population structure and demographic history** Charleston Chiang[1], Caoqi Fan[2] [1]Population and Public Health Sciences, University of Southern California, [2]Vibrant Therapeutics

Learning the demographic histories of nonequilibrium populations helps us understand the causes of population structure, the pattern of genetic variation, and the evolution of traits. Many existing methods to infer population structure or demographic history from genetic data use relatively low-dimensional summaries, such as the allele frequency spectra, which often ignore the linkage information between markers. In principle, much more information is available from the sequence of gene-genealogical trees, known as the ancestral recombination graph (ARG), that describes the history of sampled alleles. As a step toward capturing all the available genomic information, we introduce two methods that leverage the ARG to infer population structure and demographic histories. First, we describe a framework to infer the expected relatedness between pairs of individuals given an ARG of the sample, which we call the eGRM. We show that the eGRM better captures the structure of a population than the canonical Genetic Relationship Matrix (GRM), even when using limited genetic information found on a genotyping array. Moreover, the eGRM can reveal the time-varying nature of population structure in a sample. Second, we devised a method called gLike that derives the full likelihood of a genealogical tree under any hypothesized demographic history. Employing a graph-based structure, gLike summarizes the relationships among all lineages in a tree with all possible trajectories of population memberships through time and efficiently computes the exact marginal probability under a parameterized demographic model. Through extensive simulations of multiple admixtures, we showed that gLike accurately estimates dozens of demographic parameters, including ancestral population sizes, admixture timing, and admixture proportions, and outperforms conventional demographic inference methods that leverage only the allele frequency spectrum. We applied both methods to real-world human genomic data from Finnish, Latino American, and Native Hawaiian cohorts to gain further insights into the patterns of population structure and to estimate parameters of the admixture histories. Taken together, our studies demonstrate the power of leveraging the genealogical trees for downstream population genetic inferences.

232 **Creating a fully-differentiable coalescent simulator using StyleGAN** Dylan Ray, Will Booker Genetics, UNC Chapel Hill

Simulation has long been one of the most important tools in population genetics research, enabling us to explore highly entropic distributions of evolutionary histories, involving recombination, mutation, selection, and demographic changes. Simulations aid in the development, testing, and training of tools used to make evolutionary inferences from real data collected from natural populations. While highly versatile and increasingly computationally efficient, population genetic simulations construct a series of inherently discrete events drawn from probability distributions which are in turn conditional upon past events, and thus writing the full likelihood or its derivative with respect to some parameter such as recombination rate or effective population size given a set of inferred genealogies is often cumbersome, analytically intractable, and/or difficult to compute. Given this fact and the high-dimensional nature of genealogies, Approximate Bayesian Computation

with summary statistics is often used in place of the full likelihood function when inferring demographic parameters from real data sampled from natural populations. Here we propose a novel method for a fully differentiable genetic simulator using a Generative Adversarial Network (GAN) that learns a continuous latent space meant to represent a uniformly random mixture of many closely related demographic models, giving an easily sampled distribution with a smooth, fully specified likelihood. We trained a GAN to capture the distribution of single genealogies, show that the resulting GAN is able to compress genealogies efficiently via an easily learnable back-projection, and that the learned latent space and the distribution of replicates it encodes reproduce many of the properties of the original statistical manifold. By mapping regions of latent space to the demographic parameters they were simulated with we define a twice-differentiable likelihood function w.r. to the replicate and any given parameter set within the boundaries, thereby paving the way for the direct estimation of population genetic parameters via gradient descent and broad studies of metrics such as Fisher information which gives the distribution of error for unbiased MLEs. We show that the latent space produced by our GAN can be used to infer population genetic parameters with accuracy comparable to a a recent approach using deep neural networks trained to infer parameter values from population genetic alignments.

233 **Bayesian phylodynamic inference of population dynamics with dormancy** Suvadip Sana[1], Lorenzo Capello[2], Ishani Chopra[3], Wai Tung `Jack' Lo[4], Perry Xu[5], Andrew G. Clark[5], Martin T. Wells[1], Jaehee Kim[3] [1]Department of Statistics and Data Science, Cornell University, [2]Departments of Economics and Business, Universitat Pompeu Fabra, [3]Department of Computational Biology, Cornell University, [4]Department of Computer Science, Cornell University, [5]Department of Molecular Biology and Genetics, Cornell University

Many organisms respond to environmental fluctuations by utilizing reversible dormant states or "seedbanks". This life-history strategy significantly alters the fundamental evolutionary and ecological forces acting on the population, leading to changes in patterns of genetic diversity and population demography. Two fundamentally different models of dormancy have been proposed based on the average time individuals spend in the dormant state in comparison to the evolutionary timescale measured by the coalescent: "weak" seedbank that models dormancy induced by scheduled seasonality (e.g., plants or invertebrate species) and "strong" seedbank where individuals stochastically switch between active and dormant states (e.g., bacteria).

Because the weak seedbank has been shown to be statistically equivalent to the Kingman coalescent with a population-rescaled mutation rate, inference under the weak seedbank coalescent directly extends the existing methods. The strong seedbank coalescent, however, fundamentally differs from existing coalescent models. While it shares similarities with the two-population structured coalescent in that individuals can stochastically transition between states, its key distinction lies in allowing only active state lineages to coalesce, whereas those in the dormant state cannot. This asymmetry in coalescence events presents challenges in applying existing inference methods developed for the structured coalescent. Consequently, despite the significant role of dormancy in the eco-evolutionary dynamics of many organisms, no methods currently exist for inferring population dynamics involving dormancy and associated parameters.

Here, we developed a Bayesian phylodynamic method under the strong seedbank coalescent that enables the joint inference of genealogy, dormancy model parameters, and evolutionary model parameters from genetic data. We 1) provide a genealogical density under the strong seedbank coalescent; 2) prove a new phylogenetic likelihood formula for the strong seedbank tree; 3) propose new tree operators for efficiently exploring the tree space for the strong seedbank tree; 4) validate our method both with synthetic and real data; and 5) implement our inference framework as a package in BEAST2. Our work serves as the groundwork for developing theoretical foundations and more refined inference methods for populations undergoing dormancy.

234 **Tests of Ghost Introgression into Extant Lineages** Margaret Wanjiku, Arun Sethuraman Biology, San Diego State University

Gene flow from unsampled or extinct ghost populations leaves signatures on the genomes of individuals from extant, sampled populations, often introducing biases, data misinterpretation, and ambiguous results when estimating evolutionary history from population genomic data. Here, we utilize extensive simulations under various ghost topologies, with no gene flow to extensive gene flow to and from an unsampled ghost population. These models help us systematically assess biases while accounting or not accounting for gene flow from ghost populations in demographic history (mutation-scaled effective population sizes, divergence times, and migration rates) under the Isolation with Migration (IM) model. Estimates of evolutionary history across all scenarios of deep divergence of an outgroup ghost indicate consistent a) under-estimation of divergence times between sampled populations, (b) over-estimation of effective population sizes of sampled populations, and (c) under-estimation of migration rates between sampled populations, with increased gene flow from the unsampled ghost population.

Additionally, considering the large effects of gene flow from ghost populations, we propose a multi-pronged approach to account for the presence of unsampled ghost populations in population genomics studies to reduce erroneous inferences. We present three statistical tests to test for the presence of an unsampled ghost in population genomic data. They utilize (1) inference of population structure under the admixture model, (2) inference of the distribution of coalescent times across genomic loci, and (3) inference of the goodness of fit under the IM model to test for the presence of an unsampled ghost population among sampled population genomic data. We recommend these tests as a necessary first step before estimating evolutionary history under restrictive (e.g., two population) demographic models.

235 **Stabilizing selection shapes the distribution of shared variation after archaic introgression** Aaron P Ragsdale Integrative Biology, University of Wisconsin-Madison

Genomic studies show that admixture commonly occurs between diverged populations and sometimes between closely related taxa. Human history in particular involves repeated migration, admixture and introgression events. Some genetic segments of present-day populations trace to Neanderthals, Denisovans and potentially other hominin lineages, and there is growing evidence that early *H. sapiens* reciprocally contributed genetic material to Neanderthals. Bidirectional introgression introduced genetic variation that contributed to phenotypic traits in both humans and Neanderthals. Past episodes of selection on trait-affecting alleles have shaped genetic variation in functional genomic regions, leaving footprints that can be observed in the genomes of Neanderthals and present-day populations.

Many phenotypic traits are subject to stabilizing selection, which acts to maintain population-average phenotypic values near some optimum. Drawing on classical theory and recent computational developments for the site-frequency spectrum, we develop a population genetic approach to model genetic and phenotypic variation for traits under stabilizing selection, allowing for complex demographic history involving migration and admixture. We use this to predict the genetic architecture of traits under stabilizing selection after introgression, and we show that stabilizing selection results in selection against introgressed ancestry surrounding functional regions. By contrasting to predictions based on models of deleterious load and genomic incompatibilities, we show that stabilizing selection can instead explain observed co-occurrences of introgressed ancestry deserts in both humans and Neanderthals. Because many traits are under stabilizing selection, we argue that it is a useful null model for studying natural selection and the architecture of complex traits after introgression between diverged lineages.

236 **A machine vision guided robot for fully automated embryonic microinjection** Andrew D Alegria[1], Amey S Joshi[1], Jorge B Mendana[2], Kanav Khosla[1], Kieran T Smith[3], Benjamin Auch[2], Margaret Donovan[2], John Bischof[1], Daryl M Gohl[4], Suhasa B Kodandaramaiah[1] [1]Mechanical Engineering, University of Minnesota, [2]University of Minnesota, [3]Fisheries, Wildlife and Conservation Biology, University of Minnesota, [4]Genetics, Cell Biology, and Development, University of Minnesota

Microinjection is a widely used technique for transgenesis, mutagenesis, cell labeling, cryopreservation, and *in vitro* fertilization in many organisms. Microinjection requires specialized skills for each target organism and involves rate limiting and labor-intensive preparatory steps. Here we constructed a machine vision guided generalized robot that fully automates the process of microinjection in fruit fly *(Drosophila melanogaster)* and zebrafish (*Danio rerio*) embryos. The robot uses machine learning models trained to detect individual embryos in images of agar plates, and models trained to identify specific anatomical locations within each embryo in 3D space using dual view microscopes. The robot uses this information to serially perform microinjection in each detected embryo without any human intervention. We constructed and used three such robots to automatically microinject tens of thousands of Drosophila and zebrafish embryos. We systematically optimized robotic microinjection for each species and validated the use of the robot by performing routine transgenesis with proficiency comparable to highly skilled human practitioners while achieving up to 4x increases in microinjection throughput in Drosophila. The automated microinjection robot was utilized to microinject a pool containing tens of thousands of uniquely barcoded plasmids to rapidly generate more hundreds of unique transgenic Drosophila lines and to carry out a novel measurement of the number of independent germline integration events per successfully injected embryo. Next, we showed that robotic microinjection of cryoprotective agents in zebrafish embryos significantly improves vitrification rates and survival of cryopreserved embryos post-thaw as compared to manual microinjection. We are currently using the robotic microinjection system to perform a large-scale mutational scanning experiment to dissect a large development enhancer region. In the future, we anticipate that this versatile automated microinjection system can be adapted to carry out microinjection in a wide range of other organisms.

237 **The Janelia Atalanta plasmids provide a simple and efficient CRISPR/Cas9-mediated homology directed repair platform for Drosophila** David Stern[1], Elizabeth Kim[2], Emily L Behrman[3] [1]Janelia Research Campus, Howard Hughes Medical Institute, [2]Janelia Research Campus, HHMI, [3]HHMI

Homology-directed repair (HDR) is a powerful tool for modifying genomes in precise ways to address many biological

questions. Use of Clustered Regularly Interspersed Short Palindromic Repeats (CRISPR)-Cas9 induced targeted DNA double-strand breakage has substantially simplified use of homology-directed repair to introduce specific perturbations in *Drosophila*, but existing platforms for CRISPR-Cas9-mediated HDR in *Drosophila* involve multiple cloning steps and have low efficiency. To simplify cloning of HDR plasmids, we designed a new plasmid platform, the Janelia Atalanta (pJAT) series, that exploits recent advances in dsDNA synthesis to facilitate Gateway cloning of gRNA sequences and homology arms in one step. Surprisingly, the pJAT plasmids yielded considerably higher HDR efficiency (approximately 25%) than we have observed with other approaches. pJAT plasmids work in multiple *Drosophila* species and exhibited such high efficiency that previously impossible experiments in *Drosophila*, such as driving targeted chromosomal inversions, were made possible. We provide pJAT plasmids for a range of commonly performed experiments including targeted insertional mutagenesis, insertion of phiC31-mediated attP landing sites, generation of strains carrying a germ-line source of Cas9, and induction of chromosomal rearrangements. We also provide "empty" pJAT plasmids with multiple cloning sites to simplify construction of plasmids with new functionality. The pJAT platform is generic and may facilitate improved efficiency CRISPR-Cas9 HDR in a wide range of model and non-model organisms.

238 **Building metabolic pathway resources for *Drosophila melanogaster*** Steven J Marygold[1], Peter D Karp[2], David P Hill[3], Peter D'Eustachio[4], Jason M Tennessen[5] [1]FlyBase, University of Cambridge, [2]Bioinformatics Research Group, SRI International, [3]The Jackson Laboratory, [4]Department of Biochemistry and Molecular Pharmacology, New York University Grossman School of Medicine, [5]Department of Biology, Indiana University

The ability to study metabolism in *Drosophila melanogaster* relies on having an accurate, comprehensive and up-to-date representation of its metabolic pathways and networks. However, currently available resources (e.g. KEGG, Reactome, FlyCyc) are incomplete/inaccurate as they are based on outdated functional annotations or are generated computationally via orthology. Furthermore, many discrepancies exist between these databases and none of them are integrated with FlyBase, which is the primary source for *Drosophila* functional genomic information and reagents. Therefore, there is an urgent need to establish a set of accurate, canonical metabolic pathways for *Drosophila*, enabled through manual assessment and annotation by expert biocurators.

We are addressing this need using the following approaches. We started by systematically reviewing all known/predicted *Drosophila* enzymes, verifying Gene Ontology (GO) and Enzyme Commission (EC) annotations to >3,500 enzyme-encoding genes within FlyBase. These enhancements then allowed us to compute an updated *Drosophila* metabolic network within the BioCyc database. Compared to the previous version, this revised 'FlyCyc' includes >50 additional metabolic pathways and identifies >600 additional enzyme-encoding genes, thereby providing researchers with much-improved *Drosophila* metabolic pathway diagrams and enhanced capabilities to analyze 'omics data within the BioCyc platform.

We will use the updated FlyCyc, together with orthology-based pathway predictions from Reactome, as a basis to create GO-Causal Activity Model (GO-CAM) representations of *Drosophila* metabolic pathways. GO-CAMs are created manually by expert curators and are directly linked to the primary GO annotations. This means that each pathway is manually verified with transparent evidence for each reaction, and allows for the creation of tissue-, context- and *Drosophila*-specific versions of metabolic pathways. Moreover, the GO-CAM framework is being employed across Model Organism Databases, making them easily comparable and inter-operable.

The new *Drosophila* metabolic pathway resources will be invaluable for the research community and will be made available through the FlyBase, BioCyc and Alliance of Genomic Resources websites.

239 **The Alzheimer's Disease Fly Cell Atlas (AD-FCA): A Whole-Organism, Single-Cell sequencing resource on Brain-Body Interactions** Ye-Jin Park[1,2,3,4], Tzu-Chiao Lu[1,2], Tyler Jackson[1,2,5], Jiaye Chen[6], Yanyan Qi[1,2], Chung-Yi Liang[1,2,7], Lindsey Ran[8], Erin Harrison[1,2], Christina Ko[8], Madeline Burns[1,2], Hugo J Bellen[1,4], Hongjie Li[1,2] [1]Department of Molecular and Human Genetics, Baylor College of Medicine, [2]Huffington Center on Aging, Baylor College of Medicine, [3]Program in Development, Disease Models & Therapeutics, Baylor College of Medicine, [4]Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, [5]Program in Cancer Cell Biology, Baylor College of Medicine, [6]Program in Quantitative & Computational Biosciences, Baylor College of Medicine, [7]Institute of Biochemistry and Molecular Biology, National Yang Ming Chiao Tung University, [8]Neuroscience Program, BioSciences Department, Rice University

Brain aging and neurodegeneration have been extensively investigated, with a predominant focus on the nervous system, but emerging evidence indicates that the effects of brain aging and diseases extend beyond the central nervous system to peripheral organs. Alzheimer's Disease (AD), for instance, has been associated with disruptions in the gut microbiome, respiratory system, cardiovascular function, and hormone regulation, underscoring the involvement of peripheral tissues in

the disease process. However, a comprehensive understanding of how impaired neurons impact peripheral tissues within the broader context of the whole organism has been lacking. To address this gap, we generated the Alzheimer's Disease Fly Cell Atlas (AD-FCA). This atlas profiles single-nucleus transcriptomes of the entire Drosophila organism, comparing normal aging flies with experimental flies where we induce neuronal insults through Abeta42 or Tau transgenes. The AD-FCA characterizes 219 distinct cell types from over 624,000 nuclei and analyzes transcriptomic changes in both the nervous system and peripheral tissues at the cellular level, allowing comparisons between genotypes, ages, and sexes. This pioneering whole-organism AD atlas serves as a valuable resource for the AD research community, facilitating the discovery of progressive changes that likely occur in non-neurological tissues in response to AD, thus offering fresh insights into the realm of brain-body communication.

240 **OligoY pipeline allows full Y chromosome painting assays** Isabela Almeida[1], Henry AB Bruno[1], Mara MLS Pinheiro[1], Antonio B de Carvalho[2], Maria Vibranovski[3,4] [1]Genetics and Evolutionary Biology, University of São Paulo, [2]Genetics, Federal University of Rio de Janeiro, [3]Genetics and Evolutionary Biology, University of Sao Paulo, [4]School of Mathematical and Natural Sciences, Arizona State University

Y chromosomes remain understudied for most species due to their haploid and highly repetitive nature, posing a challenge for assembly algorithms and leading to contig-fragmentation and sequence loss. As a result, the Y chromosome has received little attention from cytogeneticists, even though doing so would allow them to better understand its function throughout the cell cycle and provide new insights into its evolutionary history and relationships with other regions of the genome. Importantly, the conventional protocol for designing probes used in full chromosome fluorescent labeling experiments (FISH Oligopaint) does not include repetitive sequences to avoid off-target hybridization. For the Y chromosome, the remaining non-repetitive sequences are numerically insufficient to design probes and efficiently perform FISH Oligopaint assays.

OligoY pipeline generates FISH Oligopaint probes for the Y chromosome of any species by using a genome assembly and female and male reads to enhance the number of known sequences. The pipeline effectively uses repetitive sequences unique to the target chromosome to design probes, all while guaranteeing the user the autonomy to choose parameters, thus maximizing overall efficiency of cytogenetic experiments. After extensive in silico and in situ tests and validations with *Drosophila melanogaster,* we showed for the first time a pipeline for probe design that significantly increases previous Y chromosome staining with no off-target signal.

241 **PANGEA: A New Gene Set Enrichment Tool for Common Research Organisms** Claire Hu[1], Aram Comjean[1], Helen Attrill[2], Giulia Antonazzo[3], Jim Thurmond[4], Weihang Chen[5], Stephanie Mohr[5], Nicholas Brown[3], Norbert Perrimon[5] [1]Genetics, Harvard Medical School, [2]Physiology, University of Cambridge, [3]University of Cambridge, [4]Indiana University, [5]Harvard Medical School

Over the years, the Drosophila RNAi Screening Center (DRSC) bioinformatics group has implemented a suite of informatics tools (https://fgr.hms.harvard.edu/tools), including gene-centric resources that facilitate ortholog and paralog mapping, and mining of information about orthologs and paralogs in common genetic model species; reagent-centric resources that help researchers identify RNAi and CRISPR sgRNA reagents or designs; and data-centric resources for visualization and mining of transcriptomics data, protein modification data, protein interactions, and more. Our resources are actively updated and expanded based on community input. For example, GuideXpress was recently expanded to support sgRNA design and ortholog search for the blacklegged tick (*Ixodes scapularis*). In addition, we recently launched PANGEA, a new tool for gene set enrichment (GSEA). GSEA plays an important role in large-scale data analysis, helping scientists discover underlying biological patterns over-represented in gene lists resulting from 'omics' or other large-scale studies. Gene Ontology (GO) annotation is the most frequently used classification mechanism for gene set definition. PANGEA (PAthway, Network and Gene-set Enrichment Analysis; https://www.flyrnai.org/tools/pangea/), allows a more flexible and configurable approach to GSEA using a variety of classification sets. PANGEA supports GO analysis using different sets of GO annotations, such as the set of GO annotations that exclude results from high-throughput studies. PANGEA also supports GSEA with pathway annotations and protein complex datasets from various resources, as well as gene expression and disease annotations from the Alliance of Genome Resources. Visualizations include an option to view a network of gene set-to-gene relationships, and comparisons of multiple input gene lists. PANGEA will facilitate GSEA for *Drosophila, C. elegans,* zebrafish, and mammalian genes (human, mouse, and rat) based on high-quality annotated information available for these species. Altogether, our established and new resources support research for major model organisms at all stages of the research pipeline, from development of candidate gene lists and identification of reagents to data analysis, visualization, and integration.

242 **The genetic basis of novel cell type evolution in the *Drosophila* sex comb** Ben Hopkins[1], Olga Barmina[2], Artyom Kopp[3] [1]Evolution & Ecology, University of California – Davis, [2]Evolution & Ecology, University of California, Davis, [3]University of California, Davis

The evolution of new cell types has been a major contributor to the diversification of animal life and underlies many of its key innovations, from the immune system to the brain. However, our understanding of the genetic mechanisms through which new cell types originate remains limited. Arguably, the most conspicuous novel cell types in *Drosophila melanogaster* are those of the sex comb, a recently evolved, male-specific structure found on the foreleg tarsus of species in the *Sophophora-Lordiphosa* radiation. We know that the sex comb evolved through rewiring the differentiation program that builds mechanosensory bristles by linking it to the expression of *doublesex*. However, the identities of the downstream genes that drive this transformation and the mode of gene expression evolution responsible remains unknown. Is the transformation driven by quantitative or heterochronic changes in the expression of genes that are shared with mechanosensory bristles? Or by the novel gain of expression of genes that aren't active in the mechanosensory bristles? Using a time-series single-cell RNA-seq dataset of the developing tarsus, coupled with hybridisation chain reaction (HCR) in situs, we show that the cells of the sex comb exhibit elements of all three modes of gene expression evolution. The bristle-building genetic program is initiated earlier in sex comb cells than in the surrounding mechanosensory bristles, conserved elements of this program are upregulated relative to their expression in the surrounding mechanosensory bristles, and the expression of several genes that aren't expressed in tarsal mechanosensory bristles, including *b* and *Pxd*, appears to have been gained in sex comb cells. We further show that the deployment of *b* and *Pxd* expression in bristle cells isn't unique to the sex comb, but rather a feature of several large bristle and bristle-like structures elsewhere in the fly, such as the preapical bristles, wing pegs, and genital claspers. It therefore appears that the sex comb evolved, at least in part, through the redeployment of an existing gene module in a new cellular context. We also show that this gene module appears to be active in the sex comb cells of other *Drosophila* species from across the *Sophophora* subgenus, suggesting that the genetic basis of sex comb tooth development is largely conserved.

243 **Comparative developmental genetics of female-limited mimicry polymorphisms** Sofia I. Sheikh[1], Nicholas W VanKuren[2], Meredith M Doellman[2], Phoebe Hall[2], Marcus Kronforst[2] [1]Ecology and Evolution, University of Chicago, [2]University of Chicago

Sex-limited polymorphisms, such as damselfly female color morphs and butterfly mimicry polymorphisms, are frequently both adaptive and drive phenotypic diversification, yet the molecular mechanisms by which the development of multiple complex phenotypes can be limited to one sex remain unclear. Considerable work has been done exploring the ecological pressures and evolutionary processes that necessitate and maintain genetic variation resulting in multiple adaptive morphs. However, very little is known about the developmental genetics of discrete phenotypic morphs. One powerful system to investigate this is the *Papilio* swallowtail butterflies, in which multiple closely related species have evolved a female-limited mimicry polymorphism (FLMP) wherein females develop either mimetic or non-mimetic wing color patterns. While the color patterns of the morphs are strikingly different across species, each polymorphism is regulated by allelic variation at *doublesex* (*dsx*). How and why this gene has been repeatedly involved in the evolution of sex-limited polymorphisms remains unclear. Across three species with FLMP, we found that in each case both the mimetic and non-mimetic females develop male-like color patterns when we knockdown Dsx expression with RNAi, suggesting that this gene controls both sexual dimorphism and female-limited polymorphism. We also found that the derived *dsx* allele in the species *P. lowii* has acquired unique spatiotemporal expression patterns as shown by antibody staining. Moreover, these patterns differ from how *dsx* is expressed in the mimetic females of the closely related species *P. alphenor.* To uncover the downstream genes involved in the color pattern switch, we used RNA-seq and compared the results to previous work in *P. alphenor*. Although some genes are DE in both species, the temporal pattern of differential expression is notably different, suggesting distinct mechanisms of the *dsx* switch function. Lastly, we paired Dsx antibody staining with other candidate gene expression using HCR to determine how *dsx* modifies existing gene regulatory networks to drive the production of distinct color patterns. Our results indicate that, despite the shared use of *dsx*, the functional basis of female-limited mimicry polymorphism appears to be different between *P. lowii and P. alphenor*. These results indicate that deeply conserved developmental pathways are highy labile, permitting multiple underlying functions to arrive at the same state of sex-limited polymorphism in closely related species.

244 **Chromatin Dynamics and Aging in *C. elegans*** Siu Sylvia Lee Molecular Biology and Genetics, Cornell University

We are interested in understanding the interplay between chromatin dynamics, gene expression, and aging. We use *C. elegans* as a model to dissect how specific histone-modifying factors modulate longevity and explore how the global chromatin dynamics change with aging. We demonstrated that the chromatin factors SET-26 and HCF-1 act in the soma to modulate stress responses and longevity. We revealed that SET-26 localizes to chromatin by binding to the histone mark H3K4me3, subsequently recruiting HCF-1. Additionally, we identified the histone deacetylase HDA-1 playing an antagonizing role to SET-26/HCF-1. Interestingly, HDA-1 localizes to genomic regions closely aligned with the SET-26 and HCF-1 binding sites but is recruited to the chromatin independently of SET-26 or HCF-1. Gene expression profiling unveiled that SET-26/HCF-1 and HDA-1 exert opposing effects on the expression of specific target genes, which likely contribute to their antagonistic roles in longevity. To further comprehend how specific chromatin perturbations impact aging, we have probed the age-dependent dynamics of several key histone modifications. We found that while the repressive mark H3K27me3 remains stable with age,

the heterochromatin mark H3K9me3 exhibits significant redistribution, displaying both global loss and local gain. Additionally, although the active histone modification H3K36me3 remains stable with aging, the levels of H3K36me3 have a causal relationship with the age dynamics of gene expression. Future studies will delve into the functional implications of these changes in determining longevity.

245 **Vitamin B12 Protects Against DGLA-Induced Ferroptosis in *C. elegans*** Michael S Mortensen, Jennifer L Watts School of Molecular Biosciences, Washington State University

Ferroptosis is a novel form of regulated cell death characterized by membrane destruction brought about by iron-dependent lipid peroxidation of polyunsaturated fatty acids (PUFAs). Since its discovery in 2012, ferroptosis has been implicated in various biological processes and conditions, including tumor suppression, aging, and neurodegenerative diseases such as Alzheimer's and Parkinson's disease. Our lab discovered that the omega-6 PUFA, dihomo-gamma-linolenic acid (DGLA), is capable of inducing sterility in the nematode, *Caenorhabditis elegans* (*C. elegans*), through triggering ferroptosis specifically in the germ cells of young animals. Furthermore, DGLA is also sufficient to induce ferroptosis in human cancer cells, marking this PUFA as a ferroptotic trigger across models. Our research group recently identified that DGLA has a greatly diminished effect in *C. elegans* fed on bacteria containing a higher level of vitamin B12 compared to their standard bacterial food source. Furthermore, we uncovered that dietary vitamin B12 supplementation suppresses DGLA-induced ferroptosis in *C. elegans* in a dose-dependent manner. Vitamin B12 works as a cofactor to the methionine synthase enzyme that functions within the methionine cycle, which is a process revolving around methyltransferase production. We found the loss-of-function mutant for the methionine synthase ortholog in *C. elegans*, *metr-1*, elicits a severe sterility response to DGLA, even on bacterial strains with adequate levels of vitamin B12. Furthermore, *metr-1* worms are not rescued by dietary vitamin B12 supplementation when cotreated with DGLA, indicating that vitamin B12 protects from DGLA-induced ferroptosis directly through its role as a cofactor in the methionine cycle. These findings highlight a role for protection against ferroptosis dependent on vitamin B12 and its function in the methionine cycle.

246 **Neurobehavioral and mobility phenotypes of adenylosuccinate lyase deficiency are due to distinct mechanisms of SAICAR toxicity** Sabrina Amita Sony, Corinna A Moro, Latisha P Franklin, Mia M Peifer, Wendy Hanna-Rose Biochemistry and Molecular Biology, The Pennsylvania State University

Adenylosuccinate lyase (ADSL) deficiency is a rare disorder that causes muscle dysfunction, behavioral abnormalities, and autistic-like symptoms. Deficiency of this purine biosynthetic enzyme leads to the buildup of substrate SAICAR and a disruption in the homeostasis of purines. Each effect is thought to contribute to generating the phenotypes, but the mechanisms linking metabolic effects to behavioral symptoms are unknown. We use *C. elegans* to investigate the neurobehavioral functions of *adsl-1.*

adsl-1(RNAi) animals exhibit slow and uncoordinated movement, an increased tendency to reverse and a novel learning phenotype. Reduction of *adsl-1* function does not prevent learning but causes a distinct behavioral output after cue-pairing in a gustatory plasticity paradigm. To determine the effect of distinct metabolic changes on phenotypes, we assessed phenotypes after supplementing cultures with excess purines and after manipulating SAICAR levels via pharmacological approaches. Our results indicate that increased SAICAR levels contribute to both learning and mobility phenotypes. In contrast, purine homeostasis does not appear to underlie the mobility phenotypes. However, supplementation with adenosine, but paradoxically not guanosine, can partially restore learning.

Metabolomics analysis revealed that tyrosine metabolism is perturbed when *adsl-1* function is reduced, which led us to discover that the learning difference is a result of a deficiency of the tyrosine-derived biogenic amine tyramine. Loss of TDC-1, which synthesizes tyramine, or the TYRA-2 tyramine receptor, causes an *adsl-1*-like learning difference, and the learning phenotype of both *adsl-1* and *tdc-1* is ameliorated with tyramine supplementation. The working model that reduced *adsl-1* function inhibits tyramine production is also supported by the observation that *adsl-1* mutants manifest the distinct head oscillation phenotype seen in *tdc-1* mutants. While tyramine supplementation restores learning, it has no effect on mobility of *adsl-1* animals, suggesting that the mechanisms by which SAICAR influences mobility and learning are distinct.

Finally, we have shown that the restorative effect of adenosine on learning does not extend to the head oscillation phenotype, suggesting that we have revealed an unexpected role for adenosine directly in gustatory plasticity as opposed to in ameliorating the metabolic effects of reduced *adsl-1* function on tyramine availability.

Keywords: Purine Metabolism, ADSL Deficiency, *C. elegans*, Behavior, Tyramine

247 **Nutrient-Induced Overcoming of Dual Inhibition on MYRF Cleavage on the Cell Membrane is essential for Temporal Developmental Control in *C. elegans*** Zhimin Xu, Zhao Wang, Shiqian Shen, Lifang Wang, Yingchuan B Qi ShanghaiTech

University

The regulatory principles governing post-embryonic development, especially those related to timing control, remain largely elusive. MYRF, a transmembrane transcription factor, plays a pivotal role in *C. elegans* larval development, and its absence results in early larval arrest. MYRF is well-known as a master regulator of myelination. However, its presence across metazoans and widespread expression hints at functions extending beyond myelination. Loss of MYRF results in developmental lethality in both invertebrates and vertebrates, and in humans, MYRF haploinsufficiency is linked to *MYRF*-related Cardiac Urogenital Syndrome. Despite its importance, the mechanisms underlying MYRF's involvement in animal development remain largely uncharted.

MYRF stands out as an unconventional transcription factor, which is initially inserted in the membrane, and then undergoes intramolecular chaperone-mediated trimerization. This trimerization triggers self-cleavage, allowing its N-terminal segment to enter the nucleus for transcriptional regulation. We previously observed that full-length MYRF traffics to the cell membrane in *C. elegans*, and the self-cleavage is temporally controlled by yet-to-be-identified mechanisms.

In this study, we unveil that the proteolytic processing of MYRF is negatively regulated by dual inhibitory interactions, involving both MYRF itself and a second transmembrane factor, PAN-1. Releasing these inhibitions is crucial for self-cleavage. The processing of MYRF oscillates with the four consecutive stages of larval development, likely influenced by the internal nutrient state, as discontinuing feeding effectively blocks MYRF's cleavage.

To overcome the early lethal consequences of MYRF deletion, we established a system for the inducible degradation of MYRF protein. Our findings show that MYRF plays a vital role at each larval stage, operating within specific, short time frames. This reveals its broad yet temporally specific involvement in developmental progression. Notably, MYRF is responsible for promoting the transcriptional activation of the key developmental timing gene miRNA *lin-4*.

These findings unveil a previously uncharted pathway that connects the overall nutrient status to transcriptional developmental programs.

248 **Loss of the H3K9me2 demethylase *jhdm-1* in *C. elegans* results in a transgenerational decrease in chemotaxis** Jaely Z Chavez[1], Mackenzie S Roberson[1], Monica Reeves[2], Karen L Schmiechel[1], David J Katz[2] [1]Biology, Oglethorpe University, [2]Cell Biology, Emory University

Recently in *Caenorhabditis elegans*, we showed that animals mutant for the COMPASS H3K4 methyltransferase complex member *wdr-5,* experience a global transgenerational enrichment of repressive H3K9me2 marks. The accumulation of H3K9me2 in these animals is associated with a progressive longevity phenotype where animals achieve significantly longer lifespans with increasing generations. The importance of the management of H3K9-dependent heterochromatin is further underscored by the fact that this expanded longevity can also be recapitulated by inhibition of the putative H3K9me2 demethylase JHDM-1. To determine whether the accumulation of H3K9me2 affects behavior, we performed chemotaxis assays on *jhdm-1* mutants. We find that *jhdm-1* mutants exhibit significantly reduced chemotactic behavior towards food in comparison to wild-type N2 worms. Consistent with this being an epigenetic effect, the chemotaxis index (C.I.) in *jhdm-1* mutant worms declines transgenerationally by 52.5% between generations F3 and F7 ($C.I._{F3}$=0.80 and $C.I._{F7}$= 0.43). To our knowledge, this is the first example of a transgenerational behavior phenotype potentially caused by the accumulation of histone methylation across generations. Interestingly, after generation F7, *jhdm-1* mutants gradually restore their chemotactic behaviors to levels comparable to those seen in early generations ($C.I._{F13}$= 0.86). The transgenerational decline in chemotactic behavior and the subsequent reversion of the phenotype in *jhdm-1* mutants is phenocopied in *wdr-5* mutants, which also aberrantly accumulate H3K9me2. Taken together, these data are consistent with the interpretation that transgenerational establishment of repressed chromatin through the accumulation of H3K9me2 can result in abnormal behavior in *C. elegans*. We are currently performing RNA-Seq and analyzing H3K9me2 ChIP data to test this hypothesis.

249 ***lon-1* as a nexus of both positive and negative transcriptional outputs of BMP signaling in *C. elegans*** Maria V Serrano, Sergio Moreira-Antepara, Jun Liu Cornell University

Bone Morphogenetic Protein (BMP) signaling regulates a wide variety of developmental and homeostatic processes. However, very few direct target genes have been identified and characterized. The BMP pathway is conserved in *C. elegans* and is known to regulate both body size and postembryonic mesoderm development. Previous work has suggested that *lon-1* transcription is negatively regulated by BMP signaling (Morita et al 2002, Maduzia et al 2002). *lon-1* encodes a protein in the CAP (Cysteine-Rich Secretory Protein, Antigen 5, and Pathogenesis-Related 1) superfamily, and *lon-1(0)* mutants are long.

Using two complementary approaches, we have found that *lon-1* expression is likely directly regulated by BMP signaling, both

positively and negatively. Using a single copy *lon-1* transcriptional reporter system, we identified a region in the *lon-1* promoter that mediates its response to BMP signaling. CHIP-seq data generated by the modENCODE consortium shows that this region is bound by both SMA-3, a Smad protein, and SMA-9, a zinc finger transcription factor and homolog of Drosophila Schnurri. When we deleted this region in the endogenous *lon-1* promoter using CRISPR, we found that *lon-1* function is compromised, exhibiting phenotypes in both body size and mesoderm development in sensitized genetic backgrounds. We have also used an endogenously tagged and fully functional V5::LON-1 to monitor LON-1 protein expression in various BMP pathway mutants. Results from these analyses indicated that *lon-1* expression is regulated both positively and negatively by BMP signaling, and that the regulation exhibits developmental stage specificity. These findings highlight the complex and redundant regulatory mechanisms underlying BMP signal transduction that ensures the robustness of development and homeostasis.

250 **The origin and evolution of de novo genes and de novo proteins** Li Zhao The Rockefeller University

Understanding the origin and evolution of genes is crucial for explaining the origin and evolution of novel phenotypes. While most new genes derive from duplication-related processes, recent studies show that de novo genes, originating from ancestrally non-genic sequences, also contribute to gene and functional innovation. However, the initial steps in the birth process of de novo genes and their maintenance in populations and species were largely unknown. We combined population genetics, whole-genome alignments, computational structure modeling, and functional approaches to study the origination, evolution, and protein structures of lineage-specific de novo genes. We observed a gradual shift in some of their functional and structural properties. Intriguingly, minimal protein structural changes occurred in both young and old de novo genes. Ancestral sequence reconstruction showed that well-folded proteins often originate as folded, some enriched with transmembrane and signal proteins. We also used ATAC sequencing, single-cell RNA sequencing, and deep learning to investigate the regulatory dynamics and mechanisms of these novel genes. Our study provides a systematic overview of the origin, evolution, expression regulation, and structural changes of de novo genes.

251 **A vast evolutionarily novel translatome participates in conserved cellular processes** Aaron C Wacholder[1], Saurin Parikh[1], Nelson Coelho[2], Carly Houghton[2], Lin Chou[2], Anne-Ruxandra Carvunis[1] [1]Computational and Systems Biology, University of Pittsburgh, [2]University of Pittsburgh

Ribosome profiling experiments demonstrate pervasive translation of eukaryotic genomes outside of annotated coding sequences. This “noncanonical” translatome encodes thousands of proteins that potentially participate in biological processes but have never been studied in depth. We developed a novel approach to identify the noncanonical translatome at high sensitivity by integrating ribosome profiling reads across hundreds of published experiments. Applying this approach *to S. cerevisiae*, we identified a yeast translatome consisting of over 18,000 noncanonical coding sequences in addition to around 6000 annotated protein-coding genes. To better understand the role of noncanonical translation, we then characterized the yeast translatome by evolutionary properties and phenotype.

Using comparative genomics, we find that the yeast translatome can be divided into two classes that can be defined evolutionarily. The smaller class consists of coding sequences that are conserved over long evolutionary time; these are mostly annotated and tend to be long and highly expressed. The larger class consists of evolutionarily young coding sequences that emerged recently from noncoding sequences; most are short, relatively lowly expressed and unannotated. Employing a genetic screen in which translation is experimentally disabled, we find that a large fraction of both canonical and noncanonical recently-emerged coding sequences show substantial reductions of fitness despite lacking evolutionary conservation. Moreover, we find that the potential roles of a subset of recently-emerged ORFs can be inferred from their interactors in the yeast genetic interaction network. Novel ORFs are rapidly integrated into conserved cellular networks, and appear to be involved in diverse processes including RNA processing, DNA repair and cell growth.

Overall, our results demonstrate the existence of thousands of evolutionarily unconserved coding sequences, most of which are unannotated and have never been studied, that appear to play key roles in major biological processes.

252 **Evolutionary Signatures of Host-Pathogen Interactions through the Lens of Paleogenomics** Flavio De Angelis, C. Eduardo Guerra Amorim California State University Northridge

Exposure to pathogens stands as one of the most powerful selective pressures in human history. Large-scale genome-wide association studies (GWAS) have illustrated that the genetic predisposition to infections, as well as resistance against pathogens, arise from the contribution of thousands of loci across the genome. To model the polygenic inheritance of these traits, one can integrate the effects of multiple variants into polygenic risk scores (PRS), offering an estimate of an individual’s genetic potential for a trait. Based on this, we sought to calculate immune-related PRS for over 3,000 ancient human individuals, in order to characterize the evolutionary signatures of human host-pathogen interactions during past epidemics in Eurasia. We hypothesize that major epidemics imposed selective pressure on genetic variants underlying

resistance and predisposition to infectious diseases, modeled here as polygenic traits, and that this process has likely left a discernible signature in the genome, detectable through the calculation of PRS for ancient individuals across different epochs. By combining GWAS with paleogenomic data, we show that major epidemics in human pre- and historical eras have shaped the genetic variation associated with polygenic traits that underlie infectious disease susceptibility. Notably, five events – the transition to agriculture, Justinian Plague, Antonian Plague, Black Death, and Measles outbreaks – are associated with statistically significant shifts in the distribution of PRS calculated based on these traits. Among the biological processes implicated in the adaptation to disease outbreaks are lipid metabolism and lipoprotein clearance, the differentiation and development of megakaryocytes, and the response to hormonal stimuli, particularly insulin, emphasizing systemic involvement in host defenses.

253 **Horizontal gene transfer as a mechanism for evolution of novel immune defenses in Drosophila** Rebecca Tarnopol[1], Josephine A Tamsil[2], Jaden Ha[2], Gyöngyi Cinege[3], Zoltan Lipinzski[4], Bernard Y Kim[5], Lilla B Magyar[3], Kirsten I Verster[5], Éva Kurucz[3], Edit Ábraham[4], Susan L Bernstein[2], István Andó[3], Noah K Whiteman[2,6] [1]Plant & Microbial Biology, UC Berkeley, [2]Molecular & Cell Biology, UC Berkeley, [3]Institute of Genetics, Biological Research Centre -- Szeged, [4]Institute of Biochemistry, Biological Research Centre -- Szeged, [5]Biology, Stanford University, [6]Integrative Biology, UC Berkeley

Immune systems are among the most dynamically evolving traits across the tree of life. Even with a limited immune repertoire, insects have evolved unique defense strategies to neutralize parasitoid wasps, which impose some of the strongest selection on insect populations in the wild. Studies of *Drosophila* parasitoid defense systems have focused on cell-mediated defense systems, where the parasitoid is encapsulated by host blood cells and neutralized. We previously discovered that *Drosophila ananassae* possesses a non-canonical immune response to parasitoids that involves two toxin genes, cytolethal distending toxin B (*cdtB*) and apoptosis inducing protein of 56kDa (*aip56*), that were horizontally transferred from phages or bacteria to the ancestor of the *ananassae* group ~21 mya. While these genes are necessary for *D. ananassae* to mount a full immune response against parasitoid wasps with diverse infection strategies, a direct role for these toxins in parasitoid defense is unknown. Here, we recapitulated the horizontal transfer of *cdtB* and *aip56* into flies by expressing *cdtB* and two *cdtB::aip56* "fusion" genes from *D. ananassae* in transgenic *D. melanogaster*, which does not natively encode *cdtB* or the *fusion* genes. We found that one widely conserved *cdtB::aip56* fusion gene (*fusionB*) promotes fly survival and suppresses wasp development when expressed in *D. melanogaster* fat bodies. *fusionB* arrests fly development when expressed constitutively, suggesting constraints evolved on its expression in its native hosts. Heterologous expression experiments in yeast indicate that the fusion genes have evolved eukaryotic signal peptides that are essential to the growth inhibition phenotype we observe in eukaryotic hosts. Our findings demonstrate that horizontal gene transfer can promote the rapid evolution of innate immune modules in animal hosts.

254 **Evolutionary diversification and repeated gene capture by telomeric retrotransposons across the *Drosophila* genus** Jae Hak Son[1], Christopher E. Ellison[1], Mia T. Levine[2] [1]Department of Genetics, Human Genetics Institute of New Jersey, Rutgers, The State University of New Jersey, [2]Department of Biology, Epigenetics Institute, Penn Center for Genome Integrity, University of Pennsylvania

Transposable elements (TEs) are mobile genetic elements that can move from one position in the host genome to another and must replicate faster than their host to avoid extinction. TEs often evolve antagonistically with their host in a classic evolutionary arms race. On the other hand, the co-evolution between TEs and the host genome can be mutualistic, where TEs are co-opted to benefit their host. Telomere-specialized non-LTR retrotransposons in *Drosophila* have been known for their mutualistic relationship with their host. These elements have replaced the role of telomerase, which is absent across the *Drosophila* genus, and replicate specifically to chromosome ends to protect them from erosion. However, more recent work has identified rapid evolution in many telomere-binding proteins, which is more consistent with antagonistic evolution rather than mutualism. We recently found that the *D. melanogaster TART-A* telomeric transposon has captured a portion of the piRNA gene, *nxf2*, which allows it to target *nxf2* for suppression, again consistent with antagonistic evolution. To reveal whether the antagonistic evolution between the telomeric transposons and the host occurs across the *Drosophila* genus, we have examined the evolutionary diversification of telomere-specialized retrotransposons across the *Drosophila* genus using the long-read genome assemblies from 109 *Drosophila* species. Based on phylogenetic analysis of the *pol* gene, we identify 6 major telomeric retrotransposon clades. Telomeric TEs exhibit a complex pattern of gain, loss, duplication, and horizontal transfer within and between these clades. The ancestral clade (TR1) has been lost in the *melanogaster* group and the HTT clade, first described in *D. melanogaster*, replaced the ancestral clade in the group most likely via horizontal transfer. We also found that 13 *Drosophila* species independently lost all telomeric retrotransposons. We next find repeated capture of piRNA effector proteins by telomeric TEs, Piwi in the *montium* subgroup and Aub in the *willistoni* and *Zaprionus* groups. The capture of an *aub* fragment appears to have occurred independently at least four times within the *Zaprionus* subgroup. By sequencing small RNAs in a subset of these species, we also find that piRNAs from the gene-captured region of the telomeric TEs are likely targeting Piwi/Aub for suppression. We therefore propose that gene capture by telomeric TEs represents a form of counter-

silencing by TEs against their host.

255 **Duplication, transposition, and divergence of the telomerase RNA underlies the evolution of Mimulus telomeres** Surbhi Kumawat, Jae Young Choi University of Kansas

One of the most fascinating phenomena in evolutionary biology is the rapid evolution of molecular complexes with conserved functions across the tree of life. Studying these complexes have led to novel insights of function and evolution in universally important molecular systems. Here we present results from studying the evolution of the telomere, a nucleoprotein complex that protects chromosome ends in all organisms with a linear chromosome.

Telomere has a crucial role of genomic stability and protection, hence components of the telomere are thought to be under strong evolutionary constraint. In vertebrates, for instance, the DNA sequence of the telomere has not changed for 500 million years, but in that same time plant telomeres have evolved an enormous range of sequence variation. It is fascinating that plant telomeres have deviated from the ultra-constrained evolution, but what mechanism drives the sequence variation is largely unknown. Here, we present results from Monkeyflower (Mimulus) telomeres and propose a novel model to explain telomere sequence variation in plants.

We investigated the evolution of Mimulus telomeres by studying the long noncoding telomerase RNA (TR), which is a core component of the telomere maintenance complex and determines the telomere DNA sequence. We conducted total RNA-based de novo transcriptomics and genome analysis on 22 species, and discovered Mimulus species have evolved at least three different telomere sequence variation. Unexpectedly, we discovered several species with evidence of duplicated TR genes. This was surprising as the telomere maintenance complex uses a single TR gene to extend chromosome ends, hence any extra TR copies might interfere with normal telomere maintenance functions. However, we discovered a Mimulus species (M. lewisii) with two divergent TR duplicates that were functional and resulted in the species with a sequence heterogeneous telomere. Interestingly, evolutionary analysis of the M. lewisii TR paralogs indicated it had arisen from a transposition-mediate duplication process. Further analysis of the TR across multiple Mimulus species we discovered the TR gene had frequently transposed and inserted into new chromosomal positions during the evolution of the Mimulus genus.

We propose the TR transposition, duplication, and divergence model to explain telomere sequence evolution in Mimulus and all plants. This novel model posits complex evolutionary changes in the TR involving transposition-mediated gene duplication results in plant species to evolve telomeres with mixed sequences. These species eventually revert to a single telomere sequence, which facilitates the turnover of the telomere sequence.

256 **Selective dynamics of interruptions at short tandem repeats** Michael E. Goldberg[1], Harriet Dashnow[1], Kelley Harris[2,3], Aaron R. Quinlan[1] [1]Departments of Human Genetics and Biomedical Informatics, University of Utah, [2]Department of Genome Sciences, University of Washington, [3]Computational Biology Division, Fred Hutchinson Cancer Research Center

Short tandem repeats (STRs) are hotspots of genomic instability that mutate at rates orders of magnitude greater than non-repetitive genomic loci. In the germline, STRs typically mutate through replication slippage, which manifests as expansions or contractions of a locus by one or more repeat units. Somatic and germline expansions at some STR loci are linked to Mendelian diseases, while variation at other noncoding loci have recently demonstrated associations with complex traits, possibly by altering transcription factor affinity and occupancy of nearby binding sites. Accordingly, some STRs are inferred to be under purifying selection, regardless of their instability.

A major determinant of an STR's mutation rate is the homology of its repeat units; one or more 'interruptions', or bases that disrupt the locus's canonical repeat, have been shown to significantly decrease mutation rate in both the germline and the soma; the effect size of this decrease scales with the greatest remaining stretch of perfect homology. More broadly, interruptions may act as *cis*-acting anti-mutator alleles, in perfect linkage disequilibrium with the repeat allele whose mutation rate they decrease. However, interruptions may themselves be deleterious at these constrained loci, particularly at noncoding loci in gene regulatory elements, possibly disrupting the formation of secondary structures key to their function. We therefore hypothesized that the frequency of interruptions could depend on a locus's purifying selection, where the fitness effects of both expansions but also interruptions could be more deleterious than at neutral loci.

To test this hypothesis, we examined the distribution of interruptions at nearly 650,000 autosomal 2-6 bp motif STRs. We find that STRs within enhancers and promoters, loci putatively under selection, harbor fewer interruptions than those falling outside. Similarly, STRs are less interrupted when they fall within enhancers linked to highly constrained genes compared to those connected to more neutrally evolving genes. In contrast, purifying selection is positively associated with interruptions in coding STRs. Our findings indicate that the abundance of interruptions may be partially explained at coding STRs by the benefit

of a lower mutational burden at their linked loci. In contrast, maintaining a minimum core stretch of homology may be critical for the function of noncoding STRs that fall within regulatory elements while outweighing the benefits of lowering mutation rate.

257 **Dusky-like shapes the corneal lens by maintaining apical expansion of retinal cells and establishing a scaffold of ZP domain proteins** Neha Ghosh, Jessica E Treisman Cell Biology, NYU School of Medicine

Apical extracellular matrix (aECM) assumes distinct shapes to mediate functions such as morphogenesis, hearing, and fertility. Zona Pellucida (ZP) domain-containing proteins promote aECM attachment to cell membranes, potentially controlling its shape. The *Drosophila* corneal lens is a biconvex structure composed of aECM. We have found that *duskylike* (*dyl*), which encodes a transmembrane ZP domain protein, is essential for normal corneal lens shape; in *dyl* mutant ommatidia, external parts of the corneal lens structure are lost and its internal curvature is increased. During pupal development, loss of *dyl* from the corneal lens-secreting cone and primary pigment cells causes their apical constriction and apicobasal contraction, accompanied by changes in the distribution of actomyosin and β_H-spectrin. We infer that Dyl maintains the apical expansion of these cells by attaching their apical plasma membranes to the aECM under tension. Loss of these attachments in the absence of Dyl may result in ommatidial contraction that pulls the corneal lens basally, altering its curvature. Consistent with this hypothesis, artificial induction of apical constriction by expressing a constitutively active form of Myosin light chain kinase is sufficient to produce the same changes in corneal lens shape seen in *dyl* mutants. Dyl is only transiently expressed in the mid-pupal retina; however, we found that it affects the organization of other ZP domain proteins such as Dumpy (Dpy) and Piopio (Pio) that are maintained until adulthood. These ZP domain proteins have a functional role, as *dpy* mutant ommatidia also show defects in corneal lens shape. Chitin, a major corneal lens component, is deposited above the retinal cells and below a layer of Dpy and Pio, and its accumulation is delayed in both *dyl* and *dpy* mutant ommatidia. These observations suggest that Dyl assembles a scaffold of proteins including Dpy and Pio that retains secreted chitin to establish the normal corneal lens shape. Our work provides mechanistic insights into how the corneal lens develops the curvature necessary to focus light onto the retina.

258 **A novel protein Outspread determines organ dimension during salivary gland tubulogenesis** Ji Hoon Kim, Shravan Balasubramaniam, Parama Paul, Deborah J Andrew Johns Hopkins University

Epithelial tubular organs are essential for viability in all higher multicellular organisms. The optimal functionality of a tubular organ demands its proper architecture, which is achieved during development. Salivary gland (SG) development in the Drosophila embryo provides an excellent model system to study morphogenesis from a 2-dimensional (2D) epithelial sheet into a 3-dimensional (3D) epithelial tube. This process is driven by morphogenetic signals acting on non-muscle myosin II (MyoII) to induce changes in cell shape and arrangement. We have searched for genetic factors that affect SG morphogenesis and found that a novel gene – *outspread* (*osp*) – is important for shaping the 3D structure of the SG. *osp* expression in the SG requires the FoxA transcription factor Fork head (Fkh), which controls SG cell invagination and tube formation. Osp is a large cytosolic protein with two pleckstrin homology (PH) domains that could mediate lipid binding and membrane association. Osp is closely related to a mammalian protein – Myosin Phosphatase Rho Interacting Protein (MPRIP) – suggesting a potential function in the Rho GTPase-MyoII signaling pathway. Indeed, endogenous Osp protein colocalizes with apical MyoII in invaginating SG cells and, when overexpressed, Osp strongly localizes to the supracellular MyoII cable that encircles the SG placode. Loss of *osp* results in shorter SG tubes with wider lumens and Osp overexpression results in longer SG tubes. Similar changes in SG tube dimensions result from perturbing MyoII function: hyperactivation of MyoII decreases SG tube length whereas MyoII depletion specifically in the SG generates elongated SG tubes. Interestingly, *osp* genetically interacts with *arc*, a regulator of Crb, which antagonizes MyoII function in the SG, to aggravate SG morphological defects. Based on these findings, we propose that Osp suppresses MyoII activity during SG invagination thereby providing a novel regulatory mechanism to determine organ geometry during tubular morphogenesis.

259 **The pioneer transcription factor *zelda* is crucial for tissue patterning and morphology in the regenerating *Drosophila* wing imaginal discs** Anish Bose, Keaton Schuster, Chandril Kodali, Rachel Smith-Bolton University of Illinois at Urbana Champaign

The *Drosophila* wing imaginal disc, the larval precursor of the adult wing, is capable of regeneration. During wing disc regeneration, the damaged tissue proliferates and organizes cell fates to re-pattern the tissue to form the adult wing. However, the process behind the re-establishment of cell fate during regeneration as well as the progression from the regenerative state back to normal development is poorly understood. In this study, we show that the pioneer transcription factor Zelda has a novel role in re-patterning the regenerating tissue, allowing it to transition back to normal development and progress through morphogenesis. While Zelda is expressed in the developing wing disc, it is not required for normal wing development. By contrast, Zelda is upregulated after damage, and optogenetic inactivation or RNAi knockdown of Zelda resulted in various cell fate and patterning defects such as 1) missing and/or ectopic veins, 2) thick vein tissue on the distal edge, 3) missing

wing margin, 4) posterior-to-anterior cell fate transformations, and 5) blisters. To identify genes that are regulated by Zelda during regeneration, we performed CUT&RUN to identify Zelda binding sites. Interestingly, Zelda had very few binding sites in undamaged discs but was bound near genes important for wing development during late regeneration. Indeed, we found that inactivation of Zelda resulted in a delayed transition from regeneration to normal developmental patterning, and mis-patterning of genes such as *wingless*, *blistered*, *delta,* and *cut*, resulting in mis-regulation of vein and margin cell fate. We found that Zelda binds near genes important for EGF, TGF-b, Notch, Dpp and Hh signaling, which could account for Zelda's role in vein cell fate. Inactivation of Zelda during regeneration also reduced the expression levels of *taranis* and *osa*, which we have previously shown act to ensure correct *engrailed* expression during regeneration, protecting posterior cell fate from disruption by regeneration signaling. Zelda was also bound near and required for expression of integrins, accounting for the wing blistering phenotype. Thus, this study reveals a key role for Zelda in regulating cell fate and patterning genes during the transition from regeneration back to normal development.

260 **Tissue regeneration following necrosis requires non-apoptotic caspase activity** Jacob W Klemm, Robin Harris School of Life Sciences, Arizona State University

Necrosis is a catastrophic type of tissue death that can occur in almost any tissue type and arise from several types of injury and inherited and congenital conditions. Characterized by the sudden loss of membrane integrity, necrotic cell death often spreads to adjacent, healthy cells, resulting in collective tissue death. A better understanding of how necrotic cells interact with the surrounding tissue is crucial to effectively treating necrotic wounds. However, a lack of accessible genetic models to study the interactions between necrotic and healthy cells has impaired progress in the field. To address this, we established a novel genetic ablation system to drive necrotic cell death in the *Drosophila* wing imaginal disc and study the tissue response that follows.

With this model, we quickly found that tissues are competent to regenerate from necrosis and this regenerative response is unique to necrotic ablation. Following damage, significant apoptosis is induced at a distance from the wound, which we call necrosis-induced apoptosis (NiA). Unlike typical damage-associated apoptosis, NiA cells are not regulated by the JNK pathway, a highly conserved regulator of both apoptosis and regeneration. However, NiA are necessary for regeneration; limiting NiA activity results in a reduced capacity to regenerate, as assayed by adult wing size. Thus, following necrosis, tissues respond by inducing NiA to promote regeneration.

We are currently investigating the precise mechanism by which NiA cells promote tissue repair and have found that NiA promote regenerative cell proliferation. EdU labeling reveals high levels of proliferation at the wound edge that is abolished when NiA activity is blocked via RNAi. However, NiA cells do not appear to secrete mitogens involved in apoptosis-induced proliferation (AiP), suggesting that NiA may promote proliferation via a different mechanism. Using a caspase sensitive GFP reporter to label NiA cells, we have found that NiA appear to persist in the disc proper throughout regeneration, suggesting that these cells may survive apoptotic signaling to directly repair the tissue. To test this hypothesis, we are designing caspase-based lineage trace experiments to track the fate of NiA cells and determine if NiA contribute to the regenerated wing tissue. As NiA represent a unique response to tissue necrosis, further characterization may inform the treatment of necrotic wounds in a clinical setting.

261 **Unscheduled endocycles impair growth of the *Drosophila* wing disc** Yi-Ting Huang, Lauren Lian Hesting, Brian R. Calvi Indiana University Bloomington Biology

How tissues grow and regenerate is incompletely understood. Some tissues grow through an increase in cell size (hypertrophy) by switching to a variant endocycle which cells grow and duplicate their genome through repeated G and S phases without division. Cells can also undergo an unscheduled switch to endocycles in response to aging, stress, and environmental inputs. We call these induced endoreplicating cells (iECs) to distinguish them from scheduled developmental endoreplicating cells (devECs). While iECs aid in wound healing and tumor suppression, they also contribute to cancer therapy resistance and tumor regrowth. Much remains unknown, however, about the regulation and growth of these unscheduled iECs and how they impact normal or pathological growth.

We have been using the *D. melanogaster* wing disc as an *in vivo* genetic model to evaluate how unscheduled iECs affect growth. To address whether iEC hypertrophic growth can replace cell division for tissue growth, we induced iECs in clones and also in different regions of the wing disc by using GAL4/UAS to inhibit Cyclin A. We found that iECs initially grew in cell size and accumulated total tissue mass at a rate proportional to mitotically-dividing controls, but then later iEC growth slowed and resulted in significant tissue undergrowth. Further analysis of endocycle dynamics revealed variation among different iECs, which arrested at different terminal ploidies. These iECs had DNA repair foci near heterochromatin suggestive of replication stress. Analysis of our RNA-Seq data from S2 iECs revealed an upregulation of numerous genes that are associated with

senescent cell cycle arrest. We found that these genes are also upregulated in wing disc iECs *in vivo*, suggesting that iEC growth is limited by a senescent-like arrest. These cells also had activated Jun N-Terminal Kinase (JNK) stress pathway. Inhibiting JNK activity revealed that JNK signaling mediates both senescent-like response and iEC growth arrest. We are currently evaluating how iECs influence proliferation of neighboring cells and the extent to which it resembles a wounding and regeneration response. Altogether, our results indicate that growth of unscheduled iECs is limited by a senescent-like arrest that has severe negative consequences for tissue growth. More broadly, our findings are providing clues to how iECs may paradoxically cause human tissue undergrowth or contribute to increased cell proliferation during tumorigenesis.

262 **Nutrient-dependent dedifferentiation in the midgut epithelium promotes adaptive growth in *Drosophila*** Yuichiro Nakajima[1], Hiroki Nagai[1], Luis Augusto Eijy Nagai[2], Sohei Tasaki[3], Ryuichio Nakato[2], Masayuki Miura[1] [1]Graduate School of Pharmaceutical Sciences, University of Tokyo, [2]Institute for Quantitative Biosciences, University of Tokyo, [3]Graduate School of Science, Hokkaido University

Post-developmental organ resizing improves organismal fitness under constantly changing nutrient environments. Although stem cell abundance is a fundamental determinant of adaptive resizing, our understanding of its underlying mechanisms remains primarily limited to the regulation of stem cell division. In mammals, cellular plasticity, or dedifferentiation, has been identified in multiple tissues, especially in the intestinal epithelium where both absorptive and secretory lineages undergo dedifferentiation into intestinal stem cells (ISCs) upon severe injury or during inflammatory tumorigenesis. However, it is remains largely unclear whether cell fates are plastic under physiological conditions or as the result of naturally occurring perturbations. Here we demonstrate that nutrient fluctuation induces dedifferentiation of enteroendocrine cells (EEs) in the *Drosophila* adult midgut to drive adaptive intestinal growth. From lineage tracing and single-cell RNA-sequencing, we identify a subpopulation of EEs, or AstC-positive EEs that convert into functional ISCs in response to dietary glucose and amino acids by activating the JAK-STAT pathway. We further show that EE-derived ISCs are multipotent but preferentially generate new enterocytes, leading to a rapid increase in gut size. Genetic ablation of EE-derived ISCs severely impairs ISC expansion and midgut growth despite the retention of resident ISCs, and *in silico* modeling further indicates that EE dedifferentiation enables efficient increase in the midgut cell number while maintaining epithelial cell composition. Our findings thus uncover a physiologically-induced dedifferentiation that ensures ISC expansion during adaptive organ growth in concert with nutrient conditions.

263 **Two sequential gene expression programs bridged by cell division support long-distance collective cell migration** Jingjing Sun[1], Aswini Babu[1], Frank Macabenta[2], Ayse Damla Durmaz[1], Angelike Stathopoulos[1] [1]California Institute of Technology, [2]California State University Monterey Bay

The precise assembly of tissues and organs relies on spatiotemporal regulation of gene expression within migrating collectives to coordinate cell behavior. In Drosophila embryos, the midgut musculature is formed through collective migration of caudal visceral mesoderm (CVM) cells, but how gene expression changes as cells migrate is not well understood. Here, we focused on ten genes expressed in the CVM and cis-regulatory sequences controlling their expression. While some genes are continuously expressed, others are expressed only early or late during migration. Late expression relates to cell cycle progression, as driving string/Cdc25 causes earlier division of CVM cells and precocious expression of late genes. In particular, we found that cell cycle effector transcription factor E2f1 is a required input for late gene CG5080. Furthermore, while late genes are broadly expressed in all CVM cells, early gene transcripts are polarized to anterior or posterior ends of the migrating collective. We show this polarization requires transcription factors Snail, Zfh1, and Dorsocross. Collectively, these results identify two sequential gene expression programs bridged by cell division that support long-distance directional migration of CVM cells.

264 **Regulation of the Competency to Amplify Intermediate Progenitor generation during Neurogenesis** Cyrina M Ostgaard[1], Arjun Rajan[2], Cheng-Yu M Lee[2] [1]Cell and Developmental Biology, University of Michigan, [2]University of Michigan

Intermediate progenitors (IPs) are neural stem cell progeny that undergo limited proliferation to increase neuron production. Subsets of these cells likely function as transit-amplifying cells to increase IP generation per asymmetric stem cell division. How this competency is instilled in stem cells is unknown largely due to the inability to define functionally relevant enhancers. I used fly larval brain neural stem cells (neuroblasts; NBs) to investigate regulation of the competency to amplify IP generation because cell types in NB lineages are well characterized. A type I NB asymmetrically divides to generate a ganglion mother cell (GMC) that produces two neurons. By contrast, a type II NB generates an intermediate neural progenitor (INP) that amplifies GMC generation increasing neuron production 6-fold or more per asymmetric division of a type II NB compared to a type I NB. We combined cell type-specific chromatin accessibility, occupancy by functionally relevant transcription factors and histone marks to define 4332 neurogenic enhancers in NBs. I confirmed the sufficiency of dozens of these candidate enhancers to drive reporter expression in larval brain NBs. Our data suggest that Sp/KLF family transcription factor Buttonhead (Btd; Sp8 in vertebrates) promotes NB competency to generate INPs while achaete-scute family transcription factor Asense (Ase; Ascl1 in

vertebrates) limits this competency. By correlating Btd-bound neurogenic enhancers to transcripts uniquely enriched in type II NBs and INPs, we identified 19 transcription factors including Bi (Tbr-2 in vertebrates) that likely function downstream of Btd to promote INP generation. We also identified 24 transcription factors that likely function downstream of Ase to inhibit INP generation based on their neurogenic enhancers containing a human Ascl1-binding motif and their transcripts enriched in type I NBs or INPs. I will combine loss- and gain-of-function approaches to validate the roles of these candidate regulators of the competency to generate INPs in NBs. I am also testing whether the Ase regulatory network functions as a barrier to reprogramming type I NBs to generate INPs following Btd mis-expression. Strategies that increase or decrease the generation of differentiated cells on-demand by manipulating stem cell competency to transiently amplify IPs could increase the efficiency of tissue regeneration and provide novel therapeutic targets for treating certain childhood tumors.

265 **Stress-responsive keratins regulate innate immunity in inflamed skin** Erez Cohen[1], Yang Xu[2], Craig N Johnson[1], Kaylee Steen[1], Johann E Gudjonsson[3], Carol A Parent[2,4,5], Pierre A Coulombe[1,3,5] [1]Cell and Developmental Biology, University of Michigan Medical School, [2]Pharmacology, University of Michigan Medical School, [3]Dermatology, University of Michigan Medical School, [4]Life Sciences Institute, University of Michigan, [5]Rogel Cancer Center, University of Michigan

A small group of keratin intermediate filament genes, the type II *KRT6* (protein K6A-C) paralogs and the type I *KRT16* (K16) and *KRT17* (K17), are robustly induced in surface epithelial keratinocytes in response to environmental stressors and in inflammatory skin diseases, including psoriasis, atopic dermatitis, and others. Mutations in these keratins cause Pachyonychia Congenita (PC), a rare genetic disorder showing striking anomalies in differentiation and homeostasis in ectoderm-derived epithelial appendages and glabrous skin. Accumulating evidence has highlighted multiple roles for keratins in regulating cellular signaling, yet the role of stress-responsive keratins in differentiation and inflammation remains ill-defined. By combining single cell transcriptomic data from human inflammatory skin diseases, *in-vivo* mouse models of single keratin deficiencies along with *ex-vivo* keratinocyte cell culture models, we identified stress-responsive keratins as potent regulators of innate immune responses. Further, and despite the high sequence homology between them, we show that K16 and K17 associate with distinct molecular pathways and exert opposing impacts on immune responses.

Both K16 and K17 are induced in keratinocytes within hours after exposure of mouse skin to stressors. Additional exposure to topical stresses within 24 hours after their induction results in a transient amplification of the neutrophil influx into the skin. Studies in *Krt17* null mice and *KRT17* null human keratinocyte cultures show that this response requires a K17-dependent sustainment of Protein Kinase C a activity and consequent release of neutrophil chemoattractants by stressed keratinocytes. In stark contrast, parallel studies involving *Krt16* null mice and *KRT16* null human keratinocyte cultures suggest that K16 functions to dampen innate immune activation by attenuating cytokine release in response to stressors. Preliminary evidence further suggest that K16 is both co-regulated and physically interacts with activators of type I interferon response, an established signaling pathway activated in stress-responsive keratinocytes. These data introduce a new paradigm uncovering the complexity of the interplay between stress-responsive keratins and innate immunity in skin, with significant implications for chronic inflammatory skin diseases and the rare genetic disease Pachyonychia Congenita.

266 **Evidence that Orthologous Loci Containing R-spondin 2 Regulate Respiratory Responses to Air Pollution in Mice and Humans** Samir Kelada[1], Adelaide Tovar[2], Gregory J Smith[1], Heather P. Wells[1], Neil E Alexis[1], David P. Peden[1] [1]University of North Carolina, [2]University of Michigan

Respiratory responses to air pollution exposure are complex traits, but few loci that contribute to variation in response have been identified and/or replicated in either humans or mice. We focus here on responses to ozone (O_3), an ambient air pollutant common in urban areas. Laboratory studies have shown that acute O_3 exposure causes airway inflammation and epithelial injury that varies widely across humans and inbred strains of mice. Additionally, epidemiologic studies have shown that ambient O_3 exposure is associated with the onset and/or exacerbation of both asthma and COPD. We sought to identify novel genetic loci that regulate responses to O_3 using the Collaborative Cross (CC) mouse genetics reference population, and then test whether orthologous loci also influence responses in humans. To that end, we conducted a QTL mapping experiment utilizing 56 CC strains, quantifying O_3-induced inflammation and injury phenotypes. We identified a suggestive QTL for lung injury on Chr 10 (peak = 26.2 Mb; confidence interval [CI]: 24.6–43.6 Mb)) and a genome-wide significant QTL on Chr 15 (peak = 47.1 Mb; CI: 40.2–54.9 Mb). We subsequently narrowed the Chr 15 QTL region to 41-45 Mb, a region containing 10 protein coding genes, through additional analysis of the QTL allele effects and CC founder strain haplotypes. In a subsequent experiment with CC mice, we replicated the QTL effect and evaluated the expression of the 10 candidate genes. We found that the expression of one candidate gene, *Rspo2,* paralleled lung injury over time after O_3 exposure, with lower expression linked to higher lung injury. Using a neutralizing antibody approach, we depleted RSPO2 in mice and found that this led to heightened O_3-induced lung injury and inflammation. Serendipitously, an epidemiologic study reported a genotype-by-air pollution exposure interaction in COPD with rs10086579, a common genetic variant near human *RSPO2*. We then genotyped 75 human volunteers who previously underwent an acute O_3 exposure in an environmental chamber and found a highly suggestive

association between rs10086579 and O_3-induced airway inflammation. Collectively, these results suggest that genetic variation in orthologous regions of the mouse and human genomes are associated with response to O_3 and that these genotype-by-exposure interactions may alter risk of COPD.

267 **A European effort for therapeutic gene editing in Rett syndrome: from organoids to mouse models** Tania Sorg[1], Susanna Croci[2], Andrea Rosetti[3], Angel Edo[4], Caterina Lo Rizzo[5], Sergio Daga[2], Maria Antonietta Mencarelli[5], Roberto Canitano[6], Marina Sica[7], Francesco Molinaro[7], Lino Nobili[8], Giulia Prato[9], Giulia Nobile[9], Silvio Boeri[9], Aglaia Vignoli[10], Maria Paola Canevini[11], Ilaria Vigano[12], Mario Chiariello[13], Miguel Chillon[14], Julia Ladewig[15], Yann Herault[1], Alessandra Renieri[2], Ilaria Meloni[2] [1]PHENOMIN - ICS, [2]Medical Genetics, University of Siena, [3]Central Institute of Mental Health (ZI), [4]Vall d'Hebron Research Institute, [5]Genetica Medica, Azienda Ospedaliero-Universitaria Senese, [6]Division of Child and Adolescent Neuropsychiatry, University Hospital of Siena, [7]Pediatric Surgery, Department of Women and Children, S. Maria alle Scotte Hospital, University of Siena, [8]Department of Neurosciences, Rehabilitation, Ophthalmology, Genetics, Maternal and Child Health, University of Genoa, [9]Child Neuropsychiatric Unit, Instituto G. Gaslini, [10]Health Sciences Department University of Milano, [11]Health Sciences Department, University of Milano, [12]Epilepsy Center, ASST Santi Paolo Carlo, [13]Core Research Laboratory, ISPRO Institute for Cancer Research, Prevention and Clinical Network, [14]Vall d'Hebron Research Institute, Catalan Institution for Research and Advanced Studies, [15]Central Institute of Mental Health, Heidelberg University/Medical Faculty Mannheim

Rett syndrome is a rare neurodevelopmental disorder and the second most common cause of intellectual disability in women after Down syndrome. Classic form of the disease is caused by *MECP2* mutations. Reactivation of *Mecp2* in symptomatic KO mice can revert disease phenotypes, suggesting that RTT is not irreversible. Gene editing represents an extremely promising therapeutic approach, since it allows maintaining the endogenous regulatory framework. The approach recently made its way to clinical trial for Leber Congenital Amaurosis (NCT03872479), demonstrating its translational potential. To validate its applicability to the 4 most common *MECP2* hotspot variants, we established an international consortium that was funded from the EU in 2021. We engineered a CRISPR/Cas9 gene editing toolkit composed of a dual plasmid system specific for each *MECP2* mutation. We collected RTT samples and reprogrammed iPSCs from 2 patients for each variant to generate brain organoids, 3D structures which closely mimic early human brain development *in vitro*. RTT organoids have been generated for selected mutations and undergo a detailed characterization. In RTT 3D models we are also validating the infection efficiency of the available chimeric AAV7m8 virus that has been chosen for the *in vitro* experiments.

In addition, NGS analysis in RTT fibroblasts obtained from *MECP2* patients demonstrated a high editing efficiency, in particular up to 90% and 72% of HDR for R306C and for R168X variants respectively. We tested also AAV7m8 in iPSC-derived neurons with T158M and evaluated HDR efficiency. However, these viruses are still far from optimal since a significant portion spreads to peripheral organs reducing the efficiency of the approach and increasing the risk of toxic effects. For this reason, new chimeric serotypes with higher specificity and selectivity have been designed and are currently under characterization.

Finally, mouse model colonies harbouring 3 variants have been generated to further test the approach *in vivo*. A behavioural phenotyping pipeline has been defined and allowed us to characterize the clinical features in our conditions. One of these variants will be used in combination with the most promising AAV vector to evaluate the rescue *in vivo*.

Our work will represent a real opportunity for the application of gene therapy for RTT, thus providing the first real possibility for an RTT therapy.

268 **Humanization of the mouse telomerase reverse transcriptase gene reset telomeres to human length** Fan Zhang, De Cheng, Suwen Wang, Jiyue Zhu College of Pharmacy and Pharmaceutical Sciences, Washington State University

Telomeres shorten with each cell division and eventually cause replicative senescence, serving as a biomarker of human aging. Mice, however, have excessively long telomeres and exhibit widespread telomerase activity, which constrains their utility as models for human diseases and longevity. To overcome this challenge, we genetically engineered a humanized version of the mouse telomerase reverse transcriptase gene, *Tert* $^{(tm1\ (TERT)Jzhu)}$ (*hmTert*) in embryonic stem cells, by replacing the 5' intergenic region, introns 2 and 6 of the mouse *Tert* gene with human counterparts that contained multiple known regulatory elements of the human *TERT* gene. Mice with a germline *hmTert* gene were generated and bred in the C57BL/6J genetic background. The *hmTert* gene, encoding the unaltered mouse TERT protein, was repressed in most adult tissues and only expressed in gonads and a limited subset of immune cells, mimicking the regulation of the human *TERT* gene. The *hmTert* gene rescued telomere dysfunction in late generations of *mTert*-knockout mice. Through successive intercrosses of B6;129S6-*Tert*$^{tm1(TERT)Jzhu}$ mice, telomere length decreased progressively and eventually stabilized at an average length below 10 kb. The *Tert*$^{h/h}$ mice acquired an average 10-12 kb telomere length resembling that of humans, in contrast to the over 50-kb average telomere length found in C57BL6J mice. Despite having very short telomeres and no telomerase in most adult tissues, these mice

displayed normal body weight and maintained cellular homeostasis in high-proliferative tissues, including testes, intestine, and bone marrow. Our data demonstrate that humanizing the regulation of the mouse*Tert* gene resets mouse telomeres to human lengths. This transformation provides mice with humanized telomere homeostasis and a promising model to explore essential aspects of human aging and cancer.

269 **A missense mutation in *Birc6* causes dwarfism in mice** Julie Ruston[1], Zachary Klugman[1,2], Danilo J Shevkoplyas[1], Monica J Justice[1,2] [1]Genetics and Genome Biology, Hospital for Sick Children, [2]Molecular Genetics, The University of Toronto

Our lab identified a mouse line with a small size phenotype in a dominant N-ethyl-N-nitrosourea (ENU) mutagenesis screen for suppressors of the phenotype in methylCpG binding protein 2 (*Mecp2*) mice. Sequence analysis found a missense mutation in a highly conserved arginine in Baculoviral inhibitor of apoptosis repeat-containing 6 (*Birc6)*, a member of the inhibitor of apoptosis protein (IAP) family. BIRC6 plays a role in inhibiting apoptosis, but has been implicated in additional molecular pathways including autophagy, cell cycle regulation and the DNA damage response. Homozygotes for a null allele die at birth due to placental failure, yet heterozygotes for a null allele are normal in size. The causative nature of the lesion was confirmed using CRISPR/Cas genome editing to engineer an identical allele, which also has a dominant small size phenotype. *Birc6*$^{Sum20\text{-}Jus}$/+ mice are smaller than littermates from mid-gestation through adulthood. At three months, the mice are approximately 50% of the size of their wild type littermates, exhibiting proportional dwarfism with pathological changes in bone, thyroid and pituitary. IGF1, but not growth hormone (GH) is decreased, and the mice have primary hypothyroidism (high TSH, normal T4). Tandem mass tag (TMT) spectrometry quantification of proteins in the brain links BIRC6 mutation to perturbations in cell cycle and metabolic pathways. Together, our data suggest that mutations in BIRC6 cause a dominant small stature phenotype due to signalling anomalies that perturb the endocrine pathway. An association between *Birc6* and dwarfism has not been previously reported; therefore, this work identifies a new model of proportional dwarfism and a new function for BIRC6.

270 **The host-transposase fusion *THAP7* is a transcription factor implicated in vertebrate development and human intellectual disability** Rachel L Cosby[1], Jennifer Sinclair[1], Catrina Rateb[1], Steven Gay[1], Lisa Kratz[2], Jennifer Panlilio[1], Alban Ziegler[3], Fowzan S Alkuraya[4], Harold A Burgess[1], Todd S Macfarlan[1] [1]National Institute of Child Health and Human Development, [2]Kennedy Krieger Institute, [3]Centre Hospitalier Universitaire d'Angers, [4]KFSHRC

Transcription factors (TF) and their networks can evolve via fusion between host- and DNA transposase-derived protein domains. Several host-transposase fusions have been implicated in vertebrate development and developmental disorders, but the function of most remain unknown. We identified homozygous and compound heterozygous missense variants in human *THAP7*, a TF derived from a *P*-element-like transposase fusion, which segregate with intellectual disability in two families, suggesting *THAP7* regulates neurodevelopment. To determine THAP7 function in development, we generated THAP7 mutant mice and zebrafish using CRISPR technology. We demonstrate that *Thap7* null mice are viable, with males displaying subtle but significant impairments in working memory and contextual learning, while females display deficits in spatial and contextual learning. Thus, *Thap7* null mice partially recapitulate the human phenotype.

In contrast, *thap7* null zebrafish died shortly after juvenile stages and were significantly smaller than their WT siblings. Using RNAseq and ChIPseq, we found that Thap7 binds the promoters of the glutaryl-CoA dehydrogenase a and b (*gcdha/b*) genes, whose expression is silenced in *thap7*$^{-/-}$ larvae. Human GCDH deficiency causes glutaric acidemia type I (GA1), where glutaric acid (GA) accumulation leads to striatal neuron degeneration and death. We hypothesized that downregulation of *gcdha/b* leads to GA accumulation and subsequent growth impairment and death of *thap7*$^{-/-}$ fish. Using mass spectrometry, we found that *thap7*$^{-/-}$ larvae have ~7 fold higher GA and detectable 3-hydroxy glutaric acid (3-OH-GA) compared to their sibs, suggesting that *thap7*$^{-/-}$ fish die due to GA1-like symptoms.

The disparate phenotypes between fish and mammals suggested that THAP7's function may have diverged in vertebrates. We performed THAP7 ChIPseq in juvenile mouse brains and mouse (mESCs, 3T3, Neuro2a, and GC1), human (293T, K562, HepG2), and zebrafish (ZFL) cell lines to identify THAP7 target genes. We found that while THAP7 binds a significant number of gene promoters in two or more species (n=1679, ~50%), it also binds some promoters in only one cell type or species. Conserved THAP7 targets are enriched for fundamental housekeeping processes including RNA processing and cell proliferation, whereas zebrafish specific THAP7 targets are enriched for developmental processes such as organ development and morphogenesis (Biological Process GO), consistent with the more severe developmental phenotype seen in fish. Our results suggest that, while THAP7's molecular function as a TF is preserved, its biological function has diverged between fish and mammals. Our research underscores THAP7's role in vertebrate development and human intellectual disability, and elaborates on the origin and function of host-transposase fusion genes.

271 **Defects in maternal LSD1/KDM1A reprogramming may contribute to phenotypes observed in human neurodevelopmental disorders** Carrie Eilleen Falkenberry[1], Monica Reeves[2], Rhea Rastogi[2], Alyssa Scott[2], David John Katz[2] [1]Cell Biology at Emory University, Emory University, [2]Cell Biology, Emory University

The lysine demethylase 1A (LSD1/KDM1A) is an epigenetic reprogramming enzyme that removes H3K4me1/2 and is required maternally for proper development in *C. elegans* and mice. Complete knockout of maternal KDM1A in mice results in embryonic arrest at the 2-cell stage due to failure to shut off maternal genes during the maternal to zygotic transition. This finding led us to consider the possible roles of maternal KDM1A in inherited disease. To study this, we developed a hypomorphic *Kdma1a* allele (M448V) in mice that decreases the ability of KDM1A to bind to RCOR1/2(CoREST), resulting in inefficient demethylation. When KDM1A reprogramming is partially compromised only maternally, progeny show a high rate of perinatal lethality, developmental delay, craniofacial abnormalities and abnormal behavior. Three of these phenotypes, developmental delay, craniofacial abnormalities and abnormal behavior, are also observed in KDM1A patients and in patients with the related Kabuki Syndrome. This raises the possibility that maternal defects could contribute to these diseases. To take an initial look at what changes might be inherited when KDM1A is hypomorphic maternally, we also performed RNAseq in progeny at embryonic day 13.5 (e13.5). Despite the fact that these embryos showed no obvious phenotypes, the overall gene expression changes can be distinguished by maternal genotype. This suggests that failure to completely reprogram KDM1A maternally in the oocyte can result in heritable genes expression changes in the progeny. Intriguingly, using gene ontology analysis, we observe that mammalian phenotypes associated with the genes that are significantly upregulated in our RNAseq analysis include decreased body weight/postnatal growth retardation and preweaning lethality, both of which we observe later in development in the progeny of mothers with maternally compromised KDM1A reprogramming. This hints that genes that may be causing the perinatal lethality and developmental delay may already be starting to be misexpressed at e13.5 272 **Chance, individuality, and phenotypic variation in health and disease** Joseph Nadeau[1], Andrew Pospisilik[2] [1]Maine Medical Center, [2]Van Andel Institute

What if our ideas about phenotypic variation overlook a primary determinant? Fisher's century-old variance model, Phenotype V_P = genetics V_G + environment V_E + error V_e, guides many areas of biological research. But substantial phenotypic variation is not represented in this model. On average 50% of variability is neither genetic nor environmental. We propose that considerable non-G and non-E variation emerges during development, arising from stochastic noise that triggers probabilistic epigenetic changes that once established are stable and deterministically propagated throughout life. These epigenetic changes lead to wide variation in phenotypic outcomes across many traits, in many species, and in health and disease. Individuality emerges from this interplay between genes, environment and chance. A deep understanding of organismal biology and the goals of Precision Medicine depend on discovering the mechanistic origins and systems properties of this surprisingly pervasive and strong but generally neglected dimension of phenotypic variation. I will share evidence and arguments about chance as a primary driver of non-G non-E phenotypic variation, propose an *'accidental individuality'* model, and suggest a phenotype-driven strategy to improve diagnosis and treatments for disease involving a virtuous cycle of discovery, experiments and translation between model organisms and humans.

273 **The nonsense-mediated mRNA decay pathway degrades regulatory non-coding RNAs** David J Young, Nicholas R Guydosh Laboratory of Biochemistry and Genetics, NIDDK/NIH

The nonsense-mediated mRNA decay (NMD) pathway targets mRNAs undergoing premature translation termination for degradation, including nonsense alleles associated with human disease. One potential therapeutic approach for such cases involves stabilization of the mRNA via pharmaceutical suppression of NMD and induction of stop codon readthrough. It is therefore important to understand the natural role of NMD in the cell. RNA-seq of yeast lacking NMD surprisingly revealed that >80% of genes targeted by NMD appear to lack obvious premature termination codons (PTCs). One possible explanation for this targeting is that translation of cryptic open reading frames (ORFs) results in widespread premature termination events. To test this hypothesis, we developed a combined approach using RNA-seq to identify transcript isoforms targeted by NMD and a novel 40S ribosome profiling strategy to find the boundaries of cryptic ORFs by using peaks on start and stop codons. We identified novel translation events on approximately three quarters of the targets that initially appeared to lack PTCs. Interestingly, most of these cryptic events occur on non-coding RNA (ncRNA) transcript isoforms. Many of them appear to have regulatory roles in two-promoter systems and share properties with long un-decoded transcript isoforms (LUTIs). Transcription of LUTIs has been shown to repress the canonical gene promoter through repressive chromatin marks. We found these LUTI-like transcripts generally encode multiple 5' upstream ORFs (uORFs) that often trigger NMD. These LUTI-like transcripts have roles in many metabolic pathways, for example nitrogen sensing where they are poised to regulate expression of *DAL5, DAL7*, and other genes. Elimination of uORFs in the *DAL5* and *DAL7* LUTI-like transcripts resulted in their stabilization, thus confirming that termination events at 5' uORFs sensitize these transcripts to NMD. We also inserted a sequence that induces transcription termination into the *DAL5* LUTI-like transcript and observed derepression of a short *DAL5* transcript that originates from a downstream promoter. This confirms that transcription from the *DAL5* LUTI-like promoter inhibits the downstream canonical promoter. The ncRNAs produced from these LUTI-like promoters are a novel class of NMD substrates. Furthermore, NMD is critical for removing these repressive regulatory mRNAs from the cytoplasm of the cell, potentially to prevent unproductive translation and the synthesis of toxic peptides.

274 **Understanding the mechanisms controlling deposition and interplay of co-transcriptional nucleosome modifications** Tasniem Fetian, Brendan M McShane, Karen M Arndt Biological sciences, University of Pittsburgh

The wrapping of eukaryotic DNA around histones to form nucleosomes allows efficient DNA packaging but presents a barrier to proteins that perform DNA-templated transactions. Multiple regulatory mechanisms have therefore emerged to modulate nucleosomal properties and DNA accessibility. Monoubiquitylation of H2B (H2Bub) on K123 in budding yeast (K120 in humans) is a dynamic co-transcriptional histone modification that modulates chromatin on structural and functional levels. In yeast and higher eukaryotes, the Paf1C transcription elongation factor is required for H2Bub and facilitates its coupling to transcription. A small domain within the Rtf1 subunit of Paf1C, named the Histone Modification Domain (HMD), directly interacts with the multi-functional ubiquitin conjugase Rad6 leading to H2Bub stimulation both in vivo and in vitro. To understand how Rad6 is recruited to its histone substrate, we employed a multi-faceted approach to identify the site of HMD interaction within Rad6. By combining genetic, biochemical, and genomic approaches, we characterized separation-of-function mutations in *S. cerevisiae RAD6* that disrupt the Rad6–HMD interaction and hence H2Bub, while other functions of Rad6 are largely unchanged. Mutating either side of the proposed Rad6–HMD interface results in virtually indistinguishable transcriptome profiles as measured by RNA-seq. Our results promote a model in which a highly specific Rad6-HMD interface selectively targets Rad6 to its nucleosomal substrate during transcription. While the molecular events that couple H2Bub to transcription are now coming into focus, the direct contributions of this conserved modification to transcription and its coordination with other epigenetic modifications remain to be fully elucidated. Previous studies revealed a synthetic lethal relationship between H2Bub and H2A.Z, the H2A histone variant that is enriched at the +1 nucleosome of genes. However, it is unclear how these two epigenetic modifications are coordinated and why cells lacking one of the two are so dependent on the other for viability. Our ongoing genetic and genomic experiments are directed towards investigating the impact on the transcriptome upon the concurrent loss of H2A.Z and H2Bub and pinpointing mechanisms that are responsible for the synthetic lethality.

275 **Insights into yFACT-gene interactions and the mechanisms underlying a human developmental disorder through analyses of histone mutants in yeast** Andrea A Duina, Alex Pablo-Kaiser, McKenzie G Tucker, Grace A Turner, Elijah G Dilday, Avery G Olmstead, Caroline Tackett, Rose Johnson, Shelby Worsham, Joey Beard, Reece Forrest, Lillian Francis, Will Griffin, Agustin Kalinowski, Jackson Parks Biology Department, Hendrix College

In previous work in yeast, we identified a region of the nucleosome whose integrity is required for proper interactions between the histone chaperone complex yFACT and genes. More specifically, mutations within this region, which we refer to as ISGI (Influences Spt16-Gene Interactions), cause a shift in the distribution of yFACT toward the 3' ends of transcribed genes, an effect that we have attributed to impaired yFACT dissociation from genes following the transcription process. Interestingly, an arginine substitution at the ISGI residue H3-L61 within the human histone H3.3 protein (H3.3 L61R) has recently been shown to be associated with a novel neurodevelopmental condition in humans called Bryant-Li-Bhoj syndrome, raising the possibility that our work in yeast may provide insights into this condition.

In this presentation, I will first describe preliminary results from ChIP-seq experiments that suggest that ISGI mutants interfere with proper yFACT dissociation from genes at the genome-wide level in yeast. I will then present data in support of the notion that the defects seen in yFACT-gene dissociation due to expression of H3-L61R in yeast may be informative in the understanding of the molecular defects underlying the Bryant-Li-Bhoj syndrome in human patients. Finally, I will discuss ongoing experiments to assess the functional defects caused by additional amino acid substitutions identified across the human H3.3 protein that are also associated with the Bryant-Li-Bhoj syndrome using yeast cells as model system. Overall, our work is providing further insights into the impact of ISGI mutants on yFACT-gene interactions across the yeast genome and into the molecular defects caused by histone mutants that have been implicated in a neurodevelopmental condition in humans.

276 **Regulation of heterochromatin formation and mRNA export via potential targets of Dsk1 and Kic1 kinases** Aditi Vyas[1], Anna Freitas[1], Zachary Ralston[1], Margaret Nurimba[1], Xiaojing Yang[2], Chao Tang[2], Bashar Alhoch[1], Peter Zang[1], Camille Ylagan[1], Alanna Sugarman[1], Zhaohua Tang[1] [1]W. M. Keck Science Department, Claremont McKenna College, Scripps College and Pitzer College, [2]Center for Quantitative Biology, Peking University

Dsk1 and Kic1/Lkh1 are LAMMER-related kinases and while members of this kinase family have been previously identified as important regulators of cellular function with roles in mitotic cycle, differentiation and cellular development, the complex biological functions and molecular targets through which these kinases regulate cellular pathways remain unclear. Our previous research suggests that Dsk1 and Kic1 kinases play a role in heterochromatin formation and nuclear export of mRNA. To investigate possible functions of the kinases, we performed a genome-level epistasis assay. Rresults from that screening provide strong evidence for genetic interaction between Dsk1 kinase and components of the DASH complex - a complex of kinetochore associated proteins. This data, combined with the results from a functional heterochromatin silencing assay, and the similarity in nuclear localization between Kic1 and Swi6/HP1 implicate the role of both, Dsk1 and Kic1, in centromere

heterochromatinization. Additionally, GFP-tagged Swi6 protein molecules appear mildly delocalized to the cytoplasm in the kinase-deletion strains. Immunofluorescence analysis in WT cells confirms the co-localization of GFP-Kic1 with Swi6 in the nucleus, supporting the notion of a functional relationship between Kic1 and Swi6. Another line of experiments uncovered a role of the Dsk1 and Kic1 kinases in nuclear export of mRNA, independent from the known role of the kinases in mRNA splicing. Results from a biochemical investigation also identified the Poly(A) binding protein (Pabp) in a physical complex with Dsk1. Using Pabp-GFP tagged strains we have been able to confirm that while the WT strains exhibit a ubiquitous Pabp protein distribution through the cellular cytoplasm and nucleus, the kinase deletion strains display a higher nuclear retention pattern of Pabp molecules. Consistently, results from FISH assays show some degree of nuclear retention and co-localization of the global mRNA population with the Pabp protein molecules in the kinase-deletion strains. Moreover, western blot analysis reveals a reduction of total Pabp protein in the *dsk1-* and *kic1-* deletion strains when compared to WT. Our results, taken together, indicate that Dsk1 and Kic1 may exert their effect on centromeric heterochromatinization via Swi6/HP1 protein and affect mRNA export through modulating Pabp protein stability and cellular localization.

277 **Allelic variation in codon bias and mRNA folding stability act on transcript abundances, translation, and protein abundances via both shared and distinct mechanisms in yeast** Daniel A Pollard[1], Anastacia Wienecke[2], Maggie Barry[3], Nadine Tietz[4] [1]Biology, Western Washington University, [2]University of North Carolina, [3]University of Oregon, [4]Western Washington University

Heritable variation in protein abundance is a major driver of trait variation and yet the mechanisms by which polymorphisms in gene transcripts act on transcription, mRNA stability, translation, and protein stability are not well resolved. Properties of transcripts such as usage of codons with more abundant cognate tRNAs (codon bias) and mRNA folding strength (mF) are strongly implicated factors, and yet the specific mechanisms of their actions and how they interact with each other, and other properties of transcripts, are open questions for the field. Using RNAseq and mass spec data for 22 Saccharomyces cerevisiae isolates, we examined the association of polymorphic transcript properties with transcript abundance (TA), protein abundance (PA), and their ratio PA/TA for more than a thousand genes with linear mixed-effect models. We found that allelic variation in codon bias is positively associated with logTA, log(PA/TA), and logPA, consistent with slow translational elongation destabilizing transcripts. However, allelic variation in mF is negatively associated with logTA but positively associated with log(PA/TA) and logPA, suggesting structure may destabilize transcripts while also enhancing either translation or protein stability through unknown mechanisms. Despite the negative association between mF and logTA, we found that the interaction between codon bias and mF is positively associated with logTA, log(PA/TA), and logPA, suggesting a joint mechanism between codon bias and mF and a duel role for mF on TA. We next asked if the location in the transcript for a polymorphic codon or a polymorphic stem loop structure alters its effects. Codons throughout the CDS acted on logTA but only codons in domain encoding regions and near the 3' end of the CDS acted on log(PA/TA) and logPA, implying distinct mechanisms for codon bias acting on transcript stability and translation elongation. mF across the CDS consistently acted on logTA, log(PA/TA), and logPA, while mF just before the start codon impacted logTA and mF in 3' UTRs impacted log(PA/TA) and logPA, further supporting both shared and distinct mechanisms for mF acting at the transcript and protein levels. Our results present the most comprehensive characterization to date of how polymorphisms in transcripts influence protein expression.

278 **Modularizing the budding yeast transcription factor repertoire** Daniel T. Lusk, Zachary Krieger, Alessandro L.V. Coradini, Yiwei He, Chenghao Du, Cara B Hull, Nicolette E. Romo-Zelada, Oscar M. Aparicio, Ian M. Ehrenreich Department of Biological Sciences, USC

Natural genomes are disorganized, with functionally related genes typically spread across many chromosomes. This disorganization can make it difficult to study how sets of genes collectively give rise to cellular life and its diversity. Synthetic genomics approaches can be used to reorganize functionally related genes into modules, thereby producing organisms with simplified genomes that facilitate basic research and biotechnology. Such modularization is challenging because it requires building a neochromosome containing a set of functionally related genes and deleting the endogenous copies of these genes from their native loci. As a proof-of-principle for how to modularize many functionally related genes, we are producing a strain of the budding yeast Saccharomyces cerevisiae with nearly all ~200 RNA polymerase II-interacting transcription factors relocated to a synthetic neochromosome. This involves de novo synthesis of the transcription factor neochromosome and highly multiplexed deletion of endogenous transcription factor copies by CReATiNG (Cloning, Reprogramming, and Assembling Tiled Natural Genomic DNA), a method we recently developed to build synthetic chromosomes from natural DNA. I will present the prototyping of our modularization strategy with Chromosome XVI, a roughly megabase sized chromosome containing ~20 transcription factors. I will also describe how our approach will be extended to the rest of the genome.

279 **The fourth zinc finger is a negative regulator of yeast transcription factor Fzf1** Ying Du, Wei Xiao Biochemistry, Microbiology and Immunology, University of Saskatchewan

A *Saccharomyces cerevisiae* transcription factor Fzf1 contains five Cys_2His_2 zinc finger domains and regulates at least five genes in response to diverse chemical stresses. *DDI2* and *DDI3* are duplicated genes that encode cyanamide hydratases and are induced by cyanamide; *SSU1* encodes a plasma membrane protein to efflux and reduces sulfite toxicity; *YHB1* encodes a dioxygenase and is induced by nitric oxide, while *YNR064c* encodes an epoxide hydrolase. Fzf1 coordinately regulates these genes through binding to a promoter consensus sequence CS2 using its N-terminal three zinc fingers (ZF1-3), while how ZF4 and ZF5 function remains unknown. Interestingly, amino acid substitutions in ZF4 including C157S, C162S and H180D have been reported to confer either sulfite resistance or increase basal-level *YHB1*expression, suggesting that Fzf1-ZF4 serves as a negative regulator. To test this hypothesis, we created yeast strains with these ZF4 point mutations and conducted cell survival and qRT-PCR assays to assess sodium sulfite resistance and Fzf1 downstream gene expression. These *fzf1-ZF4* mutants exhibited increased resistance to sodium sulfite compared to wildtype and *fzf1Δ* cells, and this resistance is dominant over wildtype *FZF1*. All *fzf1-ZF4* mutants displayed increased basal-level expression of *FZF1* downstream genes, and the degree of sodium sulfite resistance was highly correlated to *SSU1* transcript levels. A ZF4 international deletion mutant *fzf1-ΔZF4* behaved similarly as *fzf1-ZF4* point mutations, while Fzf1-ZF1-3 alone does not appear to support sodium sulfite resistance or its downstream gene expression, indicating that ZF5 plays a role in maintaining Fzf1 regulatory functions. In an EMSA assay, purified Fzf1 and Fzf1-ΔZF4 displayed comparable affinities for the target CS2 sequences, indicating that in the absence of relevant chemical stress, ZF4 inhibits Fzf1 activation instead of affecting its binding to the target CS2s.

280 **The Sex of the Fat Body is a Locus of the Sex Difference in Reproductive and Ingestive Response to Energy Deficits** Attilio Ceretti, Jill E Schneider Biological Sciences, Lehigh University

There are sex differences in the reproductive and ingestive responses to energy deficits in many species (reviewed by Schneider et al., 2013), but the loci of these sex differences remain unknown. In previous experiments using Drosophila melanogaster, we found that copulation rate is decreased and time spent with food is increased after food deprivation (FD) in females, but the same traits were significantly less affected by the same level of FD in males. Next we asked whether these sex differences could be prevented by masculinizing particular tissues. We used RNA-interference (RNAi) for the Tra2 gene to masculinize only the nervous system, only the fat body, or all cells in 2X:2A flies. Global masculinization of all cells in the 2X:2A flies masculinized courtship behavior and the reproductive response to FD. Masculinization of only the nervous system fully masculinized courtship behavior, but did not masculinize the ingestive and reproductive responses to FD. The females with masculinized nervous systems significantly decreased courtship rate compared to fed females and males (FD or fed) ($P < 0.01$), and displayed female levels of FD-induced time with food compared to male controls ($P < 0.01$). By contrast, masculinization of the fat body masculinized the reproductive and ingestive response to FD. The 48-h FD females (2X:2A) with masculinized fat bodies showed no significant decrease in copulation rate compared to fed controls, and decreased FD-induced time spent with food compared to female controls and FD males from the same background ($P < 0.01$). Thus, our genetic manipulation of the fat body successfully masculinized the reproductive response to energy deficits of the 2X:2A females. In wild-type females, the availability of oxidizable glucose was both necessary and sufficient for normal copulation rate. We hypothesize that the female-typical response to energy deficit lies outside the nervous systems, perhaps in insulin signaling controlled by the fat body.

281 **Sexual dimorphism in tumor growth requires innate immune cells from the tumor microenvironment and systemic regulation** Xianfeng Wang[1], Hongcun Bao[2], Anindita Barua[2], Yi-Chun Huang[2], Fei Cong[2], Wu-Min Deng[2] [1]Department of Biochemistry and Molecular Biology, Tulane University School of Medicine, [2]Tulane University School of Medicine

Cancer is a systemic disease that impacts the entire body. While interactions between cancerous tissue and other tissues have been observed for a long time, the exact mechanisms by which cancer cells communicate with other tissues to induce systemic effects are still not well understood. Furthermore, many types of cancer exhibit sexual dimorphism in terms of growth. However, the systemic-level mechanisms underlying such dimorphic regulation remain poorly characterized. Using a *Drosophila* tumor model in which Notch signaling is constitutively activated in a transition zone (TZ) of larval salivary gland (SG) imaginal ring (ImR), we found that tumors from female TZ tumors grow up to 2.5 times as large as the male tumors. Notably, wildtype SG ImRs do not exhibit sexually dimorphic growth during development. Our results reveal that the JNK pathway is the key factor causing sexual dimorphic in tumor growth. Leveraging single-cell RNA sequencing, we identified Eiger, a ligand of the JNK pathway originating from hemocytes. Knocking down Eiger in hemocytes led to a reduction in tumor size and sexual dimorphism. Further investigations have demonstrated found Upd2, a cytokine and leptin orthologue, as a downstream target of the JNK pathway, and it is upregulated more significantly in female tumors than male tumors. Tumor size, as well as sexual dimorphism, is reduced when upd2 is decreased in the tumor. Moreover, we demonstrated that the tumor produced Upd2 mimics the adipose tissue derived Upd2, systemically regulates tumor growth through the Dilp2/Insulin pathway. In summary, our findings reveal that the tumor microenvironment, involving hemocytes, underlies sexual dimorphism and the systemic regulation of tumor growth.

282 **Evolutionary and Functional Characterization of Female Control of the Mating Plug in *Drosophila melanogaster*** Jolie

A Carlisle, Rachel M.J. Craig, Nora Brown, Bianca M. Villanueva, Mikaela Matera-Vatnick, Andrew Clark, Mariana F. Wolfner Molecular Biology and Genetics, Cornell University

In many species males transfer seminal fluid proteins (Sfps) and sperm to their mates. Some Sfps are known to mediate essential reproductive processes such as female sperm storage and allow males to exert control over mating outcomes. However, from mammals to invertebrates, females are also known to exert control over their reproduction. In *Drosophila*, females can manipulate the parental contributions of their partners through molecularly controlling the number of sperm stored from a given mating, a likely regulator of this process being the *Drosophila* mating plug (MP). The MP is composed of Sfps, and some female-derived proteins, that coagulate in the *Drosophila* female reproductive tract. Rapid ejection of the MP prevents sperm retention, while delayed ejection of the MP increases the number of sperm that can be stored. Male x Female interactions mediating timing of MP ejection (MPE) are a likely focal point of sexual conflict over control of paternity outcomes.

Using the genetic variation present in the DGRP, we observed that within *D. melanogaster* there are dramatic differences in female MPE timing (>2 fold). We applied a GWAS design to identify both neuronal and oogenesis genes as candidates mediating female MPE. Using flies lacking a germline, we determined that lack of egg production causes delays in MPE, indicative of a connection between female fecundity and sperm storage. Furthermore, using publicly available single-cell atlas of the fly brain and network analysis, we determined that most of our neuronal gene candidates are part of networks that regulate sex-specific behaviors and development . Using RNAi we have validated many of these neuronal candidates' roles in regulating female MPE.

Female-derived MP proteins may also contribute to timing of MPE. We have investigated the evolution of these proteins and discovered that many male and female MP genes are closely paralogous to each other and predicted to interact via rapidly evolving interfaces, suggestive of evolution under sexual conflict. We have traced the evolution of protein families containing these paralogous male and female reproductive proteins and begun to investigate their function. Together our work uses variation between and within *Drosophila* species to investigate the molecular and behavioral mechanisms mediating female control of the mating plug.

283 **Identification of female ovulation-regulating membrane receptors/proteins in *D. melanogaster*** Mengye Yang[1], Melissa White[1], Jennifer Apger-McGlaughon[1], Geoffrey Findlay[2], Ryan Vignogna[1], Christopher Fromme[1], Mariana Wolfner[1] [1]Cornell University, [2]College of the Holy Cross

Female post-mating responses (PMRs), including increased ovulation, are initiated by male seminal fluid proteins (Sfps) and then manipulated by female pathways and molecules. The implementation of the PMR's large-scale homeostatic changes is complicated, requiring the coordination of multiple tissues, including inter-organ signaling between the nervous system, midgut, fat body, and ovary. Ovulation is the process of releasing mature oocytes from the ovary to the uterus, through the oviduct. A male Sfp ovulin stimulates ovulation by activating female octopamine (OA) neuronal signaling in the hours following mating. Despite the key role OA signaling plays in the ovulation regulation, the broader landscape of female molecular mechanisms governing ovulation remains largely unexplored. Here, we aim to identify female membrane receptors and proteins affecting ovulation to elucidate novel signaling pathways involved in ovulation mediation, and significantly advance our understanding of the complex orchestration of ovulation as well as the reproductive dynamics in *Drosophila melanogaster*.

Using male protein ovulin as a probe, we performed evolutionary rate co-variation screens and AlphaFold-Multimer prediction screens to identify ovulation-regulating protein candidates. We narrowed down the candidate list to twelve strong receptors/proteins based on their effect on egg-laying and/or their expression pattern. Subsequent ovulation assays were performed to examine the ovulation rate in female flies subjected to knockdown or depletion of these candidates, shedding light on their potential roles in ovulation and determining if they act through ovulin. For strong candidates displaying neuronal expression, we investigated whether they are expressed in the female reproductive tract neurons using a Gal4 driven by their endogenous promoters, and also carried out pan-neuronal knockdown as well as specific octopaminergic Tdc2 neuronal knockdown of these proteins to ascertain their action location. To date, we have identified five novel female ovulation-regulating proteins with ovulin-dependent or ovulin-independent roles, several of which are required in Tdc2 neurons to influence ovulation.

284 **Structure-expression analysis of different-sized tandem duplicates of the *Alcohol dehydrogenase* locus in *Drosophila melanogaster*** Matt Seltzer, David Loehlin Biology, Williams College

Tandem gene duplicates are important parts of eukaryotic genome structure, yet the phenotypic effects of new tandem duplications are not well-understood. Previous work suggests that tandem duplications containing an entire gene do not always simply double that gene's expression. This study aims to identify factors that influence tandem duplicate expression by comparing multiple duplicates of the same gene produced from a variety of endpoints. Two hypothesized factors of primary interest are 1) cis-regulatory elements, which could influence expression depending on the sequence content of the duplicated

block, and 2) gene proximity, which would depend on size but not sequence content of the duplicated blocks. We apply a new method, Recombinase-Mediated Tandem Duplication (RMTD), to precisely duplicate the *Alcohol dehydrogenase* (*Adh*) gene in *D. melanogaster*, by pairing 5 left-side and 5 right-side breakpoints. We report preliminary analysis of expression (ADH enzyme activity) from flies with ~20 different tandem duplicate blocks. Expression appears to vary primarily with presence/absence of upstream segments in the duplicated block, suggesting a role of undocumented regulatory sites. Accounting for this variation indicates a possible additional role for distance-dependence of gene expression beyond sequence content.

285 **What vs. When: Determining functional differences between canonical histone H3.2 and variant histone H3.3 in post-mitotic cells** Jeanne-Marie E McPherson[1], Robert E Duronio[2], Daniel McKay[2] [1]Genetics, University of North Carolina at Chapel Hill, [2]Genetics, Biology, University of North Carolina at Chapel Hill

Histone proteins organize DNA into chromatin, which regulates all DNA-dependent processes. The genome encodes two types of histones: canonical histones that are expressed only during S-phase, and variant histones that are expressed throughout the cell cycle. Canonical histone H3.2 and variant histone H3.3 are some of the most highly conserved proteins among eukaryotes, suggesting that each histone type performs unique functions. Despite this conservation, it is not known if variant H3.3 function is mediated by its unique protein sequence or by its cell-cycle independent expression. Canonical H3.2 and variant H3.3 differ by just four amino acids. Three of these residues mediate interactions with histone chaperones and thus influence where H3 types are deposited in the genome. The fourth residue at position 31 can be post-translationally modified on H3.3, and this phosphorylation has been linked to gene regulation. To uncouple H3 protein identity from timing of expression, we generated *D. melanogaster* CRISPR mutants that express H3.2 from the endogenous *H3.3* genes ($H3.3^{H3.2}$). Because the adult brain is primarily composed of post-mitotic neurons that accumulate replication-independent histones, we examined the effects of $H3.3^{H3.2}$ mutations on adult behavior and genome organization in brains. We found that $H3.3^{H3.2}$ mutants have reduced lifespan and behavioral defects. Notably, these defects are rescued by expressing one copy of wild-type *H3.3,* indicating that the H3.3 protein is required for normal post-mitotic cell function. Mutation of the H3.3-specific residue S31 had no impact on lifespan and mild behavioral defects, demonstrating that loss of S31 is not the main driver of $H3.3^{H3.2}$ mutant phenotypes. An important corollary to this finding is that interactions between each histone type and their respective chaperones are critical for normal genome function. To understand how these interactions impact genome organization, we performed ATAC-seq in 1-day and 10-day old $H3.3^{H3.2}$ and $H3.3^{S31A}$ mutant brains. We found that although overall patterns of chromatin accessibility do not substantially change in either mutant at either age, quantitative differences in accessibility are detectable at many locations. We are testing whether these changes in chromatin accessibility affect gene expression. Our work is revealing how histone type contributes to control of genome function.

286 **Impact of *de novo* transposition events on the 3D nuclear architecture and sequence structure of telomeres and centromeres in multigenerational heat-shock lines of *Drosophila melanogaster*** Ryan Pellow[1], John Atagozli[1], Josep Comeron[1,2] [1]Department of Biology, University of Iowa, [2]Interdisciplinary Program in Genetics, University of Iowa

Transposable elements (TEs) make-up a substantial portion of most eukaryotic genomes. These “jumping genes” or transposons are key drivers of evolutionary innovations and adaptations, often as a result of their functional motifs altering gene regulatory programs. Advances in chromosome conformation capture methodologies (e.g., Hi-C) have also allowed detecting significant associations between TE presence and the looping mechanisms of chromatin which in turn shape the 3D nuclear organization. The ability to capture the impact and dynamics of TEs on genomic properties, however, is limited by the difficulty to capture *de novo* insertions and characterize the before-and-after in the same genetic background. To address this challenge, we have generated long-term heat-shock mutation accumulation lines (HSMAL) from different isogenic strains of *Drosophila melanogaster*, where virgin 2-day old females were exposed to moderate heat stress (36.5°C for 20 minutes) before mating. Over the course of 50 generations of heat-shock, we have performed DNA-seq (both Illumina short-read and Nanopore ultra-long read), total RNA-seq, and Hi-C. By leveraging the DNA-seq data, we have been able to generate HSMAL specific references, map *de novo* TEs and quantify transpositions bursts genome-wide. The RNA-seq data confirms transposition bursts resulting from increased transcriptional activity of specific TEs, while also highlighting the direct and indirect impacts of TE insertions on the transcriptome. We also demonstrate the ability of *de novo* TEs to both create and disrupt topologically associated domain (TAD) boundaries using Hi-C data. Finally, our NanoPore sequencing data identifies not only centromeric and telomeric sequence variation between natural strains of *D. melanogaster*, but also changes resulting from the generational heat-shock.

287 **Investigating the role of the microbiome on gonadogenesis** Taylar J Mouton, Meg Susil, Nichole Broderick Biology, Johns Hopkins University

Animal gut microbes have been shown to impact most aspects of host physiology. In humans, these microbes, or microbiome, contribute to a growing number of host disease states. However, the high complexity of the human microbiome makes it

harder to isolate variables and define mechanisms. Additionally, it is nearly impossible to study how the previous generation's microbiome status impacts their offspring and subsequent generations. Thus, model organisms, such as Drosophila melanogaster have provided a valuable tool to study host-microbiome interactions. The D. melanogaster microbiome has relatively low-complexity and the microbes can be readily cultured. Interestingly, some studies have reported that parental microbiome status can exert unexpected consequences on offspring development and physiology, spanning for multiple generations. While these studies indicate the microbiome impacts host physiology and development intergenerationally, they have attributed different bacterial strains and signaling pathways to these impacts. Therefore, it is still unknown how exactly the microbiome could be impacting early development to contribute to the faithful maintenance of processes like oogenesis and early embryogenesis. The goal of this research was to characterize the impact of the microbiome on D. melanogaster fecundity. To this aim, we've measured the fecundity of axenic or microbiome-free flies compared to conventionally reared flies that have their microbiome. We found that while the total number of eggs laid by axenic and conventionally reared female flies over a 30-day period does not significantly differ, the daily trajectory of eggs laid by conventionally reared flies to axenic flies is significantly different, with axenic flies laying more eggs than their conventionally reared counterparts as they age. Additionally, immunofluorescence data indicates that at the cellular level there are differences between gonads of axenic and conventionally reared flies. These results together demonstrate the importance of assaying a female's egg laying lifespan when assaying their fecundity, especially when comparing conventionally reared and axenically reared flies.

288 **Quantifying dynamics of optogenetic signaling activators in zebrafish embryos** Allison Saul[1], Patrick Müller[2], Katherine Rogers[3] [1]NICHD, National Institutes of Health, [2]Universtität Konstanz, [3]National Institutes of Health

Embryonic cells are thought to decode signaling intensity, duration, and dynamics to choreograph cell fate decisions. To investigate how different signaling features drive fate, we are developing optogenetic tools that use light to independently manipulate these features in transparent zebrafish embryos. Effective application of these tools requires an understanding of how optogenetically controlled signaling pathways respond to light exposure: how strongly, how quickly, and for how long? To address these questions, we are reading out optogenetically activated BMP, Nodal, and FGF signaling using western blotting or immunofluorescence staining. To avoid problematic, inadvertent light exposure during sample processing, we fix embryos to effectively "freeze" them in time prior to carrying out either assay. For the western protocol, we have adapted a method to liberate protein from fixed samples using Tris, SDS, and heat. We plan to collect samples before, during, and after light exposure to quantify the on/off kinetics of our optogenetic tools. In addition, we will expose embryos to different light intensities to determine the relationship between light intensity and signaling levels. This characterization will enable us to properly apply our tools to provide insight into how signals are interpreted by cells to choreograph differentiation and fate decisions. Funding: NIH Intramural ZIAHD009002-01 to KWR.

289 **Single-cell analysis of shared signatures and transcriptional diversity during zebrafish development** Abhinav Sur[1], Yiqun Wang[2], Paulina Capar[1], Gennady Margolin[3], Morgan K Prochaska[1], Jeffrey A Farrell[1] [1]Division of Developmental Biology, National Institute of Child Health and Human Development, National Institutes of Health, [2]Department of Molecular and Cellular Biology, Harvard University, [3]Bioinformatics and Scientific Programming Core, National Institute of Child Health and Human Development, National Institutes of Health

During development, animals generate distinct cell populations with specific identities, functions, and morphologies. We mapped transcriptionally distinct populations across 489,686 cells from 62 stages during wild-type zebrafish embryogenesis and early larval development (3–120 hours post-fertilization). Using these data, we identified the limited catalog of gene expression programs reused across multiple tissues and their cell-type-specific adaptations. We also determined the duration each transcriptional state is present during development and identify unexpected long-term cycling populations. Focused clustering and transcriptional trajectory analyses of non-skeletal muscle and endoderm identified transcriptional profiles and candidate transcriptional regulators of understudied cell types and subpopulations, including the pneumatic duct, individual intestinal smooth muscle layers, spatially distinct pericyte subpopulations, and recently discovered *best4*+ cells. To enable additional discoveries, we make this comprehensive transcriptional atlas of early zebrafish development available through our website, Daniocell. Funding: NIH Intramural ZIAHD008997 to JAF.

290 **Safe harbor landing sites for reproducible transgenesis and variant testing in zebrafish** Robert L. Lalonde[1], Harrison H. Wells[1], Cassie L. Kemmler[1], Susan Nieuwenhuize[1], Raymundo Lerma[1], Alexa Burger[1], Christian Mosimann[2] [1]Department of Pediatrics, Section of Developmental Biology, University of Colorado School of Medicine, Anschutz Medical Campus, [2]University of Colorado School of Medicine, Anschutz Medical Campus

Transgenic zebrafish strains are a major tool for biomedical research, enabling live imaging of developmental processes, cell lineage tracking, mechanistic studies, and gene variant testing in a vertebrate model *in vivo*. However, routine transgenesis in zebrafish with random DNA integration via Tol2 or I-SceI presents considerable challenges: the creation of high-quality, single-

copy transgene integrations with reproducible activity remains time-, labor-, and resource-intensive and faces unpredictable variability due to chromatin effects. Targeted vector integration into validated genomic loci using phiC31 integrase-based *attP*/*attB* sequence recombination has transformed mouse and *Drosophila* transgenesis. While phiC31 functions in zebrafish, validated genomic loci carrying *attP*-based landing or safe harbor sites validated for a wide variety of transgene constructs remain missing.

Here, using CRISPR-Cas9, we converted two well-validated Tol2-based zebrafish transgenes (*ubi:Switch*, *hsp70l:Switch*) to *attP* landing site alleles we call *phiC31-Integrase Genomic Loci Engineered for Transgenesis* (*pIGLET*). Generating reporters and effector transgenes in landing sites *pIGLETa* and *pIGLETb*, we document their suitability for broad transgenesis applications. Re-creating transgenic reporters that are highly susceptible to position effects including Cre-responsive *loxP* switches, we demonstrate that both landing sites are well-suited to predictably generate transgenes with faithful activities in different developmental cell lineages, organs, and Cre/*lox* applications. For both landing sites, we routinely achieve germline transmission of targeted transgene integrations with 50-90% efficiency, drastically reducing resources and animal numbers needed to generate individual transgenic lines. We document that phiC31-based transgenesis into *pIGLETa* and *pIGLETb* results in representative reporter expression patterns already in injected F0 embryos, enabling injection-based screening for reporter activity and germline validation such as for gene-regulatory element discovery. We show that disease-associated enhancers can be directly compared to reference enhancer activity, enabling qualitative and quantitative enhancer testing.

Altogether, our *pIGLET* landing sites with associated protocols and plasmids enable community-accessible, reproducible, and targeted transgenesis for numerous applications while greatly reducing the workload of generating new transgenic zebrafish lines.

291 **ABE-Ultramax for high-efficiency biallelic adenine base editing** Wei Qin[1], Fang Liang[2], shengjia Lin[3], Cassidy Petree[3], Kevin huang[3], yu zhang[2,2], lin li[2], Pratishtha Varshney[3], Philippe Mourrain[4], yanmei liu[2], Gaurav Varshney[3] [1]gene and human disease, Oklahoma medical research foundation, [2]South China Normal University, [3]Oklahoma Medical Research Foundation, [4]Stanford University

Advancements in repurposing CRISPR-Cas9 technology, especially the development of base editors, have fundamentally reshaped the field of genetic variant research. When paired with tractable model organisms, such as zebrafish, these base editors accelerate and improve the accuracy of *in vivo* functional analyses of genetic variations. However, base editors are restricted by protospacer adjacent motif (PAM) sequences and specific editing windows, hindering their applicability to a broad spectrum of genetic variants. They can also induce unintentional bystander mutations and tend to have lower editing efficiencies in living organisms compared to cultured cell lines. To overcome these challenges, here we focused on adenine base editors (ABEs), which have the potential to correct approximately half of all pathogenic human point mutations, and engineered a suite of ABE variants that we call ABE-Umax with high editing efficiency and a low frequency of insertions and deletions (indels) in zebrafish. Within the ABE-Umax platform, we present ABEs with shifted, narrowed, or broadened editing windows, reduced bystander mutation frequency, as well as highly flexible PAM sequence requirements. These innovative base editors promise to overcome many limitations of their predecessors, revolutionizing disease model generation and the broader field of gene therapy.

292 **Discovering context-specific functionally-equivalent genes in research organisms using cross-species transcriptome-based machine learning** Hao Yuan[1], Christopher A Mancuso[2], Kayla Johnson[3], Ingo Braasch[4], Arjun Krishnan[3] [1]Genetics and Genome Science, Michigan State University, [2]Department of Biostatistics & Informatics, University of Colorado Anschutz Medical Campus, [3]Department of Biomedical Informatics, University of Colorado Anschutz Medical Campus, [4]Department of Integrative Biology, Michigan State University

Research organisms are quintessential for performing functional experiments, disease modeling, and drug testing of human disorders. However, evolutionary divergence between humans and research organisms complicates effective knowledge transfer across species, hindering the identification of appropriate gene targets in research organisms for studying human diseases. Common strategies use homology as a bridge for knowledge transfer, but homology does not guarantee equivalent function across species. Moreover, as the roles of genes is likely to vary across disease contexts, functional equivalence between genes across species is likely to be highly context-specific. While a number of computational methods have been developed to transfer knowledge across species beyond solely using gene homology, they do not account for disease context in knowledge transfer. To address this challenge, we have developed a novel approach to infer disease-specific genome-scale gene networks simultaneously in humans and research organisms using hundreds of thousands of existing transcriptomes in multiple species. Disease-specific signals in these massive public data are captured by a regression-based approach that identifies minimal sets of transcriptomes in human and research organisms that can recapitulate disease transcriptome(s) from patients. Then, we compare the resulting networks in human and research organisms to predict genes that are likely to

be functionally-equivalent across species based on the high similarity of their local network neighborhoods. We demonstrated the power of our approach by applying it to discover functionally-equivalent genes in zebrafish. However, our approach can be applied to any research organism with sufficient existing public transcriptomics data. Our method helps to simplify the process of selecting a well-suited organism and gene targets for functional tests. Additionally, functionally-equivalent genes identified by our approach could be integrated to Alliance of Genome Resources, offering invaluable guidance for functional tests and benefiting disease model communities. To showcase the power of our method, we conducted a case study on Facioscapulohumeral Muscular Dystrophy (FSHD) - a rare genetic muscle disease caused by heterogeneous genetic factors. We investigated potential pathogenic genes related to FSHD and found functional equivalents in research organisms.

293 **Towards large-scale computational whole-organism microanatomical phenotyping: Democratizing access to large-field submicron histotomography, cloud-based visualization, and computational workflows** Keith C Cheng[1], Daniel Vanselow[2], Michael Morehead[3], Alex Y Lin[2], Patrick J La Riviere[4], Sharon Xiolei Huang[5], Khai Chung Ang[2], Mahmut T Kandemir[6] [1]Pathology, Penn State College of Medcine, [2]Pathology, Penn State College of Medicine, [3]Isovisio, [4]Radiology, University of Chicago, [5]Information Sciences and Technology, Pennsylvania State University, [6]Computer Science, Pennsylvania State University

Histopathology is a traditionally 2-dimensional form of tissue diagnosis based on histology, whose essential features include undistorted (isotropic) and single micron resolution (equivalent to submicron digital resolution), unbiased (pan-cellular) representation of all cell types, and the ability to image sample slices more than a centimeter in largest dimension. Reverse translation of that power to the 3D realm would enable volumetric and cell population studies that addresses the model system community goal (https://doi.org/10.1242/dmm.049600) of whole-organism phenotyping for genetic phenome projects focused on mutants and chemical phenome projects focusing on treated organisms. Systems consideration of alternative 3D imaging technologies led us to focus on the development of quantitative, 3D, whole-organism phenotyping, based on the development of a 3D form of histology representing a customized form of micron-scale CT, call histotomography.

To democratize accessibility, we are working with the DOE and the University of Chicago to implement synchrotron-based histotomography for the community. To address user visualization of TB-range 3D image files, we have implemented cloud-based multi-planar visualizations on common commuters using Neuroglancer. Streaming from servers to allow cloud-based Virtual Reality visualization on normal computers is also possible.

Reaching the aspirational goal of complete, quantitative, microanatomical phenotyping in whole centimeter-wide genetic model organisms and their tissues will require community support for democratized access to histotomography. Analogous to posting of DNA sequence for the creation of bioinformatic tools, we are also working towards incorporating the goals of computational phenotyping into a Galaxy-based system of access to collections of reference and experimental images, the above cloud-based visualization capabilities and computational workflow systems designed to foster community-based computational tool development. Finally, the pan-cellular nature of whole-organism microCT/histotomography suggests their potential use as cloud-based anchors for histology and other multimodal and multi-scale images, as well as large-scale molecular analytics (spatial biology).

294 **Telomere-to-telomere genome assemblies for commonly used zebrafish laboratory strains** Javan O Okendo[1], Sergey Koren[2], Arang Rhie[2], Aranza Torrado[1], Joy M Murphy[3], Zoltan Varga[3], Adam M Phillippy[2], Shawn M Burgess[1] [1]Translational and Functional Genomics branch, National Human Genome Research Institute, [2]Computational and Statistical Genomics Branch, National Human Genome Research Institute, [3]Institute of Neuroscience, 1254 University of Oregon Eugene

The most recent zebrafish reference genome assembly was released in May of 2017. At the time, it was generated with the state-of-the-art sequencing technologies in combination with a high-density genetic map and BAC libraries made from the Tübingen line (TU). The assembly consists of 19,725 contigs assembled into 1,917 scaffolds. Recent advances in both “long-read” sequencing technologies and genome assembly algorithms have made “complete” genome assemblies possible for the first time as has been shown by the recent release of a fully assembled human genome. We have devised two separate strategies for assembling the zebrafish genome “telomere-to-telomere” (T2T): The first strategy uses homozygous TU fish generated by heat shock disruption of mitosis **I**. Cell lines were established for two HS diploid fish and then genomic DNA was isolated both from the adult tissues as well as the cultured fibroblasts. DNA from the tissue was used for PacBio HiFi sequencing and the fibroblast DNA was used for Oxford Nanopore sequencing (ONT). We performed *de novo* assembly using the Verkko genome assembler. The second strategy we termed the “3 generations” approach. One fish from each of the 4 most commonly used zebrafish lab lines: TU, AB, WIK, and TL were used as the 4 “grandparents” and were short read sequenced to document all unique, identifying SNV for each parent. One fish from each of the 2 grandparent pairings was used to generate pools of the 3rd generation offspring. The pooled genomic DNA from these offspring was used for both PacBio HiFi and ONT sequence. The SNV data from the grandparents is then used to separate all the reads into haplotype bins and all 4

haplotypes are resolved simultaneously using the Verkko assembler. The data for strategy I has a gapless assembly of 1.45GB in 25 chromosomes and an additional ~48 million bases of new sequence has been added to zebrafish reference genome. The strategy 1 genome assembly is more contiguous with N50 of 58 MBs and L50 of 11. Our strategy II shows that TU, AB, WIK, and TL zebrafish strains have varied number of unique k-mers and they exhibit different levels of heterozygosity. We hope this new assembly will open new frontiers in zebrafish genetic research.

295 **The genetic basis of copper resistance and adaptation in natural populations** Elizabeth Everman[1], Stuart Macdonald[2], John Kelly[2] [1]University of Oklahoma, [2]University of Kansas

Heavy metal pollution has pervasive environmental, health, and evolutionary impacts. In humans, health risks range from permanent neurological disease to increased morbidity of degenerative syndromes. Our previous work has demonstrated that variation in susceptibility to metal toxicity is influenced by a combination of genetic variation, environmental exposure, and their interaction. Investigation of the evolutionary processes that lead to complex trait variation has great biomedical significance as we seek to understand the gene-by-environment interactions, genetic constraints, and genetic risk factors that contribute to increased susceptibility to toxic heavy metal exposure in human populations. We focus on copper given the important role this metal plays as an environmental contaminant and as a critical micronutrient for normal physiological development and maintenance in most organisms. Recently, we used *Drosophila melanogaster* to examine natural variation in metal resistance by collecting wild flies from four populations with varying exposure risk to metal pollution, focusing on the potential evolutionary impact of mining and agricultural activities. Copper resistance varied among the wild populations, increasing in sites that have been previously subject to intense mining and agricultural activity. Using whole genome sequencing and bulked segregant analysis, we identified 288 SNPs distributed across the genome that contribute to copper resistance. Most SNPs had population-specific effects, suggesting that the effects of alleles associated with increased resistance are influenced by unique evolutionary histories as well as population-specific genetic backgrounds. SNPs with consistent effects on copper resistance were also detected, calling attention to candidates potentially involved in parallel adaptation. SNPs mapped to several novel candidates as well as to the known copper homeostasis gene *CG11825*, providing new insight on the collection of genes that influence resistance in natural populations. This work demonstrates the highly polygenic nature of copper resistance in natural populations is subject to complex interactions between genetic background and evolutionary history. Current work seeks to investigate these evolutionary patterns further through a long-term artificial selection experiment. Using an integrative approach that leverages whole genome and RNA sequencing and experimental evolution, we will track the dynamic shifts in allele frequency and gene expression in response to copper stress in diverse naturally derived genetic backgrounds. By focusing on multiple physiological and behavioral traits, these approaches will provide critical insight into the interconnectedness of multiple response traits, while also illuminating genetic factors that influence behavioral and learning disabilities linked to metal poisoning.

296 **Characterizing Epistasis in Copper Sulfate Resistance using Chromosome Fixation and Bulk Segregant Analysis** Cassandra Buzby, Federica FO Sartori, Mark Siegal New York University

Complex traits are the products of multiple genetic and environmental factors, yet how these influences interact largely remains a mystery. The contribution of genetic interactions to natural trait variation is particularly challenging to estimate experimentally, and current approaches for detecting epistasis are often underpowered. Powerful mapping approaches such as bulk segregant analysis, wherein individuals with extreme phenotypes are pooled for genotyping, obscure epistasis by averaging over genotype combinations. To accurately characterize and quantify epistasis within natural trait variation, we have engineered Saccharomyces cerevisiae strains to enable crosses in which one parent's chromosome is fixed while the rest of the chromosomes segregate. We then use bulk segregant analysis to identify quantitative trait loci whose effects depend on alleles on the fixed parental chromosome, indicating a genetic interaction with that chromosome. Using this method, we can identify interacting loci with high statistical power.

We applied this approach to a cross of a yeast strain derived from a wine barrel ("Wine") and a strain derived from an oak tree ("Oak"), from which we obtained large pools of segregating progeny fixed for chromosomes I or VIII from either parent. We tested resistance to copper sulfate, as copper is a common stressor in wild yeast; these strains show a marked difference in survival in the presence of copper, allowing us to compare variation in natural populations in a trait relevant in their different environments. We identify effects dependent on the genetic background as well as changes in additive effects resulting from removal of variation in the CUP1 locus, which encodes a metallothionein and has a large association with copper resistance. We demonstrate that this technique may be used to tease apart the roles of additive quantitative trait loci in the broader context of the genome as well as detecting loci which interact with each fixed chromosome. Our results point to further complexity of genetic architecture than previously appreciated in the trait of copper resistance, revealing specific interactions between multiple genetic factors.

297 **A molecular evolutionary cascade facilitates nematode parasitism of prey carrying toxic cardiac glycosides** Perla Achi[1], Adler Dillman[1], Simon Groen[1], Anil Baniya[1], Peter Douglas[2], Connor Goldy[1], Damaris Godinez-Vidal[1] [1]Nematology, UCR, [2]Molecular Biology, UT Southwestern Medical Center

Target-site insensitivity (TSI) is an important mechanism of animal resistance to natural and man-made toxins. TSI evolved in parallel in the monarch butterfly and other insects that specialize on milkweeds and is thought to have facilitated sequestration of cardiac glycosides (CGs) that may protect these insects from predation and parasitism. Substitution N122H in the CG-binding pocket of the molecular target, the Na+/K+-ATPase alpha subunit (ATPα), strongly enhances TSI and evolved in parallel in CG-sequestering insects across six orders. Upon performing a genetic screen of the Na+/K+-ATPase, we recently identified N122H in the entomopathogenic nematode (EPN) *Steinernema carpocapsae*, which parasitizes insects around milkweeds. This sets up the possibility that parallel evolution of N122H may not only have facilitated CG sequestration by insects, but also nematode parasitism of CG-carrying insects. Here, we show that N122H is rare among nematodes and that, among species tested for CG tolerance, *S. carpocapsae* showed significantly stronger insensitivity to diverse CGs than nematodes without N122H, including free-living *Caenorhabditis elegans* and parasites of milkweed roots. CRISPR gene editing in *C. elegans* showed N122H is sufficient for overcoming toxicity of CG levels found in sequestering insects. However, N122H was accompanied by costs related to nervous system robustness, potentially explaining its rarity among nematodes. Finally, *S. carpocapsae* was the only EPN tested that was highly successful at infecting CG-carrying insects and that displayed attraction to CGs. Taken together, our results suggest that a molecular evolutionary cascade of parallel substitutions across hosts and parasites, last sharing common ancestry 600 million years ago, may shape multitrophic interactions.

298 **Chaos below the stability: evolution-selection equilibrium model explains co-existence of resistant and susceptible strains** Pleuni S. Pennings Biology, San Francisco State University

Drug resistance is a problem in many pathogens, including viruses, bacteria, fungi and parasites. While overall, levels of resistance have risen in recent decades, there are many examples where after an initial rise, levels of resistance stabilize. The stable co-existence of resistance and susceptibility has proven hard to explain – in most models either resistance or susceptibility ultimately “wins” and takes over the population. Here we propose a simple stochastic model, akin to mutation-selection balance theory, which can explain several key observations about drug resistance: (1) the stable coexistence of resistant and susceptible strains (2) at levels that depend on drug usage (3) and the observation that resistance is often carried by many different resistant strains. It predicts that many resistant strains should continuously appear (due to positive selection within treated hosts) and disappear (due to competition with susceptible strains in the rest of the population). When resistance is due to horizontally transferred genetic elements, the model predicts that strains continuously acquire these genetic elements. We used data on 40,000 *E. coli* strains to test this prediction for a resistance mutation and two resistance genes in the UK and found that the data are consistent with the predictions.

299 **Investigating freeze-thaw tolerance in *S. cerevisiae* via experimental evolution** Leah Anderson[1], Liya Miksovsky[2], Maitreya Dunham[1] [1]Genome Sciences, University of Washington, [2]Yale University

Although freezing and thawing is commonplace for *S. cerevisiae* both in the laboratory and natural environments, cellular mechanisms for freeze-thaw tolerance remain understudied. The main goal of my project is to elucidate genetic factors that play a role in freeze-thaw tolerance and functionally characterize variation in those loci.

I conducted experimental evolution for yeast freeze-thaw tolerance by subjecting initially clonal yeast populations to strong selective pressure via exposure to serial rounds of freezing and thawing. After 20 cycles of freeze-thaw evolution, increased freeze-thaw tolerance was observed in 34 independent populations. The evolved populations were then whole-genome sequenced and analyzed for SNPs, copy number variation, and transposons that differ from the ancestral genome. We found multiple independent mutations in cell wall biosynthesis proteins, components of the RAM signaling pathway, and factors required for proper cell budding. My next steps are to verify the precise effects these mutations have on phenotype by isolating individual mutations and measuring their effects on freeze tolerance as well as other phenotypes, including cell wall integrity, budding capabilities, osmotolerance, and heat sensitivity. Preliminary data has shown that tradeoffs previously thought to exist between freeze-thaw tolerance and osmotolerance are not ubiquitous across freeze-thaw evolved yeast clones. This underscores the value of experimental evolution as a method for identifying freeze-thaw tolerance mechanisms, as it uncovers multiple genetic pathways for tolerance, some which may not exhibit previously associated tradeoffs.

This work will provide a catalog of freeze-thaw tolerance genes and provide better understanding of how changes in the genome impact survival to extreme temperature changes. Furthermore, freeze-thaw tolerant yeast generated via experimental evolution have potential for utility in both biomedical research and industrial applications, as well as providing a better understanding of how organisms in the natural world adapt to frequent temperature fluctuations in a changing global

environment.

300 **Natural hybrid zones reveal the molecular underpinnings and evolutionary history of hummingbird pollination in *Penstemon*** Lucas C Wheeler, Joshua TE Stevens, Noah H Williams, Carolyn Wessinger Biological Sciences, University of South Carolina

The hummingbird pollination system has evolved multiple times in the genus *Penstemon* from a bee-pollinated ancestral state. In section Habroanthus, despite clear signals of hybridization between species, we have found strong evidence of four convergent acquisitions of the so-called hummingbird pollination syndrome. This phenotype is characterized by long-tubed red flowers with abundant dilute nectar and exserted stamens and styles, and is predictive of hummingbird visitation in *Penstemon*. By performing genetic crosses with a bee vs. hummingbird pollinated sister species pair in section Habroanthus, we have identified regions of the genome that are tightly associated with the characteristic components of the hummingbird syndrome. QTLs include genes associated with the control of floral pigmentation and morphology. But, have these same genetic mechanisms been replicated during the evolution of the hummingbird-pollinated phenotype in other Habroanthus lineages? To answer this question we are taking advantage of a collection of hybrid zones that occur between another hummingbird vs. bee pollinated sister pair in Habroanthus: *P. eatonii* and *P. laevis*. We have performed phenotyping and whole-genome resequencing of a large sample of hybrid and parent individuals from three separate populations each. This dataset has allowed us to make use of admixture mapping to identify loci that are associated with the relevant components of the hummingbird pollination phenotype, and provides a detailed window into variations in local ancestry and the history of introgression in the hybrid zones. We find evidence that parallel evolutionary changes in at least one locus, the anthocyanin pathway branching enzyme *Flavonoid* 3',5'-*hydroxylase* (F3'5'H), occurred in both of the studied sister pairs. However, our results suggest that the molecular mechanisms underlying the other components of the hummingbird-pollinated phenotype differ along parallel lineages.

301 **Cracking coevolution: consequences of spatial dynamics on coevolving quantitative traits** Victoria Caudill, Peter Ralph University of Oregon

Coevolution between two species can lead to exaggerated phenotypes that vary in a correlated manner across space. However, the conditions under which we expect such spatially varying coevolutionary patterns in polygenic traits are not well-understood. I investigate the evolutionary dynamics of coevolution of two species undergoing reciprocal adaptation across space and time, using both theory and simulations inspired by the newt-snake system. In this system, the amount of tetrodotoxin produced by Taricha granulosa (rough-skinned newt) is strikingly correlated with resistance of one of their predators, Thamnophis sirtalis (garter snake), to this toxin. I explore how the genetic architecture of the toxin and resistance traits affects the coevolutionary dynamics by manipulating the mutation rate and the effect size of mutations, demonstrating how different genetic architectures lead to different coevolutionary outcomes in geographically explicit settings with both homogeneous and nonhomogeneous environments. I find that intermediate trait polygenicity often provides an advantage in the coevolutionary race, suggesting that there might be an optimal combination of mutation rate and effect size in the coevolutionary arms race. Furthermore, I only found strong spatial correlations between traits with heterogeneous environments, suggesting that intrinsic coevolutionary fluctuations are not sufficient to explain observed correlations.

302 **The expanded role of the conserved *snpc-1* and *snpc-3* gene families in *C. elegans* small RNA transcription** Lars Benner, Rebecca Tay, Margaret Starostik, Ayaka Inoki, Mindy Clark, Michael Schatz, John Kim Biology, Johns Hopkins University

PIWI-interacting RNAs (piRNAs) are a class of small RNAs that have a conserved function in protecting the germline genome from the deleterious effects of mobile DNA elements. In repressing these elements, piRNAs preserve the integrity of the genome and ensure its faithful transmission to the next generation. While the transposon silencing function of piRNAs is well understood, the transcriptional regulation and sexual dimorphic expression of piRNAs remain largely unknown. The conserved snRNA activating protein complex (SNAPc) is a well-established transcription factor complex that drives small nuclear RNA (snRNA) transcription. In flies and mice, the SNAPc holocomplex consists of SNPC-1, SNPC-3, and SNPC-4 subunits, which are each encoded by a single gene. In contrast, the *C. elegans snpc-1* and *snpc-3* genes have been amplified through gene duplications to comprise several paralogs, each with distinct roles. We previously showed that the SNPC-1 family protein SNPC-1.3 is a male piRNA transcription factor expressed in the male germline. Here, we provide biochemical and genetic evidence to show that the SNPC-1 paralog SNPC-1.2 constitutes a novel female piRNA transcription factor. Additionally, genetic knockout and RNAi-based knockdown assays reveal that the *snpc-3* family genes *snpc-3.1* and *snpc-3.2* comprise functionally redundant core piRNA transcription factors required for the transcription of both male and female piRNAs, while *snpc-3.4* is uniquely involved in snRNA transcription. Collectively, the *snpc-1* and *snpc-3* gene families encode specificity factors for three distinct protein complexes that discriminate between the transcription of sex-specific piRNAs and snRNAs in the *C. elegans* genome. Our work provides insights into the sexually dimorphic, piRNA-mediated regulation of germline genes to maintain proper germline development and suggests that piRNA biogenesis emerged from the diversification of the ancient

snRNA transcriptional machinery.

303 **Determination of the mechanisms governing piRNA degradation** Benjamin Pastore, Hannah L Hertz, Wen Tang Biological Chemistry and Pharmacology, The Ohio State University

Organisms are constantly under attack by foreign nucleic acids from viruses and transposons that cause genome damage and an array of genetic diseases. To combat these foreign genetic elements organisms evolved RNA- and DNA- directed immune pathways such as RNA-interference (RNAi) and CRISPR/CAS. One of the most ancient and evolutionarily conserved RNA-directed immune pathways is the PIWI/piRNA pathway. In animal germlines piRNAs, together with effector PIWI proteins, suppress transposons and are indispensable for fertility. Since their discovery, piRNA biogenesis and function have been well studied, yet until recently the mechanisms governing piRNA degradation were largely unexplored. In a recent work, we identified a piRNA quality control mechanism that is mediated by 3' nontemplated nucleotide additions (3' tailing) of RNA nucleotides. Moreso, we found that piRNA::target interactions have the capacity to induce 3' uridine (U) tailing of piRNAs and their degradation. Using genetics, high-throughput RNA sequencing, and bioinformatics, we have identified and characterized the enzymes required for piRNA 3' U tailing and degradation. Our findings suggest that piRNA 3' U tailing is concurrent, but not required for piRNA degradation. Additionally, our investigation elucidated the mechanism by which different pools of sex-specific piRNAs are regulated throughout development in *C. elegans*. In all, this work expands our knowledge of both how and why piRNAs are degraded by identifying and characterizing the proteins involved in piRNA 3' tailing and degradation, as well as assigning a physiological function of piRNA decay.

304 **Polarizing Epithelia with Branched Actin Regulators** Patricia Irizarry[1], Luigy Cordova-Burgos[2], Martha Soto[2] [1]Pathology, Rutgers Univeristy, [2]Pathology, Rutgers University

Protein trafficking helps maintain epithelial polarity, and it likely plays a role establishing epithelial polarity during development. Branched actin networks support epithelial polarity, in part by maintaining polarized protein transport. For example, loss of the branched actin regulating WAVE complex results in apical/basal defects of epithelia, including mislocalization of the Cadherin protein, a major regulator of apical/basal polarity (Cordova-Burgos et al., 2020). WAVE and Cadherin colocalize at key transport organelles, including RAB-11-positive recycling endosomes, and at the Golgi. Loss of WAVE leads to slower and mis-directed movements of the apically targeted RAB-11-positive endosomes (Cordova-Burgos et al., 2023). WAVE and Cadherin also colocalize and work together to polarize events during embryonic development (Sasidharan et al., 2018). Therefore, understanding how branched actin contributes to polarized events is essential for understanding epithelial polarity. However, in *C. elegans*, only two Nucleation Promoting Factors (NPSs) that regulate branched actin through Arp2/3 have been examined, WAVE and WASP. We therefore analyzed the orthologs of the third *C. elegans* Apr2/3 NPF, the WASH complex. The WASH complex is similar to the WAVE complex, in that both complexes include 5 paralogous components. Surprisingly, only 4 or the 5 components had been identified in *C. elegans*, and the role of WASH in trafficking had not been described. We used existing mutations, RNAi and CRISPR to determine the effects of loss of the WASH complex, focusing on two epithelial tissues: the adult intestine and the embryonic epidermis. We used our phenotypic assays to test a candidate for the missing 5th WASH component, the FAM21 proposed ortholog, CO5G5.2. Loss of any WASH component, using mutations or RNAi, resulted in the same phenotype: defective transport of cargo on RAB-5 and PI(3)P-positive early endosomes. This result suggests *C. elegans* WASH regulates sorting during endocytic recycling, through retrograde trafficking to the Golgi apparatus. Loss of WASH components also resulted in embryos that die during morphogenesis. Therefore, *C. elegans* has a conserved, 5-member WASH complex that appears to function, like its orthologs, in early endosome to Golgi retrograde transport. Our in vivo analysis of WASH function in two different times and places during development will allow us to determine conserved and divergent features of the *C. elegans* WASH complex.

305 **Investigating the Impact of PI(4,5)P_2 on Biogenesis of Extracellular Vesicle Subpopulations from *C. elegans* Cilia** Malek Elsayyid, Alexis Semmel, Jessica E Tanis Biological Sciences, University of Delaware

Extracellular vesicles (EVs) are membrane-enclosed structures that transfer bioactive proteins, RNAs, and metabolites to recipient cells. Secreted from nearly all cell types, EVs play critical roles in physiological processes and pathological conditions. In *C. elegans*, EVs are shed from primary cilia, which are specialized microtubule-based organelles that protrude from the dendritic tips of sensory neurons, and are environmentally released through a cuticle pore. We have demonstrated that two EV cargoes, polycystin TRP channel PKD-2 and ion channel CLHM-1, are present in separate EV subpopulations. However, the mechanism by which EV cargoes are enriched into specific subsets is uncharacterized. We hypothesize that phosphoinositide asymmetry throughout the cilia affects how cargoes are selectively packaged. Despite making up only a small fraction of cellular phospholipids, phosphoinositides have essential functions in vesicular trafficking, ciliary localization of receptor proteins, ion channel regulation, and endocytic and exocytic processes. Phosphoinositides localize to discrete subcompartments of the ciliary membrane, with phosphatidylinositol 4,5-bisphosphate (PI(4,5)P_2) excluded from the cilium

proper. Regulatory enzymes may play a spatially-dependent role in maintaining the lipid asymmetry necessary for proper ciliary signaling. $PI(4,5)P_2$ is converted to PI(4)P by the phosphatase INPP-1, while PI(4)P is phosphorylated to $PI(4,5)P_2$ by the kinase PPK-1. We found that INPP-1::GFP preferentially localized to the cilium proper rather than the cilium base. Using Total Internal Reflection Fluorescence (TIRF) microscopy, we observed that *inpp-1(gk3262)* animals had increased release of PKD-2::GFP-containing EVs with no impact on the CLHM-1::tdT EV subpopulation. Conversely, overexpression of PPK-1 decreased CLHM-1::tdT EV release with no impact on PKD-2::GFP EVs. Our results imply that differences in INPP-1 and PPK-1 localization could lead to enrichment of specific phosphoinositide species in ciliary subcompartments in order to regulate the release of distinct EV subpopulations.

306 **The conserved kinase NEKL-4/NEK10 orchestrates ciliary integrity and mitochondrial dynamics to modulate hyperglutamylation-induced neurodegeneration** Kaiden M Power[1], Adriele Silva[2], Shaneen Singh[2], Ken Nguyen[3], David Hall[3], Christopher Rongo[4], Maureen Barr[1] [1]Genetics, Rutgers University, [2]The City University of New York, [3]Albert Einstein College of Medicine, [4]Microbiology, Rutgers University

Neurodegenerative diseases present a severe and significant medical concern. The health of neurons depends in large part on mitochondrial localization and metabolic function. Microtubule-based transport is important for proper mitochondrial localization and function, and thus to neuron health. Consequently, proteins that affect microtubule stability play indirect yet important roles in the regulation of mitochondria function. A loss-of-function mutation of the deglutamylase CCP1 causes infantile-onset neurodegeneration and leads to excessive glutamylation of microtubules and defects in transport of mitochondria in neurons. CCP1 is evolutionarily conserved. *C. elegans ccpp-1* functions in ciliated sensory neurons where it affects microtubule stability of neuronal cilia. We performed a forward genetic screen to identify suppressors of *ccpp-1* age-related ciliary degradation. We identified a mutation in the NIMA-related kinase *nekl-4*, an ortholog of mammalian NEK10. NEK10 is associated with both cilia dysfunction and disrupted mitochondrial homeostasis in mammalian cells. We found that NEKL-4 acted as a negative regulator of ciliary stability independent of microtubule glutamylation and via an unknown mechanism.

To uncover the NEKL-4 mechanism of action and to determine the role of NEKL-4 and CCPP-1 in mitochondrial dynamics, we generated CRISPR-tagged fluorescent wild type, overexpressed, and kinase dead (KD) forms of NEKL-4. Wild-type and NEKL-4(KD) did not localize to cilia, but were associated with mitochondria. Time lapse microscopy showed that NEKL-4 and mitochondria are co-transported, which suggests that NEKL-4 may regulate mitochondria transport in the ciliated neurons. Additionally, our imaging showed that both *nekl-4* and *ccpp-1* affect mitochondrial morphology, localization, and oxidation state in these neurons, all of which may impact cilia structure. In *ccpp-1* mutants, NEKL-4(KD) translocated to cilia and suppressed ciliary degeneration. Our preliminary transmission electron microscopy analysis indicates that *nekl-4(KD)* mutants display abnormal ciliary ultrastructure, consistent with a role in microtubule stability. These results suggest that NEKL-4 mediates communication between cilia and mitochondria. Our work adds to a growing body of evidence suggesting a connection between cilia stability and mitochondrial function that, when perturbed, could instigate neuronal degeneration.

307 **Analysis of hundreds of genes with limited functional annotation that are required for normal mammalian development** David Beier[1,2], Shamil Sunyaev[3] [1]Seattle Children's Research Institute, [2]University of Washington, [3]Harvard Medical School

Genes required for human development are often haploinsufficient when heterozygous for the null allele. Using an empirical Bayes method, we estimated selection coefficients (s_{het}) for heterozygous protein truncating variants (Cassa et al., Nat Genet 2017). Other methods have been proposed (Agarwal et al., eLife 2023; Zeng et al., bioRxiv 2023) and there are powerful heuristics to assess selective constraint (Karczewski et al., Nature 2020). We found that genes under the strongest selection were enriched for autosomal dominant disease genes, embryonic lethal mouse knockouts, and known developmental signaling pathways. Re-analysis using an updated s_{het} algorithm (Seplyarskiy et al., bioRxiv 2022) of 9000 protein interactions and 6000+ mouse knockouts generated by KOMP confirms these results.

Remarkably, despite the evident importance of the highly selected genes, there is a relative lack of functional annotation. **Less than 20% of the genes in the top s_{het} decile have a human disease association.** Using a Pubmed citation metric, 2/3 of this decile have less than the average for all genes. That the functions of most genes in this cohort are not known is astonishing.

While the case for studying loci under strong selection is compelling, the task of high-throughput functional analysis is daunting, especially for genes that affect patterning and organogenesis (vs. those with cell-autonomous effects). Our efforts at whole-embryo mouse analyses have been challenging, mainly due to the task of husbandry and sample collection. Novel methods of both *in vitro* and *in vivo* perturb-seq may be useful, but these are also resource-intensive. As such, it is attractive to first pursue bioinformatic analyses to infer gene function, which is facilitated by the large amount of expression and proteomic

data now available.

We are therefore developing a ranked list of 1000 genes of limited functional annotation for which we have evidence of strong selection, using a variety of methods. Genes in this list are ranked based on similarity to known key players in human development. As features, we have combined several existing selection metrics applied across major population sequencing datasets and have amended human population genetics considerations with a new comparative approach that focuses on gene losses in the mammalian phylogeny. Next, we will use domain composition, localization signals, expression patterns and protein interaction networks to prioritize genes. This will enable the generation of functional hypotheses that can then be validated experimentally.

308 **Signatures of selection associated with haploid biased transcript exchange in murine round spermatids** Daniel E Shaw, Jeffrey M Good University of Montana

Genomic conflicts are assumed to be pervasive drivers of genome evolution, yet there is limited evidence linking rapid molecular evolution with mechanistically plausible drivers of conflict. Mammalian spermatogenesis includes a prolonged period of post-meiotic development which introduces the potential for rapid evolution driven by haploid-level selection. However, early post=meiotic cells are effectively diploid because they share transcripts through cytoplasmic bridges. Some transcript sharing is essential for proper sperm development, but it also introduces the potential for the evolution of selfish elements that evade sharing. A recent mouse single-cell expression study found extensive allelic skew in the degree to which post-meiotic genes share expressed transcripts, raising the potential for widespread genetic conflict and haploid selection at this critical stage of development. Here, we combine a comparative genomic analysis of protein-coding, gene expression, and non-coding evolution to identify signatures of selection over deep evolutionary timescales in rodents. First, we compared the mouse and rat genomes and found extensive divergence in 3' UTR of genes found to have an allelic bias in haploid transcriptomes compared to genes with equal transcript exchange. This supports the role of the UTR as a site targeted by cellular transport machinery. Second, we compared whole exome sequences from 38 murine rodents spanning the divergence between mouse and rat (~15 million years) to identify genes under pervasive positive selection across spermatogenesis and for skewed genes in house mice. We found 279 genes with skewed transcript bias evolving under positive selection across rodents. However, this was not a significantly enriched amount compared to genes with equal exchange. We found that skewed genes under positive selection were associated with sperm motility. Finally, we utilized RNA-seq data from house mice to identify co-expression modules enriched for biased transcript exchange. We found that these modules tended to be mis-regulated in hybrid crosses potentially reflecting disruption of transcript exchange as a consequence of evolutionary divergence. This suggests that mis-regulated transcript exchange between hybrid spermatids may cause intra-genomic conflicts and contribute to reproductive isolation. Together, this work supports a model of rapid molecular evolution of biased transcript exchange as a driver of genomic conflict.

309 **Quantitative Trait Locus mapping in a mouse model of ischemic stroke identifies Macrophage Scavenger Receptor 1 (*Msr1*) as modifier of cerebral infarct volume** Douglas A Marchuk[1], David L Aylor[2], Han Kyu Lee[1] [1]Molecular Genetics and Microbiology, Duke University, [2]Biological Sciences, North Carolina State University

Ischemic stroke is caused by a disruption of the blood supply to the brain leading to neuronal cell death. Genetic studies of ischemic stroke have identified numerous gene variants that increase the risk to develop stroke. In stark contrast, genetic studies of stroke outcomes, such as the infarct territory size, are confounded by many uncontrollable variables, leading to a paucity of gene targets for treatment of an incipient stroke. Using genetically diverse inbred strains of mice and a surgically induced model of ischemic stroke, we used quantitative trait locus mapping to identify novel gene targets modulating infarct size, which varies greatly across inbred strains. Although infarct size is largely determined by the extent of collateral vessel connection between arteries in the brain that enables reperfusion of the ischemic territory, we have identified strain pairs that do not vary in this phenotype, but which nonetheless exhibit large differences in infarct size. In this study we performed QTL mapping in mice from an intercross between two such strains, WSB/EiJ and C57BL/6J. We identified a strong locus on chromosome 8 that overlaps with a locus of similar direction and effect previously mapped in an intercross between C3H/HeJ and C57BL/6J strains. To identify causative genes within the overlapping genetic interval, we surveyed nonsynonymous coding SNPs and performed RNA sequencing data analysis for all three mapping strains. We identified macrophage scavenger receptor 1 (*Msr1*) as a candidate gene that harbors multiple coding SNPs predicted to be damaging. Using *Msr1*-deficient mice, we demonstrate that cerebral infarct volume after stroke induction is increased in a strain background where reperfusion effects due to collateral vessels is blunted. The identification of neuroprotective genes such as *Msr1* provides new genes for future mechanistic studies of infarction following ischemic stroke and provides novel gene/protein targets for therapeutic development.

310 **The genetic regulation of dose response in a diverse mouse cell population is revealed by cell morphology QTL (cmQTL)** Callan O›Connor[1], Gregory R Keele[1,2], Whitney Martin[1], Daniel Gatti[1], Brian R. Hoffmann[1], Ron Korstanje[1], Gary

Churchill[1], Laura Reinholdt[1] [1]The Jackson Laboratory, [2]RTI International

Genetically diverse cell populations derived from mice are powerful tools for studying gene-environment interactions. New approach methodologies such as these are of increasing interest for modeling population variability as they offer genetic diversity and potentially, predictive value for focused *in vivo* studies in extreme genotypes. Using fibroblasts derived from a laboratory mouse genetic reference population (Diversity Outbred population), we performed high-content imaging to capture hundreds of cell morphology traits during exposure to the oxidative stress and DNA damage-inducing arsenic metabolite monomethylarsonous acid (MMA^{III}). We applied dose-response modeling to capture latent parameters of dose-dependent traits (i.e. EC50) and then used these parameters to map several hundred cell morphology quantitative trait loci (cmQTL). We found that cmQTL include genes that are known to be associated with cellular response to arsenic exposure, including *Abcc4* and *Txnrd1,* as well as novel gene candidates like *Xrcc2*. We also found significant variation in baseline traits, demonstrating that genetic variation influences basic aspects of cell and nuclear morphology in culture. We show that cmQTL are reproducible, that their allele effects predict response, and that they point to key molecular initiating events that are genetically regulated. This study provides a proof-of-principle for using genetically diverse mouse cell lines in toxicology screens to identify population level responses and suggest mechanisms underlying intrinsic variation in cellular response to chemical exposure.

311 **QTL mapping reveals independent loci affecting the magnitude and composition of inactivated influenza vaccine- and adjuvant- mediated immune responses in an F2 intercross** Marta C Cruz-Cisneros[1,2], Timothy A Bell[1], Pablo Hock[1], Colton L Linnertz[1], Kelsey E Noll[3], Breantie Parotti[1], Fernando Pardo-Maneul de Villena[1,4], Mark T Heise[1,3,4], Martin Ferris[1] [1]Department of Genetics, University of North Carolina, Chapel Hill, [2]Curriculum in Genetics and Molecular Biology, UNC Chapel Hill, [3]Department of Microbiology, University of North Carolina, Chapel Hill, [4]Lineberger Comprehensive Cancer Center, UNC Chapel Hill

influenza infection. However there is still significant variation between individuals in their protection against influenza after immunization, even despite the inclusion of adjuvants which boost immune responses. Better understanding of the genetic factors that influence these intra-individual differences would provide data for next-generation vaccine and adjuvant development. We screened several strains of Collaborative Cross (CC) mice with both an unadjuvanted inactivated influenza (iFlu), and iFlu adjuvanted with alum. We observed significant and differential heritability in the magnitude and composition of the antibody responses across these two treatments. We chose to generate a large F2 intercross between CC002/Unc and CC072/TauUnc. CC002 showed a robust response to iFlu, that was not significantly improved by alum adjuvanting. In contrast, CC072 showed a muted response to iFlu, but had a robust increase in overall antibody levels following alum adjuvanting. We assigned F2 mice into two arms, as in our initial experiment (iFlu immunization alone, and iFlu immunization adjuvanted with alum). Based on the phenotypic variation in this F2 population, we have identified six quantitative trait loci (QTL) contributing to different aspects of these variable immune responses. These include four loci that only have an effect on antibody responses with unadjuvanted iFlu, one locus that only has an effect following alum-adjuvanted iFlu, and one locus that has an effect in both treatment groups. Deconvolution of the mechanisms underlying these loci will help identify pathways critical to understanding and developing novel immunization and adjuvanting strategies.

312 **Characterizing the influence of genetic variation on cell states** Selcan Aydin[1], Daniel A Skelly[1], Ted Choi[2], Laura G Reinholdt[1], Christopher L. Baker[1], Gary Churchill[1], Steven C Munger[1] [1]The Jackson Laboratory, [2]Predictive Biology, Inc.

Genetic variation leads to phenotypic variability in pluripotent stem cells which limits their use in regenerative medicine. Recent studies have investigated the impact of genetic variation on pluripotency maintenance and differentiation capacity. However, our understanding of how differences in the pluripotent state influence gene regulation in later stages of development is limited. In this study, we present a genetic characterization of neural progenitor cell (NPC) lines that are differentiated from embryonic stem cell (ESC) lines derived from genetically diverse Diversity Outbred (DO) mice. We have measured the expression of more than 14,000 genes in 186 DO NPC lines. For 127 of these DO lines, we quantitated over 12,000 genes in both genetically identical ESC and NPCs. Gene expression showed variable agreement between the two cell states. Neural development-related genes were more abundant, while genes involved in pluripotency maintenance had lower abundance in NPCs compared to ESCs. Genetic diversity significantly influenced transcript abundance in NPCs, with over 90% of measured transcripts exhibiting non-zero heritability. Genetic mapping identified 4,060 expression quantitative trait loci (eQTL) at significance in NPCs, one-third of which were also observed in ESCs with concordant allele effects. The remaining two-thirds of eQTL were unique to NPCs and were overrepresented for genes involved in cell-cell signaling and nervous system development. Three distant eQTL hotspots, regions of the genome modulating the expression of many genes and likely harboring essential transcriptional regulators, were uniquely observed in NPCs, on Chromosomes 1, 10, and 11. Targets of the hotspot on Chromosome 1 were overrepresented for genes involved in mRNA processing, chromosome organization, and the cell cycle, particularly the spindle assembly checkpoint (SAC) and related processes. Notably, mediation

analysis identified *Pign* expression in the ESC state as the top candidate regulator. Recent work has implicated *Pign* as a crucial regulator of the SAC where aberrant *Pign* expression leads to SAC dysfunction and chromosomal missegregation. These findings suggest that genetic variation influencing gene expression in an early developmental cell state (ESC) can impact gene regulation in a more advanced developmental cell state (NPC).

313 **Leveraging Mammalian Genetics to Silence Infectious Diseases** Clare M. Smith Molecular Genetics and Microbiology, Duke University

A key feature of biological systems is genetic diversity. The fundamental importance of this diversity in evolutionary processes cannot be overstated: it is essential for population survival against challenges such as environmental change or attack by novel pathogens. This genetic diversity also presents extraordinary difficulties for infectious disease researchers defining the mechanisms of host and pathogen interactions that underly disease. Dissecting mechanisms at the molecular level is especially difficult when diversity is ignored and circumvented by focusing on genetically uniform populations, such as single inbred mouse lines. Despite some success, these approaches cannot address important biological and medical problems in which genetic diversity is most probably the fundamental element. For example, the outcome of infection with *Mycobacterium tuberculosis* (*Mtb*) varies dramatically between individuals; ranging from asymptomatic infection, to active and lethal disease. While the basis for these heterogeneous reactions is poorly understood, there is significant evidence that genetic diversity is a major underlying element. In the Smith Lab, we approach this problem by leveraging new mammalian and bacterial genetic resources to study each of these variables in isolation and in combination. Host diversity is modeled using mammalian genetic panels including the BXD, Collaborative Cross (CC) and Diversity outbred (DO) panels. Bacterial variation is concurrently incorporated using new genetic reporters or libraries of *M. tuberculosis* mutants (TnSeq). Using this highly tractable "dual genome" system, our research program focuses on defining the mechanisms by which genetic variation in the host and pathogen impact interventions and outcomes to tuberculosis in model systems and human patients. By combining both host and bacterial genetics approaches, we are defining the host pathways that mediate protection, and the bacterial tactics used to exploit and evade them.

314 **Natural partial loss of function variants in *SEL1L* rescue NGLY1 deficiency by altering ERAD and improving proteasome function** Travis Tu›ifua, Clement K Chow Human Genetics, University of Utah

N-glycanase 1 (NGLY1) deficiency is a rare disease caused by autosomal recessive loss of function mutations in the *NGLY1* gene. Patients suffer from movement disorder, developmental delay, liver dysfunction, and alacrima. NGLY1 removes N-linked glycans from glycoproteins in the cytoplasm and is thought to help clear misfolded glycoproteins from the endoplasmic reticulum (ER) through the ER associated degradation (ERAD) pathway. Despite this, the physiological significance of NGLY1 in ERAD is not understood. The best characterized substrate of NGLY1 is NRF1, a transcription factor that upregulates proteasome expression and the proteasome bounce back response.

Our lab created a *Drosophila* model of NGLY1 deficiency that faithfully recapitulates disease phenotypes in patients, including movement disorder, seizures, and lethality. We performed a *Drosophila* modifier screen using this model of NGLY1 deficiency and identified a number of modifiers that reduce the lethality of the model. In particular, we identified two putative loss of function variants in *SEL1L*: S780P and Δ806-809. Both variants are localized in the SEL1L cytoplasmic tail, an uncharacterized domain of the protein. SEL1L is a component of the ERAD complex that retrotranslocates misfolded proteins from the ER to the cytoplasm for degradation.

To test the interaction between these *SEL1L* variants and *NGLY1*, we created CRISPR mutant fly lines that carry these *SEL1L* variants in a common genetic background and tested them with our model of NGLY1 deficiency. We determined that these variants are partial loss of function. Validating our screen, the $SEL1L^{P780}$ and $SEL1L^{\Delta 806\text{-}809}$ variants increase the survival of the NGLY1 deficiency model, compared to the $SEL1L^{S780}$ variant. Further, we found that the $SEL1L^{P780}$ and $SEL1L^{\Delta 806\text{-}809}$ variants are protective against proteasome inhibition, leading to increased survival, in heterozygous *NGLY1* null flies. We also find that these variants modify general ERAD function. We hypothesize that these SEL1L variants modify NGLY1 deficiency through NRF1 signaling and ERAD. These results will provide new insights into the role of NGLY1 in ERAD and the etiology of NGLY1 deficiency. SEL1L is a strong candidate modifier gene in patients, where variability in presentation is common.

315 **The *Drosophila melanogaster* enzyme Glycerol-3-phosphate dehydrogenase (GPDH1) interacts with Target of rapamycin (Tor) to control larval growth.** Shefali A Shefali, Madhulika Rai, Jason M Tennessen Biology, Indiana University Bloomington

Animal development requires that nutritional cues are properly integrated with signaling pathways and gene expression networks. Thus, nutrient-sensing proteins play an essential role in coordinating nutrient availability with growth and maturation. Although substantial work has been conducted on the endocrine regulation of carbohydrate metabolism,

questions remain about how changes in glycolysis, itself, is communicated across tissues. Here we investigate this question using the fruit fly, *Drosophila melanogaster*, which is ideally suited for studying interorgan communication. Our preliminary studies reveal that glycerol-3-phosphate dehydrogenase 1 (GPDH1), a key enzyme that regulates abundance of the glycolytic intermediate dihydroxyacetone phosphate (DHAP), interacts with the nutrient sensor Target of rapamycin (Tor) in the larval fat body to control brain growth. Specifically, when Tor activity is inhibited within the fat body of *Gpdh1* mutant larvae, the brain experiences ectopic growth and ultimately becomes tumorous. We have also determined that this overgrowth phenotype is associated with excess cell proliferation within the brain optic lobe. As an extension of these studies, we have also determined that Tor and GPDH1 act in a negative feedback loop, where Tor inhibition in the fat-body leads to increased GPDH1 expression, which depletes the DHAP pool and further suppresses Tor signaling. Overall, our studies demonstrate how changes in glycolytic flux affect growth signaling and hold the potential to uncover a fundamental mechanism by which GPDH1 and Tor non-autonomously regulate tissue growth in response to changes in carbohydrate metabolism.

316 **Time Flies, how? Unlocking the Secrets of Aging** Hongjie Li Baylor College of Medicine

Aging phenotypes have been observed and described for centuries and a number of different aging hypotheses have been proposed. However, several critical questions remain largely unaddressed in complex organisms. For example, do different cell types age at different rates? If yes, which cell types age the fastest across the whole body?

Here I will present our recent work on the Aging Fly Cell Atlas, a single-nucleus transcriptomic map of the whole aging *Drosophila*. We characterize 163 distinct cell types and perform an in-depth analysis of changes in tissue cell composition, gene expression, and cell identities. We further develop aging clock models to predict the fly age. Combining all aging features, we find unique cell type-specific aging patterns and could quantitatively rank the aging rate for all types. This atlas provides a valuable resource for studying fundamental principles of aging in complex organisms. Based on this platform, we could now evaluate how pro-aging and pro-longevity mechanisms impact different cell types across the entire fly. In addition to Aging Fly Cell Atlas, I will also share one unpublished work on how lifespan-extending treatment affects the fly aging at cellular resolution.

317 **Extracellular vesicles mediate venom protein function in the parasitoid wasp *Ganaspis hookeri*** Nathan T. Mortimer[1,2,3], Nicholas M. Bretz[1,3], Chris Lark[3], Jeremy D. Driskell[4] [1]Department of Biochemistry & Biophysics, Oregon State University, [2]Linus Pauling Institute, Oregon State University, [3]School of Biological Sciences, Illinois State University, [4]Department of Chemistry, Illinois State University

Organisms frequently encounter potential pathogens in their environments, and understanding the molecular mechanisms that underlie host-pathogen interactions can shed light on immunity and cell signaling. *Drosophila melanogaster* larvae are commonly infected by parasitoid wasps, and this *Drosophila*-parasitoid interaction serves as a model system to better understand immunity and host-pathogen relationships. In this system, infected flies mount a robust cellular immune response to infection. To overcome host immunity parasitoids have evolved venom proteins which target specific host immune mechanisms, along with host metabolism and development, and is transferred directly into the larval hemocoel during infection. The venom from the parasitoid wasp species *Ganaspis hookeri* blocks immune cell activation in infected hosts, thereby inhibiting the ability of the host to mount an effective immune response. This venom activity is mediated by a unique venom-specific isoform of the SERCA (Sarco/endoplasmic reticulum Ca^{2+}-ATPase) calcium pump (vSERCA). Immune cell activation is dependent on a calcium burst normally mounted by hemocytes following infection, and vSERCA activity counters the intracellular rise in calcium levels, rendering infected larvae unable to mount an effective response against the wasp egg. vSERCA is a multipass transmembrane protein and so is unlikely to be stable in the aqueous environment of the venom. Instead, we find that vSERCA and other venom proteins are packaged into venom-specific extracellular vesicles. Our biophysical analysis, using ultracentrifugation, nanoparticle tracking analysis, dynamic light scattering, and tunable resistive pulse sensing suggests the presence of distinct vesicle classes in *G. hookeri* venom. Identification of protein content of purified vesicles further supports the idea that venom proteins including vSERCA can be stored as cargo within venom vesicles. We hypothesize that these vesicles provide a delivery mechanism to mediate transport of cargo into host immune cells, and we find that vesicle disruption alters venom activity in *ex vivo* calcium assays. This vesicle-mediated packaging and delivery machinery represents an important parasitoid virulence mechanism, and understanding this mechanism will provide insight into host-parasite interactions, and possible applied uses in delivery of therapeutic agents or biopesticides.

318 **A *Drosophila* model to investigate cell-intrinsic and non- autonomous toxicity of C9orf72 familial ALS and FTD** Isabel Hubbard[1], Josh Dubnau[1,2] [1]Neurobiology and Behavior, Stony Brook University, [2]Anesthesiology, Renaissance School of Medicine, Stony Brook University

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are fatal neurodegenerative diseases that lead

to severe cognitive and motor defects in patients. Both feature aggregation of the protein TDP-43. Non-cell autonomous effects are a hallmark of these disorders, which we have previously reported to be mediated at least in part by endogenous retroviruses. The most common genetic cause of both familial ALS and FTD is a hexanucleotide repeat sequence consisting of four guanine and two cytosine nucleotides (G_4C_2) in the first intron of the gene C9orf72, which can produce expansions of up to hundreds to thousands of repeats in patients. The C9orf72 repeat expansion is bidirectionally transcribed into sense and anti-sense RNA foci. Additionally, a non-canonical translation mechanism known as repeat-associated non-ATG translation (RAN translation) allows the expansion to be translated into five different dipeptide repeats (DPRs): GA, GP, GR, PA, and PR. Previous work has shown that multiple forms of the repeat cause premature death and neurodegenerative effects in animal models, including *Drosophila,* when expressed neuronally, with the arginine-rich DPRs producing the highest level of toxicity. Effects on glia, impacts on non-cell autonomous toxicity, and on activation of retrotransposons by the DPRs and RNA repeats respectively are more poorly understood. Here, we use glial cell type-specific expression of individual DPRs, of RNA repeat-only, or of the "pure" G_4C_2 repeat that is capable of producing both DPRs and RNA repeats, to systematically investigate both cell-intrinsic and non-cell autonomous toxicity of each of these components. With pan-glial expression, the pure G_4C_2 repeat and GR dipeptide are equally the most toxic forms of the repeat; but when focally expressed in SPG, the pure G_4C_2 repeat is more toxic than is the GR dipeptide. Imaging experiments reveal that while GR is the most toxic C9 transgene in the cells that it is expressed in, the pure G_4C_2 repeat causes the greatest degree of non-cell autonomous toxicity to other glial subtypes and neurons. The G_4C_2 and GR repeats, namely those capable of producing the GR DPR, also each triggered replication of the fly endogenous retrovirus mdg4, which has been shown to mediate non-cell autonomy in TDP-43 fly models. Experiments to untangle the differences in non-cell autonomy between the pure repeat and GR flies, and how mdg4 activation might be involved, are currently in progress.

319 **Yolk protein 3 (YP3) has both metabolic and immune functions in *Drosophila melanogaster.*** Krystal Maya-Maldonado, Amber Chou, Natania Kurien, Nichole A. Broderick Biology, Johns Hopkins University

The *Drosophila* YP3 protein is one of three yolk proteins involved in vitellogenesis; a process in which yolk accumulates in the oocyte to provide energy for maturation. Classically, the function of YP3 has been focused on reproduction. However, our evidence suggests it also has functions in immunity and metabolism. Previous transcriptional and proteomics studies in *Drosophila*, indicate that YP3 is altered in response to both the microbiome and during systemic infection. Comparing the YP3 protein sequence to the Conserved Domain Database, we identified conserved domains related to lipid metabolism, including a lipase conserved domain, an alpha/beta hydrolase domain, and a Triacylglycerol lipase domain. Triacylglycerol (TAG) is the most important caloric source and in *Drosophila*, TAG metabolism is crucial for several physiological processes. As such, TAG represents an important reservoir to survive stress conditions such as starvation or food deprivation. Using a loss of function YP3 mutant fly line (ΔYP3) we conducted starvation resistance assays and found that in presence of the microbiome, ΔYP3 female flies are slightly less sensitive than control flies to starvation. This difference is greatly accentuated in germ free (axenic) conditions. While control female flies are less sensitive to starvation than control flies with a microbiome, we observe that ΔYP3 germ-free females are significantly more sensitive to starvation. This suggest that YP3 has a role in the energetic status of the host that is modified by the presence of the microbiome. We next looked for potential protein motifs and domains in the YP3 protein sequence involved in immunity. We conducted a protein structure prediction and found an antimicrobial structure related to lysin proteins of phages. Such lysin proteins are peptidoglycan hydrolases that degrade the peptidoglycan layer causing bacterial lysis of both Gram-positive and Gram-negative bacteria. YP3 mutant female flies (ΔYP3) systemically infected with the Gram-negative bacterium, *Pectobacterium carotovorum (Ecc15)* exhibited higher pathogen load than controls, suggesting a role for YP3 in pathogen clearance during systemic infection. Considering our evidence, we propose that YP3 exerts both metabolic and immunity functions in the host.

320 **Tau functions in glia lipid droplet formation and protects against neuronal ROS with implications in disease progression.** Lindsey D Goodman[1], Isha Ralhan[2], Ye-Jin D Park[1], Matthew J Moulton[1], Oguz D Kanca[1], Ziyaneh S Ghaderpour Taleghani[1], Kanae Ando[3], Maria Ioannou[2], Hugo J Bellen[1] [1]Baylor College of Medicine, [2]University of Alberta, [3]Tokyo Metropolitan University

Toxic reactive oxygen species (ROS) become aberrantly upregulated in Alzheimer's Disease (AD) and tauopathies, causing oxidative stress (OS). Connections between ROS and lipid metabolism came upon our discovery that glia form lipid droplets (LD) in response to neuronal OS. This involves the active production and export of peroxidated (O_2^-)-lipids from stressed neurons, the shuttling of these lipids to glia via apolipoproteins, endocytosis of the lipids into glia, and their incorporation into LD. LD-mediated breakdown of these O_2^--lipids effectively reduces ROS levels in both neurons and glia, protecting the cells from damage. Evidence is accumulating that defects in glial LD formation contributes to AD disease progression. Here, we considered connections with the important disease-associated protein, Tau. Using established tauopathy Drosophila models, we specifically overexpressed Tau in neurons or glia, finding that Tau overexpression in glia disrupts LD formation in response to neuronal ROS and leaves these cells vulnerable to damage. We further probed for a physiological function of

Tau in glial LD formation, developing a novel and robust loss-of-function (LOF) fly allele and improving upon shortcomings of previously published *tau* LOF alleles. This revealed that fly *tau* loss results in reduced motor abilities and lifespans which can be rescued by re-introducing *tau* in a dosage manner with one or two copies of a genomic rescue construct. Using glia-specific rescue of fly *tau* in our mutant flies and RNAi targeting fly *tau*, we observed that Tau loss in glia is a strong contributor to these phenotypes. Mechanistically, Tau is required for glia to properly form LD in response to neuronal ROS and loss of glial Tau leaves these cells vulnerable to ROS-induced damage. Other microtubule associated proteins, Futsch and Ensconsin, were also found to be important for glial LD formation, supporting that it is Tau's function at microtubules underlying its role in this process. Last, we found that the function of Tau in glial LD formation is conserved in mammals using primary rat neuron:astrocyte co-cultures. Overall, this study uncovers an important role of Tau in glial LD formation in response to O_2^--lipid production in neurons. As defects in glial LD formation are seen with both Tau loss and overexpression, this work reveals that Tau imbalance is associated with sensitivity to ROS and has numerous implications in Drosophila and disease research.

321 **Tumor cytokine-induced hepatic gluconeogenesis contributes to cancer cachexia: insights from full body single nuclei sequencing** Ying Liu[1,1], Ezequiel Dantas[2], Miriam Ferrer[3], Yifang Liu[4], Aram Comjean[1], Emma E Davidson[3], Yanhui Hu[1], Marcus D Goncalves[2], Tobias Janowitz[3], Norbert Perrimon[1,5] [1]Dept. of Genetics, Harvard Medical School, [2]Weill Cornell Medicine, [3]Cold Spring Harbor Laboratory, [4]Harvard Medical School, [5]Howard Hughes Medical Institute

A primary cause of death in cancer patients is cachexia, a wasting syndrome attributed to tumor-induced metabolic dysregulation. Despite the major impact of cachexia on the treatment, quality of life, and survival of cancer patients, relatively little is known about the underlying pathogenic mechanisms by which tumors influence host metabolic homeostasis. Here, through examining the full body transcriptome of flies with *yki*^{act} gut tumors at single nuclei resolution, we systemically analyze the tumor-induced reprograming of host metabolism. Interestingly, we observe an abnormally increased level of hepatic gluconeogenesis in these flies. Using Drosophila and murine models, we demonstrate that hepatic gluconeogenesis is stimulated by tumor-induced Upd3/IL-6/JAK-STAT signaling. Our data further indicate that locally elevated hepatic gluconeogenesis is a causative factor of systemic metabolic defects that lead to poor prognosis. Altogether, our study uncovers a conserved role for Upd3/IL-6/JAK-STAT signaling in inducing tumor-associated host metabolic dysregulation, and as such, provides insights into the pathogenesis of human IL-6 signaling in cancer cachexia.

322 **The conserved transcription factor Hmx/HMX1 establishes a positive feedback loop to specify blue-sensitive photoreceptor fate.** Joseph Bunker[1], Mhamed Bashir[1], Sydney Bailey[2], Brooke Cayting[2], Jens Rister[2] [1]Biology, Umass Boston, [2]Umass Boston

The function of the conserved Hippo pathway in regulating growth is well understood, but recent evidence suggests an additional key role in cell differentiation. The nexus of the pathway, the Warts/Wts kinase (LATS1/2 in mammals), controls growth by repressing the co-activator and oncoprotein Yorkie/Yki (YAP/TAZ) via phosphorylation. Unphosphorylated Yki activates genes that promote growth and activates its repressor Wts, resulting in a regulation of Yki activity via negative feedback. However, the pathway is rewired in the *Drosophila* retina to control differentiation of post-mitotic color photoreceptors (PRs): Yki represses *wts* at the transcriptional level, thereby establishing a positive feedback loop that allows the pathway to function as a bi-stable switch. Furthermore, Yki promotes the blue-sensitive Rhodopsin Rh5 and represses the green-sensitive Rh6. Thus, either Wts represses Yki, giving rise to green-Rh6 (Hippo ON) fate or Yki represses *wts*, giving rise to blue-Rh5 (Hippo OFF) fate. The mechanism that establishes the positive feedback loop for the binary color fate decision is not known.

Here we elucidate a novel role for the conserved Q50 homeodomain transcription factor (TF) H6-like homeobox (Hmx) in rewiring the Hippo pathway to establish the Yki positive feedback loop. Yki, in combination with the PR permissive factors Otd and Tj, activates *Hmx* exclusively in Rh5/Hippo OFF PRs. *Hmx* knockdown causes a loss of Rh5/Hippo OFF PRs, while ectopic Hmx causes their gain, indicating that Hmx is necessary and sufficient to specify Rh5/Hippo OFF fate. Through epistasis analyses we demonstrate that Hmx acts downstream of Yki to repress both *Rh6* and *wts.* Moreover, we performed a luciferase reporter assay to show that Hmx antagonizes a second Q50 homeodomain TF, Pph13, to repress the *Rh6* promoter *in vitro* through a conserved Q50 motif. Taken together, the convergence of active Yki with PR-specific permissive factors allows for the activation of Hmx, which in turn represses *Rh6* and *wts,* thereby mediating a positive feedback loop to give rise to robust Yki activation and Rh5 expression. Our findings identify Hmx as a novel repressor of the Hippo pathway in terminal PR differentiation and demonstrate how context-specific Hippo pathway interactions give rise to unique neuronal fates.

323 **Promoter-proximal pausing of RNA Polymerase II as a key regulator of morphogenetic furrow progression in Drosophila larval eye development** Bonnie M Weasner[1], Brandon Weasner[1], Justin Kumar[2] [1]Biology, Indiana University, [2]Indiana University

The foundation of development for any organism, tissue or cell is the precise spatio-temporal control of gene expression. As such, various molecular mechanisms exist to ensure this process is executed properly. A unique mechanism deployed in higher eukaryotes, including flies and humans, is promoter-proximal RNA polymerase II (Pol II) pausing. During this type of transcriptional regulation, Pol II in conjunction with the DSIF and NELF protein complexes is recruited to the gene promoter and begins elongation but will stall ~20-60bp downstream of the transcriptional start site (TSS). Paused Pol II can then be released by the P-TEFb complex thereby allowing for productive elongation and gene expression. It has been proposed that this method of transcriptional regulation allows for synchronous gene expression in dynamically developing tissues.

We recently discovered that Pol II pausing plays a key role during the development of the eye-antennal disc. We find disruption of pause release in cells ahead of the advancing morphogenetic furrow leads to severe disruption of patterning, photoreceptor development and in some cases complete ablation of the compound eye. Furthermore, we determined these defects are the result of a halt in furrow progression rather than a lack of furrow initiation. Using CUT&RUN techniques we have examined the binding profile of stalled and productively elongating Pol II in whole eye-antennal discs and as expected find many genes which are key to proper specification, patterning and differentiation of the eye disc are subject to Pol II pausing. We are now combining INTACT nuclei isolation and CUT&RUN techniques to fine tune our analyses to specific cell populations within the disc. Our goal is to form a more complete understanding of the extent to which Pol II pausing influences development of the Drosophila compound eye.

324 **The histone acetyltransferase Nejire is recruited to the genome by the pioneer factor Zelda and activates gene expression during the maternal-to-zygotic transition.** Audrey Marsh[1], Sergei Pirogov[2], Abby Ruffridge[1], George Hunt[2], Tyler Gibson[1], Katherine Hullin[1], Mattias Mannervik[2], Melissa Harrison[1] [1]University of Wisconsin-Madison, [2]The Wenner-Gren Institute

At fertilization, the new diploid genome carries signatures left by the sperm and the egg. These features are removed from the zygotic genome as it is reprogrammed to totipotent state. At this time, the zygotic genome is transcriptionally quiescent and is gradually activated by maternally encoded factors loaded into the egg. Zygotic genome activation (ZGA) is controlled by a specialized set of transcription factors, called pioneer factors, that promote chromatin accessibility. The pioneer factor Zelda (Zld) is an essential activator of zygotic transcription in *D. melanogaster*. Before ZGA, the chromatin is in a naïve state with nucleosomes largely devoid of post-translational modifications. Zld-bound sites, however, are enriched for histone acetylation, suggesting a histone acetyltransferase (HAT) is functioning with Zld to promote ZGA. We identified that Nejire (Nej), the fruit fly homolog of the HAT family p300/CBP, co-occupies 1,202 loci with Zld in the early embryo. Indeed, recruitment of Nej and histone acetylation at these sites requires Zld. Similarly, in tissue culture histone acetylation is increased at regions where Zld functions as a pioneer factor. To determine if Nej and acetylation are necessary for ZGA, we degraded Nej and found 786 downregulated genes. These data show that pioneer factor recruitment of a HAT promotes histone acetylation and ZGA. To provide temporal control over Nej inactivation, we developed an optogenetic system. As expected, inactivation decreased histone acetylation, but counterintuitively did not disrupt Nej chromatin occupancy. Thus, we used this tool to study the role of histone acetylation in ZGA. After assaying transcription upon light exposure, we identified only a subset of Nej-dependent genes decreased in expression. Thus, there are catalytic-dependent and independent function of Nej in ZGA. To further define the relationship between Zld, Nej, histone acetylation and chromatin accessibility, we used a drug to catalytically inhibit Nej in tissue culture. We found inhibition of histone acetylation did not change chromatin accessibility, separating Zld-mediated chromatin accessibility from acetylation. Preliminary data from the embryo similarly suggests that histone acetylation is dispensable for chromatin accessibility. Combined with data from vertebrates, our work supports a conserved mechanism for ZGA in which pioneer factors prime the genome for activation by recruiting HATs to *cis*-regulatory regions.

325 ***Drosophila* hnRNP M homolog Rumpelstiltskin promotes Homie barrier activity and regulates Polycomb-dependent 3D interactions** Savanna F. Lyda[1,2], Catherine E. McManus[1], Juan Manual Caravaca[1], Yang Chen[1], Dagyeong Yang[1,2], Elissa P. Lei[1] [1]National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, [2]Biological Sciences, University of Maryland

Chromatin insulators are DNA-protein complexes that help maintain genome organization by creating boundaries that separate active and inactive chromatin and control promotor-enhancer interactions. In *Drosophila,* Homing insulator at eve (Homie) is an insulator sequence that can regulate interactions between *even-skipped* (*eve*), a Polycomb Group (PcG) regulated gene, and its cis-regulatory elements. Homie also acts as a barrier to prevent PcG repressive chromatin spreading into the neighboring essential *TER94* ubiquitously expressed gene. The mechanism behind Homie insulator activity and the requirement of trans-acting factors is unknown.

To this end, we determined that Homie barrier activity in all tissues tested relies on Rumpelstiltskin (Rump), as well as two chromatin insulator proteins, Centrosomal Protein 190kD (Cp190) and CCCTC-binding factor (CTCF). To address whether

chromatin compaction at the *eve-TER94* locus may be altered, we performed 3C analysis in Kc cells after depletion of Rump, Cp190, or CTCF. We found an increase in *cis*-looping within the PcG domain after Rump but not Cp190 or CTCF depletion. We also detected H3K27me3 spreading onto *TER94* in Rump-depleted cells and increased H3K27me3 levels at PcG domains genome-wide by ChIP-seq. To visualize potential changes in 3D genome organization after Rump depletion, we utilized Oligopaint DNA FISH to analyze pairwise PcG domain interactions in Kc cells. This analysis revealed that distances between distal PcG domains increase after Rump depletion. However, depletion of Cp190 or CTCF showed no effect, suggesting Rump regulates PcG through a mechanism unrelated to insulator regulation. We next performed immunofluorescence and ChIP-seq assays to detect Polycomb (Pc), a protein in the PRC1 complex, in Kc cells after Rump depletion. These data show global reduction of chromatin bound Pc after Rump depletion. Taken together, in Rump-depleted cells we observe increased compaction of the PcG domains *in cis* yet decreased compaction *in trans*. Future experiments aim to elucidate how Rump affects the localization of Pc to chromatin and influences reciprocal *cis* and *trans* PcG interactions. Through understanding these interactions, we seek to gain additional insight into how Rump promotes Homie barrier activity.

326 **Damage-Responsive enhancers activate the regeneration program by sensing sequential inputs** John Quinn, Robin Harris Arizona State University

In organisms that can regenerate, thousands of genes are upregulated following damage in order to regenerate missing tissue. Only recently has it been identified how these genes become activated following damage. Damage-Responsive (DR) enhancers are regeneration regulatory regions that recognize damage stimuli and respond by activating genes essential for regeneration. To study DR enhancer activity, our lab uses the wing imaginal disc, which is highly regenerative. Currently, we do not know how DR enhancers become activated following damage. My work focuses on identifying the damage-induced signals that activate DR enhancers to promote regeneration. To study regeneration, damage is caused by a genetic ablation system called DUAL control, consisting of a bipartite gene expression system that induces apoptosis in the disc while simultaneously activating the Gal4/UAS system in the surrounding regenerating cells to knockdown or overexpress any gene of interest. This system has been paired with GFP reporters of DR enhancers to visualize their activity during regeneration.

Using these techniques, it was found that the transcription factor of the JNK signaling pathway is necessary for enhancer activation following damage, but developmental instances of JNK expression is insufficient for enhancer activation. An important question that remains unresolved, is whether a damage-induced factor is needed along with JNK signaling, or is it differences in levels of JNK signaling that is required for enhancer activation. To narrow down potential candidates involved in DR activation, a damage stimulus was initiated while blocking cell death. It was found that DR is capable of being activated independent of cell death. This suggests that the activating factor is likely a direct downstream targets of JNK, one of those being JAK/STAT, which is known to be involved in regeneration. To test if the transcription factor for the JAK/STAT pathway is involved, a new DR transgenic reporter was created lacking the JAK/STAT transcription factor binding sites which reduced enhancer activation. JAK/STAT is not only required for full activation of DR but also controls the spatial domain where DR is expressed. Upon knockdown of the JAK/STAT pathway DR expression is limited to the cells directly adjacent to the wound.

Additionally, I have demonstrated that lower levels of JNK expression seen in a developmental context are insufficient for enhancer activation, and high levels of JNK expression that occur during damage are required for enhancer activation. My work has shown that both damaged-induced factors and levels of JNK signaling are essential for DR activation. Overall, my research aims to identify the minimal components necessary for DR activation, which might be used to activate DR in non-regenerative tissue to permit regeneration.

327 **Bicoid-nucleosome competition sets a concentration threshold for transcription** Eleanor Degen, Shelby Blythe Molecular Biosciences, Northwestern University

Concentration gradients of maternal transcription factors establish patterns of gene expression during a time in early embryonic development characterized by frequent mitotic divisions, rounds of genome replication, and chromatin reorganization. In the *Drosophila* embryo, an exponential gradient of the transcription factor Bicoid (Bcd) activates the earliest expressed patterning genes across the anterior-posterior axis. Bcd successfully navigates the chromatin of the replicating genome to bind its sites and facilitate transcription. However, we do not fully understand how genomic context leads to differential transcriptional outputs across Bcd concentrations. We aim to model how enhancer sequence, chromatin, and DNA replication together determine the Bcd concentration-sensitivity of the transcriptional process. By live-imaging an MS2-MCP transcriptional reporter for the Hunchback P2 (HbP2) enhancer, we have found that the length of the delay between mitosis and the initiation of transcription uniquely reflects Bcd concentration-sensitive regulation. We have defined a stochastic model of transcriptional regulation that accurately predicts transcriptional onset times using mathematical descriptions of Bcd-nucleosome competition for occupancy and the probability of DNA replication at HbP2. Our work suggests that Bcd's ability to outcompete nucleosomes dictates a Bcd concentration threshold for expression, while DNA replication limits the rate of

transcriptional activation at high concentrations where Bcd readily outcompetes nucleosomes. Disrupting nucleosome stability by promoting pioneer factor binding to HbP2 both expands the MS2 expression domain and preserves onset time variance at high concentrations, supporting these hypotheses. An understanding of the critical parameters of nucleosome positioning, stability, and replication dynamics should allow for genome-wide predictions of the concentration-sensitivity of Bcd binding events.

328 **Spatiotemporal regulation of *orthodenticle* during early embryogenesis and retinal development in *Drosophila*** Jungwon Lee, Campbell Berry, Sosina Abuhay, Grace Carey, Marjorie Wang, Rhea Datta Hamilton College

Activating and expressing the right gene, in the right tissue, at the right time is critical for proper development. Gene expression is carefully coordinated by direct binding events between cell-specific transcription factor proteins (TFs) and specific cis-regulatory elements (CREs). This two-part system regulates when, where, and at what levels the coding region of a corresponding gene is transcribed. Understanding the intrinsic mechanisms of TF-CRE interactions remains a primary challenge in developmental biology. Adding a layer of complexity to this is the fact that the same gene is often reused in multiple tissues. As a result, the development of different organ systems is contingent on the correct regulation of a shared gene which is regulated by modular CREs. The modularity built into CREs is a source of robust gene expression, but the mechanisms that dictate whether a CRE is redundant, reused, or redeployed remain poorly understood. Here we perform a detailed examination of CRE redundancy and pleiotropy at the highly conserved *otd* locus in *Drosophila* - which contains CREs that regulate the embryonic and retinal expression of *otd*. We identify multiple, redundant otd CREs that are active during embryogenesis and retinal development. We also identify TF binding sites that are enriched in embryonic CREs vs. retinal CREs, and examine whether these specific sequences inform spatiotemporal CRE activity. Finally, we aim to understand the role of chromatin accessibility at the regulatory loci of genes that are active in two developmental contexts.

329 **Integrator-mediated clustering of poised RNA polymerase II synchronizes histone transcription** Feiyue Lu[1], Brandon J Park[2], Rina Fujiwara[3], Jeremy E Wilusz[3], David S Gilmour[2], Ruth Lehmann[4,5], Timothee Lionnet[6,7,8] [1]Institute for Systems Genetics, NYU School of Medicine, [2]Center for Eukaryotic Gene Regulation, Department of Biochemistry and Molecular Biology, The Pennsylvania State University, [3]Verna and Marrs McLean Department of Biochemistry and Molecular Pharmacology, Therapeutic Innovation Center, Baylor College of Medicine, [4]Whitehead Institute for Biomedical Research, [5]Department of Biology, Massachusetts Institute of Technology, [6]Institute for Systems Genetics, NYU Grossman School of Medicine, [7]Department of Cell Biology, NYU Grossman School of Medicine, [8]Department of Biomedical Engineering, NYU Tandon School of Engineering

Dynamic clustering of transcription players, including RNA polymerase II (Pol II), is thought to rely on multivalent interactions of their intrinsically disordered regions, thereby enhancing active transcription. Using the histone locus bodies (HLBs) of *Drosophila* nurse cells as a model, we find that Pol II forms long-lived, transcriptionally poised clusters distinct from liquid droplets, which contain unbound and paused Pol II. Depletion of the Integrator complex endonuclease module, but not its phosphatase module or pausing factors disperses these Pol II clusters, leaving HLBs intact. Consequently, histone transcription fails to reach peak levels during S-phase and aberrantly spills over throughout the cell cycle. We propose that clustering sequesters numerous poised Pol II molecules near gene promoters to ensure synchronous and efficient gene activation at desired times.

330 **Establishing the zebrafish as a model to study the pharynx** Kiyohito Taimatsu, John Prevedel, Aniket V Gore, Amit Puthan, Miranda Marvel, Daniel A Castranova, Madeleine Kenton, Gennady Margolin, Andrew Davis, Van Pham, Brant Weinstein NICHD, NIH

The pharynx and associated organs have important roles in breathing, eating, drinking, digesting, speaking and protecting the body from infection. Pharyngeal dysfunction can manifest as dysphagia, persistent palatal displacement, respiratory function decline, or exercise intolerance. Secondary complications are serious and life threatening and can include aspiration pneumonia, weight loss, and death. However, pharynx development is not well understood, in large part because of the inaccessibility of the developing pharynx to observation and experimental manipulation in most model organisms. I am establishing the zebrafish as a powerful model for observation and genetic and experimental analysis of pharynx development. Although the pharynx is more accessible in zebrafish than in mammalian models, it is still difficult to observe clearly because of its deep location and surrounding opaque tissues. I have developed powerful new tissue clearing methods customized for use with Hybridization Chain Reaction (HCR) to permit labeling and high-resolution imaging of pharyngeal tissues and cells even in older developing animals and adults. I have used these and other methods to describe developing and adult pharynx anatomy, and I have used scRNAseq to identify resident cell types of the pharynx and their gene expression signatures. My anatomical and molecular findings show the zebrafish pharynx is a complex structure with numerous specialized cell types, many of which correspond well to cell types identified in the mammalian pharynx. I have also used genetic screens to identify

pharynx-specific mutants that I am currently characterizing in detail. One mutant has more ionocytes and less mucous cells in the pharynx, suggesting a hidden balancing system between these cells, and demonstrating that genetic mutants can reveal new and unknown mechanisms in pharyngeal development. By developing new methods, uncovering mutants, and compiling fundamental information on pharyngeal anatomy and resident pharyngeal cell types, I am establishing the zebrafish as a valuable new model for experimental and genetic analysis of the pharynx.

331 **Dixdc1b is a novel downstream effector of Nckap1l (Hem1) during biliary system morphogenesis.** Kathryn M. Tuscano[1], Isabela M. Rivera Paz[1], Donavan S. O'Brien[1], Takuya Sakaguchi[2] [1]Cleveland Clinic Foundation, [2]Cleveland Clinic

Impaired formation of the biliary system contributes to cholestatic liver diseases. Cdk5 orchestrates branching morphogenesis of the intrahepatic biliary network by regulating its downstream effectors, including *nckap1l*, a Wave Regulatory Complex (WRC) component. We combined a forward genetic approach in zebrafish with unbiased computational quantification to identify a new mutation that genetically interacts with the *cdk5-nckap1l* pathway. The interacting mutation affects the *DIX Domain Containing 1b (dixdc1b)* gene, the homolog of a known substrate for Cdk5. *dixdc1b* mutant larvae show intrahepatic biliary network phenotypes similar to that in *nckap1l* mutant larvae. The genetic interaction between these two mutations is so strong that even double heterozygous larvae for *dixdc1b* and *nckap1l* consistently show a phenotype indistinguishable from *dixdc1b* homozygous mutant larvae, indicating that these two genes function in the same pathway. Overexpression of *dixdc1b* in *nckap1l* mutant larvae rescued all prominent intrahepatic biliary network phenotypes, including altered network branching pattern, actin dynamics, expression of WRC component proteins, and biliary system functions. In contrast, overexpression of *nckap1l* did not rescue the *dixdc1b* mutant phenotypes. These data together indicate that *dixdc1b* is a downstream effector of the *cdk5-nckap1l* pathway to regulate the branching morphogenesis of the intrahepatic biliary network. This study suggests that combined heterozygosity in components of this cascade may provide a genetic basis for some cases of cholestatic liver disease that may have been diagnosed as sporadic.

332 **Discovery of a new external organ in the zebrafish, an exciting model to study the immune response *in* and *ex vivo*** Daniel Castranova[1], Madeleine Kenton[1], Aurora Kraus[1], Jong Park[1], Marina Venero Galanternik[2], Gilseung Park[1], Daniel Lumbantobing[3], Miranda Marvel[1], James Iben[1], Louis Dye[1], Van Pham[1], Lucas Blevens[4], John K. Frazer[4], Brant M Weinstein[1] [1]NICHD, NIH, [2]University of Utah, [3]Smithsonian Institution, [4]University of Oklahoma

We recently discovered an external lobular structure on the outside of the adult zebrafish, just rostral to the gills and dorsal to the pectoral fin. The structure is only a few millimeters long, is not covered with scales or pigment cells, is transparent, and has a plexus of blood and lymphatic vessels on the inside. When removed, the lobe fully regenerates in a few weeks. The outer dermal layer of this lobe is teeming with immune cells, suggesting a role in immune surveillance. The lobe is easily removed and imaged and can be soaked in various antigens and other compounds to see how different cell types respond and interact. Interestingly, when lobes were soaked in fluorescently labeled SARS-CoV-2 spike protein, it was taken up by lymphatic vessels specifically, while lipopolysaccharide (bacterial) was taken up by goblet cells on the surface of the organ, and poly I:C (viral) was taken up by macrophages. Because it is external, transparent, and contains a variety of immune cells including T and B cells, neutrophils, and macrophages, and because zebrafish transgenic lines are available for high resolution imaging of immune, vascular, and other cell populations, this newly discovered tissue provides a superb model for *in vivo* and *ex vivo* imaging of the interaction between immune cells and their surrounding tissues, including blood and lymphatic vessels.

333 **Decoding Neutrophil Dynamics During Mycobacterial Infection Using Live Imaging, Single-Cell, and Dual Host-Pathogen RNA-Seq Approaches** Gopinath Viswanathan[1], Erika J Hughes[1,2], Ana María Xet-Mull[1], Eric M Walton[1], Graham Alexander[3], Devjanee Swain-Lenz[1,4], David M Tobin[5,6] [1]Molecular Genetics and Microbiology, Duke University, [2]University Program in Genetics and Genomics, Duke University, [3]Sequencing and Genomics Technologies Core Facility, Duke University, [4]3Sequencing and Genomics Technologies Core Facility, Duke University, [5]Molecular Genetics and Microbiolgy, Duke University, [6]Department of Immunology, Duke University

Tuberculosis (TB), caused by *Mycobacterium tuberculosis*, remains a substantial global threat claiming the lives of around 1.6 million people worldwide in 2021. It stands as the second most deadly infectious disease after COVID-19, emphasizing the urgent need for proactive measures to address its impact. TB granulomas, the pathological hallmark of TB infection are known to harbor neutrophils, but their role during mycobacterial pathogenesis has not been fully explored. Upon infection with *Mycobacterium marinum* (*M. marinum*), adult zebrafish form mature granulomas with conserved characteristics of human TB granulomas. Here we use Myco-GEM, a granuloma explant system in zebrafish, to assess neutrophil dynamics and to directly manipulate neutrophil biology during mycobacterial infection. Using long-term high-resolution confocal imaging, we found active recruitment of neutrophils to the interface between the granuloma's necrotic core and its cellular layers. We observed heterogeneous populations of neutrophils with discrete behaviors in different microenvironments within the granuloma both via microscopy and through single-cell RNA-seq analysis of granuloma-associated neutrophils. We describe

strategies using this platform to manipulate neutrophil behavior within granulomas both pharmacologically and genetically, revealing their host-detrimental functions. By conducting bulk dual RNA-seq analysis on granulomas with dysfunctional neutrophils, we identified that specific neutrophil populations exert diverse effects on both host immune cells and the mycobacteria. They were found to exhibit immunoregulatory functions and additionally, could modulate the expression of the mycobacterial DevR regulon, a set of genes responsive to stress conditions such as hypoxia and nitric oxide thereby promoting mycobacterial survival within the granulomas. These findings provide new insight into the regulation of immune responses and the complex interplay between neutrophils and mycobacteria in granulomatous environments.

334 **A high-throughput whole-animal screen to identify modifiers of atherogenic lipoproteins** Daniel Kelpsch[1], Lishann Ingram[1], Liyun Zhang[2], Yuki Lin[1], Ikrak Jung[2], Stefan Harry[1], Mira Sohn[1], Thomas Lectka[1], Rexford Ahima[2], Jeff Mumm[2], Steven Farber[1] [1]Johns Hopkins University, [2]Johns Hopkins School of Medicine

Metabolic dysfunction is the leading cause of worldwide mortality and exhibits complex etiology. Increased apolipoprotein B (ApoB)-containing lipoproteins (B-lps) is a hallmark of cardiovascular and metabolic diseases. However, these B-lps transport lipids through the plasma to peripheral tissues and are essential to life. A single ApoB molecule decorates each B-lp and is functionally essential. However, the cellular mechanisms that regulate ApoB and B-lp production, secretion, transport, and degradation remain to be fully defined. Human B-lp biology is remarkably conserved in the zebrafish, making it the ideal system for identifying novel mechanisms of ApoB modulation. Therefore, the Farber lab generated an in vivo chemiluminescent reporter of ApoB that does not disrupt ApoB function. We performed a high-throughput chemiluminescence whole zebrafish screen of 3000 compounds and identified 48 ApoB-lowering compounds. One hit, enoxolone, is reported to inhibit Hepatocyte Nuclear Factor 4α (HNF4α), an orphaned nuclear hormone transcription factor known to regulate the expression of B-lp synthesis genes. Further, a loss of function HNF4α allele reduces lipoproteins during development, phenocopying the effect of enoxolone. We hypothesize that enoxolone modulates lipoprotein levels by inhibiting HNF4α, and are testing this using pharmaco-genetic interaction studies. The results of these studies will demonstrate the utility of our whole-animal high-throughput chemical screening approach. Cinnamon oil also reduced ApoB in our screen. Using liquid chromatography to fractionate this complex oil, we identified a single chemical, eugenol, that specifically reduces ApoB levels in whole animals and circulation. However, the mechanism of action remains unknown. Our future goal is to identify how eugenol affects B-lp levels in zebrafish and confirm this effect in a mammalian model. Ultimately, this research aims not only to identify novel ApoB-modulating therapeutics that would improve metabolic disease outcomes but also to provide fundamental insights into the regulation and function of ApoB.

335 **The atypical cadherin-encoding gene *cdh16* directs establishment and plasticity of acoustic startle response thresholds** Zackary Marshall, Susannah Schloss, Nicholas Santistevan, Jessica Nelson Cell and Developmental Biology, University of Colorado Denver

Properly tuned sensory thresholds enable animals to navigate complex environments. Sensory threshold establishment, maintenance, and plasticity are disrupted in a variety of human neurological disorders, including ASD, schizophrenia, and migraine. Although these processes are crucial for species' fitness and proper neurological functioning, the underlying mechanisms are not well understood. Through a forward genetic screen, we now establish the calcium-dependent adhesion protein (cadherin) encoding *cdh16* gene as a critical regulator of acoustic startle threshold establishment and plasticity. Compared to their wild type siblings, *cdh16* loss-of-function mutations result in hypersensitivity to low-intensity acoustic stimuli. Moreover, *cdh16* mutants fail to habituate to repeated stimuli, consistent with a role for this atypical cadherin in the dynamic regulation of sensory thresholds. Interestingly, although expression of *cdh16* has been observed in the brain and other cadherins are known to regulate multiple stages of nervous system development, our work provides the first evidence of a role for *cdh16* in the nervous system. To determine when *cdh16* might regulate acoustic startle threshold establishment and plasticity, we generated a heat-shock rescue transgene. Using this tool, we observed restoration of normal levels of acoustic responsiveness and habituation learning when we induced *cdh16* expression after the acoustic startle circuit is intact, suggesting that *cdh16* is likely not involved in early stages of neurodevelopment, but is required for later processes of circuit maturation and refinement. Finally, prior work indicates that *cdh16* plays a crucial role in the development of endocrine organs that maintain calcium homeostasis. In this context, *cdh16* functions together with Wnt/β-catenin signaling. To determine whether these pathways interact in the context of sensory processing, we applied the Gsk-3 antagonist XV to *cdh16* mutants and their wild type siblings. We found that while XV caused hyposensitivity to acoustic stimuli in wild type animals, it had no effect in siblings, consistent with a role for Wnt signaling in the expression or function of *cdh16.* Together our results establish a novel role for the atypical cadherin *cdh16* as well as Wnt/β-catenin signaling in the regulation of acoustic thresholds and provide a molecular foothold to understanding how sensory thresholds are tuned during development.

336 **PCP proteins guide the way to a fast escape** Joy H Meserve[1], Maria Navarro[2], Michael Granato[1] [1]Cell and Developmental Biology, University of Pennsylvania, [2]Neuroscience Graduate Group, University of Pennsylvania

As the brain develops, neurons must wire together to assemble functional circuits capable of directing diverse behaviors. While numerous molecular pathways that guide neurons to their synaptic partners have been identified, it is unclear if distinct neuron groups in a shared circuit employ overlapping pathways for coordinated connectivity. Guided by this query, we leveraged the simple and well-defined acoustic startle circuit in larval zebrafish to explore how the planar cell polarity (PCP) pathway orchestrates circuit assembly. The startle response is a protective behavior that is both evolutionarily conserved and clinically relevant as an indicator of broader nervous system function. Central to the zebrafish startle circuit are the Mauthner neurons, a pair of gigantic reticulospinal neurons that, in response to a startling noise, activate to initiate a rapid swim escape. We discovered that the PCP-associated atypical cadherins Celsr2 and Celsr3, as well as Celsr3's binding partner Frizzled 3a/Fzd3a, promote Mauthner axon guidance and growth. Celsr3 additionally directs axon guidance of excitatory spiral fiber neurons that synapse onto the Mauthner axon. These unique axo-axonic synapses are encapsulated by astrocyte-like glia, which mislocalize in *celsr3* mutants to ectopic spiral fiber axon projections, suggesting spiral fibers promote glial guidance. Our findings also reveal divergent functions for Celsr2 and Celsr3. *celsr2* single mutants display normal startle behavior and Mauthner axon development while *celsr3* single mutants display defects that are further enhanced in *celsr3;celsr2* double mutant larvae, resulting in Mauthner cell death. This indicates redundant and/or compensatory mechanisms ensure proper startle circuit development. Overall, our results reveal that Mauthner and spiral fiber neurons utilize a shared Celsr/Fzd molecular pathway to guide axons to their synaptic partners, a mechanism that may ensure coordinated assembly of the acoustic startle circuit.

337 **Functional characterization of human *G6PD* variants using a multiplexed assay in *S. cerevisiae*** Renee C Geck, Maitreya J Dunham Genome Sciences, University of Washington

Glucose-6-phosphate dehydrogenase (G6PD) deficiency affects over 500 million people. G6PD is important in red blood cells since it produces NADPH to detoxify reactive oxygen species, so individuals with G6PD deficiency may experience hemolysis after infections or exposure to oxidants, including many drugs. However, diagnosis by activity assays can give false negatives during hemolytic crises, and since *G6PD* is on the X chromosome carriers must be identified to avoid triggers during pregnancy. Thus accurate interpretation of *G6PD* genotype is valuable for preventing adverse drug reactions.

We connected *G6PD* genetic variants to their function using assays in *S. cerevisiae*, since human *G6PD* functionally complements the yeast homolog *ZWF1*. Yeast use NAPDH to produce methionine and antioxidants, so *zwf1Δ* yeast grow poorly in the absence of methionine and presence of hydrogen peroxide. Growth rate measurements and direct competition showed that *zwf1Δ* yeast expressing high-activity G6PD variants out-competed yeast with low-activity variants in this selective condition.

In order to scale our assay to address the unmet need of over 800 identified *G6PD* variants of uncertain effect, we created a barcoded variant library of nearly all possible single missense variants in *G6PD*. We transformed *zwf1Δ* yeast with this library and grew them in turbidostats without methionine and with hydrogen peroxide to select for G6PD activity. We took 10 samples from each population over 72 hours, which we deeply sequenced to calculate barcode frequency. Using long-read sequencing, we associated each barcode with a *G6PD* variant and used the change in frequency of associated barcodes over time to calculate a functional score for each variant.

We identified several regions of *G6PD* that are intolerant to mutation and confirmed that disrupting the dimerization domain reduces function. By benchmarking our assay with variants of known clinical effect, we will compute a level of evidence that can be integrated into variant interpretation frameworks.

In the future, we are conducting additional assays to measure the effects of *G6PD* variation on G6PD protein abundance and to determine the effects of multiple missense variants in one allele, since several *G6PD* variants identified in global populations affect two residues. Altogether, our study will enable clinical interpretation of a larger number of *G6PD* alleles and increase our understanding of how variation alters G6PD function.

338 **Identifying conserved aging regulators by high throughout lifespan screen in budding yeast** Weiwei Dang Huffington Center on Aging, Baylor College of Medicine

The budding yeast, Saccharomyces cerevisiae, is one of the most genetically tractable eukaryotic models. Yeast cells undergo asymmetric cell division, producing a smaller daughter cell, and have a finite replicative lifespan. This aging model has been quite fruitful in discovering the molecular mechanisms of the aging process. However, the replicative lifespan is traditionally measured by manually dissecting mother cells from daughter cells, which is a very tedious and inefficient process. Here, we present two high throughput methods for analyzing yeast replicative aging: a microfluidic-based high throughput lifespan assay and a population-based high throughput replicative lifespan screen. We show that the microfluidic-based high throughput lifespan assay provides consistent and reliable replicative lifespan measurements for yeast strains with an increase in efficiency

by 300-fold. Screening for mutant library for certain genetic traits has been a powerful approach to under basic biology. However, even with the microfluidic lifespan assay, looking for long-lived or short-lived mutants among thousands of strains remains a daunting task. Our population-based high throughput lifespan screen approach can identify long-lived and short-lived mutants from thousands of mutant strains simultaneously in a week-long experiment. These methods provide modern, reliable, and efficient ways for characterizing aging phenotypes for yeast mutant strains.

339 **Using evolutionary rate covariation to build protein-protein interaction networks and identify organelle crosstalk** Jordan Little[1], Nathan Clark[2] [1]University of Utah, [2]Biological Sciences, University of Pittsburgh

The physical organization of the cell is relatively well understood, and it is appreciated that there is functional similarity between proteins that occupy the same subcellular location, such as within protein complexes and organelles. Determining the subcellular location of proteins is relatively straightforward via traditional bench methods, but understanding functional interactions between proteins that do not share physical proximity requires a greater degree of prior knowledge to identify them. This is especially true for proteins that are only associated under specific conditions and for brief periods of time. However, functionally related proteins are under shared selective pressures, allowing us to utilize evolutionary methods to find these extremely transient relationships. Evolutionary rate covariation (ERC) is a method that leverages the rate of evolution for a protein as a proxy for selection and then finds pairwise proteins with correlated rates which would suggest shared evolutionary pressures and thus functions.

We have used a dataset of 343 yeast genomes, with 12,552 orthologous genes, to create a functional map of the yeast cell using ERC. Using the annotated subcellular location for yeast proteins we show that protein pairs with high ERC are not exclusively located within the same organelle. This observation indicates that ERC is able to identify proteins with functional relationships that do not co-localize, or that co-localize under very specific conditions that have not yet been observed. To further investigate, we built organelle specific protein-protein interaction networks, using ERC scores as the edges, to identify which organelles have the strongest evidence of connectivity and which specific proteins are driving that connection. To investigate the broader evolutionary conservation of the interactions we also calculated the ERC scores for all yeast-mammal orthologous genes using a dataset of 120 mammals and incorporated them into the edges of the network. This evolutionary protein-protein interaction network can be analyzed as fine-tuned as individual proteins pairs, all the way up to potential cross-talk between organelles, allowing us to build a functional map of the yeast cell in a way that is yet unattainable via experimental methods.

340 **Changing course: Regulation of Hexokinase 2 nuclear access and function** Mitch Lesko[1], Daksha Chandrashekarappa[2], Annette Chiang[1], Eric Jordahl[1], Katherine Oppenheimer[1], Chaowei Shang[1], Jacob Durrant[1], Martin Schmidt[2], Allyson O'Donnell[1] [1]Dept. of Biological Sciences, University of Pittsburgh, [2]Molecular and Microbial Genetics Department, University of Pittsburgh

Glucose is the preferred carbon source for most eukaryotes. Upon entry into the cell, glucose is rapidly converted to glucose-6-phosphate by hexo- or gluco-kinases. The yeast *Saccharomyces cerevisiae* (Sc) encodes three enzymes to phosphorylate glucose: Hxk1, Hxk2 and Glk1. Though predominantly cytosolic, in yeast and mammals isoforms of these enzymes can be found in the nucleus. This led to the suggestion of 'moonlighting' functions for hexokinases in this compartment, beyond their typical role in glucose metabolism. However, the molecular details underlying the activity of hexokinases, and other glycolytic enzymes, in the nucleus are often unclear. Past studies suggested that *Sc*Hxk2 entered the nucleus in glucose-replete conditions as part of a transcriptional complex that controlled glucose-repression of gene expression. In sharp contrast to this early model, our data demonstrate that Hxk2 accumulates in the nucleus in response to glucose starvation, and these data align well with the nuclear localization changes observed for mammalian hexokinases. Using high-resolution, quantitative fluorescence microscopy in live yeast cells, we define the conditions, *cis*-acting sequences, and trans-acting regulatory proteins needed for Hxk2 nuclear translocation. Our RNAseq analysis further demonstrates that Hxk2 has no major role in regulating glucose-repression of gene expression. These data demonstrate that Hxk2 does not moonlight as a nuclear transcription factor.

What then is the nuclear function for Hxk2? Our preliminary data show that several Hxk2 mutants bypass the glucose-restricted nuclear access for this enzyme. Many of these mutants are thought to be unstable and some even form nuclear aggregates. Our studies using biochemical approaches and molecular dynamics simulations suggest that the structure of Hxk2 is more flexible in the absence of glucose and Hxk2 is less stable. These are the same conditions that allow Hxk2 to access the nucleus. Based on our findings, we propose a model where in cells experiencing glucose deprivation, Hxk2 is less likely to be bound to glucose and becomes misfolded more easily. Misfolded Hxk2 accumulates in the nucleus, where the nuclear protein quality control pathways (NPQC) help degrade it. Since all glycolytic enzymes enter the nucleus, often under stress or starvation conditions, it is tempting to speculate that NPQC could more broadly regulate glycolytic enzymes.

341 **Building synthetic chromosomes from natural DNA** Alessandro L. V. Coradini, Christopher Ne Ville, Zachary A. Krieger,

Joshua Roemer, Cara Hull, Shawn Yang, Daniel T. Lusk, Ian M. Ehrenreich Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California

De novo chromosome synthesis is costly and time-consuming, limiting its use in research and biotechnology. Building synthetic chromosomes from natural components is an unexplored alternative with many potential applications. In this paper, we report CReATiNG (Cloning, Reprogramming, and Assembling Tiled Natural Genomic DNA), a method for constructing synthetic chromosomes from natural components in yeast. CReATiNG entails cloning segments of natural chromosomes and then programably assembling them into synthetic chromosomes that can replace the native chromosomes in cells. We used CReATiNG to synthetically recombine chromosomes between strains and species, to modify chromosome structure, and to delete many linked, non-adjacent regions totaling 39% of a chromosome. The multiplex deletion experiment revealed that CReATiNG also enables recovery from flaws in synthetic chromosome design via recombination between a synthetic chromosome and its native counterpart. CReATiNG facilitates the application of chromosome synthesis to diverse biological problems.

342 **Simple-to-use CRISPR-SpCas9/SaCas9/AsCas12 vector series with multiple selection markers enabling single-step multiplex genome editing in budding yeast** Satoshi Okada, Emiko Kusumoto, Takashi Ito Department of Biochemistry, Kyushu University Graduate School of Medical Sciences

The CRISPR-Cas systems have become a widely used tool for genome editing across various organisms and are gaining popularity in the genetically tractable budding yeast *Saccharomyces cerevisiae*. The specificity of each CRISPR-Cas system is defined by the protospacer adjacent motif (PAM) it recognizes. This specificity can limit a system's ability to target specific regions if the corresponding PAM is not present, often requiring the use of an alternative system with a different PAM compatibility. To overcome this, distinct CRISPR-Cas systems have been effectively utilized for yeast genome editing, potentially expanding the range of editable sequences when used in combination. However, currently available plasmids were each developed according to varying design principles, which creates obstacles to their integrated application in genome editing procedures.

Here we report a plasmid vector series named LOBSTERS (League Of Backbone plasmid vector Series To Expand the Range of Selection markers for genome editing in budding yeast) constructed under a unified design principle. LOBSTERS includes a total of 21 plasmids, combining three different CRISPR-Cas systems with distinct PAMs (SpCas9, SaCas9, and AsCas12a) with seven selection markers (*HIS3*, *TRP1*, *LEU2*, *URA3*, *KanMX*, *HphMX*, and *NatMX*). All vectors are designed for Golden Gate Assembly compatibility, easing the construction of plasmids tailored to specific target sequences. Alongside these vectors, we developed a simple software tool to facilitate the design of the oligonucleotides for the Golden Gate Assembly.

These plasmids have demonstrated high efficiency in performing various editing tasks at single loci: inserting gene fragments into essential genes (median efficiency ~52%), deleting entire open reading frames (median ~79%), and introducing single amino acid substitutions (median ~79%).

The concurrent use of multiple markers enables multiplex genome editing in a single step. In dual genome editing, introducing a fluorescent protein gene at sites other than the 3' ends of essential genes resulted in a ~65% efficiency for obtaining double genome-edited clones. For triple genome editing, which involves a single-nucleotide insertion in a promoter sequence and amino acid substitution mutations in protein-coding regions, we achieved ~33% efficiency for triple genome-edited clones.

This integrated suite of vectors and accompanying software tool constitutes a comprehensive toolkit, streamlining the application of SpCas9, SaCas9, and AsCas12a for diverse genome editing tasks, particularly for those challenging to achieve through traditional yeast genetic methods.

343 **The genotype-phenotype-phenotype-phenotype map** Kerry Geiler-Samerotte Arizona State University

Predicting the phenotypic impacts of a mutation is a major goal in biology and medicine. But the paths linking genotype to phenotype are difficult to navigate. For one, some phenotypes impact others, so the impacts of mutation can stretch out across networks of related traits, percolating from impacts at the molecular level to higher orders of biological organization. Moreover, the impacts of mutation, and the networks of traits through which they spread, change across contexts like the environment or genetic background. Thus, comprehensively mapping genotype to phenotype is akin to untangling a ball of knotted strings, only to realize the task needs to be repeated many times. My lab implements and develops high-throughput phenotyping methods to simultaneously quantify the phenotypic impacts of many mutations across many contexts. In some projects, we quantify the correlations between phenotypes to infer the network through which a mutation's influence travels and how that network changes across contexts. In other projects, we deconvolute these high-dimensional data into an abstract

map that uses shared patterns of mutant behavior across contexts to make phenotypic predictions. Some of our work is driven by mechanistic hypotheses about how basic properties of cells change the phenotypic impacts of mutation in predictable ways, while other work focuses on large collections of adaptive mutations generated by laboratory evolution experiments. Our overall goal is to build predictive maps from genotype to phenotype and, in so doing, to generate insights about the map's structure (e.g., is it modular or interconnected?) and tools to study this map that will be broadly useful to the biology community.

344 ***Trans*-eQTL hotspots shape complex traits by modulating cellular states** Kaushik Renganaath, Frank W Albert Genetics, Cell Biology, & Development, University of Minnesota

Regulatory genetic variation shapes gene expression, providing an important mechanism connecting DNA variation and complex traits. However, the specific causal relationships between the expression of individual genes and complex traits remain poorly understood.

Here, we conducted a series of integrative analyses of published data from genome-wide transcriptomes and 46 genetically complex growth traits collected in the same 1,000 recombinant progeny of a cross between two strains of the yeast *Saccharomyces cerevisiae*. Loci mapped in these data account for majorities of heritability in each dataset, providing an ideal model for the comprehensive dissection of how natural genetic variation connects gene expression and growth.

We discovered thousands of genetic correlations between gene expression and growth, suggesting functional connections. Surprisingly, although local regulatory variation tends to have large effects on gene expression, it was a minor source of genetic correlations, accounting for an average of only 1% in the magnitude of these correlations.

Instead, genetic correlations tended to arise from multiple independent *trans*-acting regulatory loci across the genome. These loci accounted for 48% of the genetic correlations. In particular, *trans*-acting hotspots, which affect the expression of hundreds of genes, accounted for an average of 77% of genetic growth variation and 68% of the genetic correlations between gene expression and growth, significantly more than expected by chance.

Genes with genetic correlations were enriched for similar biological processes across traits, but the direction of effect of these enrichments differed between traits. For example, the expression of genes involved in the environmental stress response was negatively correlated with growth in a set of conditions including various carbon sources, but positively correlated with growth in conditions including environmental stressors such as high temperature or oxidative stress. Together, our results reveal a prominent role for *trans*-acting regulatory hotspots in shaping complex traits by altering central cellular states.

345 **Epigenetic context predicts gene expression variation and reproductive traits across genetically identical individuals** Amy Webster[1], John Willis[1], Erik Johnson[1], Peter Sarkies[2], Patrick Phillips[1] [1]University of Oregon, [2]University of Oxford

In recent decades, genome-wide association studies (GWAS) have been the major approach to understand the biological basis of individual differences in traits and diseases. However, GWAS approaches often have limited predictive power to explain individual differences, particularly for complex traits and diseases in which environmental factors play a substantial role in their etiology. Indeed, individual differences persist even in genetically identical individuals, although fully separating genetic and environmental causation is difficult or impossible in most organisms. To understand the basis of individual differences in the absence of genetic differences, we measured two quantitative reproductive traits in 180 genetically identical young adult *Caenorhabditis elegans* roundworms in a shared environment and performed single-individual transcriptomics on each worm. We identified hundreds of genes for which expression variation was strongly associated with reproductive traits, some of which depended on prior environmental experience and some of which was random. Multiple small sets of genes together were highly predictive of reproductive traits across individuals, explaining on average over half and over a quarter of variation in the two traits. We manipulated mRNA levels of predictive genes using RNA interference to identify a set of causal genes, demonstrating the utility of this approach for both prediction and understanding underlying biology. Finally, we found that the chromatin environment of predictive genes was enriched for H3K27 trimethylation, suggesting that individual gene expression differences underlying critical traits may be driven in part by chromatin structure. Together, this work shows that individual differences in gene expression that arise independently of underlying genetic differences are both predictive and causal in shaping reproductive traits at levels that equal or exceed genetic variation.

346 **What's so special about height? More hits ≠ more polygenic** Yuval Simons[1], Huisheng Zhu[2], Hakhamanesh Mostafavi[2,3], Guy Sella[4], Jonathan K Pritchard[2] [1]University of Chicago, [2]Stanford University, [3]New York University, [4]Columbia University

Over the past two decades, as genome-wide association studies (GWAS) systematically uncover the genetic basis of nearly every measurable human trait, height stands out as an outlier. While many traits have been associated with multiple genome-wide significant genetic variants (GWAS hits), height has the most hits (over 10,000) by quite a long way. ***Why?***

Using a simple model, we show that it is not the most polygenic traits that are expected to have the most GWAS hits. Instead, when a trait is highly polygenic and has many underlying variants, the effect of each variant is small. For the most polygenic traits, effects are so small that very few variants are discovered as GWAS hits. In contrast, for traits with few underlying common variants most are discovered as GWAS hits, but there are few common variants to discover. Therefore, it is "goldilocks" traits, with many but not too many underlying common variants, that have the most hits. We show that human height is the most heritable of human "goldilocks" traits, explaining why it has the most hits.

347 **Causal interpretations of family GWAS in the presence of heterogeneous effects** Carl Veller[1], Molly Przeworski[2,3], Graham Coop[4,5] [1]Department of Ecology & Evolution, University of Chicago, [2]Department of Biological Sciences, Columbia University, [3]Department of Systems Biology, Columbia University, [4]Department of Evolution and Ecology, University of California, Davis, [5]Center for Population Biology, University of California, Davis

Family studies have emerged as a gold standard for assessing causal effects of alleles and polygenic scores in genome-wide association studies (GWAS). Notably, an analogy is often made between the random transmission of alleles to children in families and a randomized controlled trial, on the basis of which family studies are claimed to provide an unbiased estimate of the average causal effect (or "average treatment effect"; ATE) of an allele. Here, we show that this interpretation does not hold in general. Because Mendelian segregation only randomizes alleles among children of heterozygotes, the effects of alleles in the children of homozygotes are not observable. Consequently, if an allele has different average effects in the children of homozygotes and heterozygotes, as can arise in the presence of gene by environment interactions, gene by gene interactions, or differences in LD patterns, family studies provide a biased estimate of the average effect in the population. At a single locus, family-based association studies can be thought of as providing an unbiased estimate of the average effect in the children of heterozygotes (i.e., a "local average treatment effect"; LATE). However, this interpretation does not extend to polygenic scores, where different sets of SNPs are heterozygous in each family; therefore, other than under very specific conditions, the within-family regression slope of a PGS cannot be assumed to provide an unbiased estimate for any subset or weighted average of families. Instead, family-based studies can be reinterpreted as enabling an unbiased estimate of the extent to which Mendelian segregation at loci in the PGS contributes to the population-level variance in the trait. Such statements are on a solid causal footing, but apply only to about half of the variance that could be explained by the PGS. In practice, the potential biases of family studies are likely smaller than those arising from confounding in standard, population-based GWASs, and so this approach remains important for understanding genetic contributions to phenotypic variation. Nonetheless, the causal interpretation of family-based GWAS estimates is less straightforward than has been widely appreciated.

348 **Using the threshold trait model of quantitative genetics to understand the evolutionary dynamics of dispersal in wing-dimorphic insects** Lisa Treidel[1], Caroline M Williams[2], Colin J Meiklejohn[1], Kristi M Montooth[1] [1]School of Biological Sciences, University of Nebraska, Lincoln, [2]Integrative Biology, University of California, Berkeley

Dispersal influences broadscale biogeographical, ecological, and evolutionary patterns and processes. Yet, because dispersal strategies involve complex morphological, physiological, and behavioral traits, our understanding of their evolutionary causes and consequences remains incomplete. Wing-dimorphic insect species in which discrete dispersing long-winged (LW) and non-dispersing short-winged (SW) morphs co-occur within populations provide a potential model to elucidate the evolution of alternative dispersal strategies. Using a recently resolved phylogeny, we conducted an ancestral trait reconstruction, of wing dimorphism in North American Field crickets (*Gryllus* spp.), a monophyletic clade of 45 genetically distinct lineages that diverged from a common ancestor only 1-2 million years ago. This analysis revealed a highly dynamic evolution with repeated evolutionary gains and losses of wing dimorphism across this species radiation. We further investigated the quantitative genetic basis of morph determination in the wing-dimorphic variable field cricket, *Gryllus lineaticeps*, using a family design with crosses of all possible morph combinations (LWxLW; SWxSW; LWxSW; SWxLW) and quantifying offspring morph frequencies and adult flight muscle maintenance. As predicted for a heritable trait, the frequency of LW offspring was significantly less in SWxSW relative to LWxLW families. The frequency of LW offspring and the maintenance of adult flight muscles was also positively correlated across families, indicating a common genetic basis of dispersal-related traits. Morph frequencies among females were more LW-biased compared to males, but males were more likely to maintain their flight muscles in early adulthood than were females. We interpret the results of both analyses using a threshold trait framework and hypothesize that these evolutionary patterns arise because morph determination is a threshold trait, controlled by an underlying unobservable environmentally sensitive quantitative trait, called liability, and a threshold. For wing dimorphisms, when liability exceeds a threshold during a critical period in development, wing and flight muscle development are proposed to be inhibited resulting in the flightless short-wing morph. The control of multiple flight related traits by liability could explain

their coordinated evolution and shifts in morph frequencies between sexes or species can evolve quickly via changes in liabilities or thresholds.

349 **Clark (2023) and the Persistence of Hereditarian Fallacies** Jedidiah Carlson[1,2], John W Benning[3], Ruth G. Shaw[4], Arbel Harpak[1,2] [1]Department of Integrative Biology, University of Texas at Austin, [2]Department of Population Health, University of Texas at Austin, [3]Department of Botany, University of Wyoming, [4]Department of Ecology, Evolution, and Behavior, University of Minnesota

Understanding of the persistence of social status in families is contentious. Scholarly assertion that such persistence is rooted in genetic variation was foundational to the development and implementation of eugenic policies in the 20th century. Hereditarian claims of an outsized role for genetics in social outcomes have continued to maintain a foothold among academics. In a recent paper, Clark (2023) measures correlations between relatives in a variety of socioeconomic status indicators, drawing on data from >400,000 individuals with rare surnames from census and population registers spanning four centuries in England. Based on a fit of these familial status correlations to a classic quantitative genetics model (Fisher, 1918), the paper argues that: (1) variation in socioeconomic status is largely determined by additive genetic variation; (2) contemporary English people "remain correlated in outcomes with their lineage relatives in exactly the same way as in preindustrial England"; and (3) social mobility has remained static over this time period due to strong assortative mating on a "social genotype."

We reanalyze the data of Clark (2023) and show that these conclusions are based on the flawed assumption that genetic inheritance is the *only* transmissible source of familial resemblance in social status. We demonstrate that these correlation estimates conflate genetic and non-genetic transmission (e.g., of wealth) within families, and how this confounding leads to the misconstrual of model parameters and fundamental errors of inference. Inconsistent with claims (2) and (3), we show that familial correlations in status are variable—generally decreasing—through the time period analyzed. Finally, we discover statistical artifacts in the data that substantially bias these correlation estimates. All these considerations, but particularly the first, invalidate use of, such data for disentangling the roles of genetic and non-genetic factors. We conclude that Clark (2023) tells us nothing about the genetic and non-genetic transmission of social status, and discuss the impacts of these and other hereditarian fallacies resurfacing in recent literature.

350 **Revealing functional consequences of eukaryotic histone H2A repertoire innovations** Pravrutha Raman[1], Sierra Simmerman[2], Hana Khan[3], Kelsey Woodruff[4], Amy Hamada[3], Toshio Tsukiyama[5], Harmit S Malik[2] [1]Basic Sciences, Fred Hutchinson Cancer Center, [2]Fred Hutchinson Cancer Center and HHMI, [3]University of Washington, [4]University of Washington, Fred Hutchinson Cancer Center, [5]Fred Hutchinson Cancer Center

Given their essential roles in fundamental biological processes, histones would be predicted to be highly conserved. Yet, histone repertoires can vastly differ across lineages due to gene duplication, gene loss, and sequence divergence. The genetic innovation of histone repertoires could confer lineage-specific adaptive advantages. Here, we investigate the unusual case of a fusion of two well-conserved histone H2A variants. Most eukaryotes possess an H2A repertoire of canonical H2A and two distinct variants H2A.Z and H2A.X, which participate in gene regulation and DNA damage response (DDR), respectively. In contrast, all *Drosophila* species encode a single H2Av gene, a functional chimera of H2A.X and H2A.Z. Our evolutionary analyses show that H2Av arose in a subset of *Diptera* (winged-insects) by *H2A.Z* acquiring the *H2A.X* C-terminal tail containing "SQ motif" required for DDR. Thus, DDR and gene regulation functions of H2A.X and H2A.Z are now confined to the same genomic location in some *Diptera*. We also find that this fusion has duplicated and acquired distinct functions in some *Drosophila* species. We hypothesize that this unusual fusion may provide an adaptive advantage by enhancing DNA repair in H2A.Z-enriched genomic regions, restricting transposition that rely on DDR to gene-poor heterochromatin in *Drosophila* genomes. To investigate this possibility, we are reversing the *D. melanogaster* H2A repertoire to its ancestral *Diptera* state by engineering distinct H2A.X and H2A.Z. This uncouples their functions and will reveal how genomic functions are altered by their fusion. We also recreated this unique evolutionary event in yeast by appending the SQ motif from yeast H2A.X onto its H2A.Z. These 'fly-like' yeast have growth rates indistinguishable from wild-type. However, a fly-like H2A repertoire dramatically reduces DDR efficiency that cannot be attributed entirely to a lack of SQ phosphorylation, since phosphomimic EQ mutations fail to enhance DDR. Thus, an H2A+H2Av repertoire impairs DDR in yeast. We are analyzing how transposition and DDR-dependent processes like meiosis are altered in fly-like yeast. Our yeast data raise the possibility that an H2A+H2Av repertoire might lead to a trade-off of compromised DDR in fly genomes and to the co-evolution of other fly chromatin factors to facilitate DDR. Together, our work reveals the unexpected evolution of conserved, essential H2A variants and their functional consequences on genome regulation and instability.

351 **The Mute button: Turning down the volume of histone expression** Mark S Geisler[1], William F Marzluff[2], Robert J Duronio[3] [1]Curriculum in Genetics and Molecular Biology, University of North Carolina - Chapel Hill, [2]Department of

Biology, Integrative Program for Biological and Genome Sciences, Lineberger Comprehensive Cancer Center, University of North Carolina - Chapel Hill, [3]Department of Biology, Integrative Program for Biological and Genome Sciences, Lineberger Comprehensive Cancer Center, Department of Genetics, University of North Carolina - Chapel Hill

Replication of a eukaryotic genome requires the production of hundreds of millions of histone proteins to package the newly synthesized DNA. To meet this large demand for histone production, all eukaryotes coordinate high level expression of replication-dependent (RD) histone gene clusters during S-phase of the cell division cycle. Regulating expression levels of RD-histone genes during S-phase is important for maintaining genomic integrity and normal cell cycle progression. This regulation, along with expression and processing of the histone RNA, occurs within a biomolecular condensate that assembles at RD-histone genes called the Histone Locus Body (HLB). Expression of RD-histone genes is activated during S phase by CyclinE/CDK2 phosphorylation of the HLB scaffold protein, MXC. However, much less is known about how histone transcription is terminated as cells exit S-phase. The HLB component Mute is a negative regulator of histone gene expression. Mutation of *mute* causes embryonic lethality accompanied by an increase in the steady state amount of RD-histone mRNA. By combining EdU labeling with fluorescent in situ hybridization (FISH) to core histone mRNAs we found that loss of Mute leads to inappropriate expression of RD-histone genes during G2 phase of the cell cycle in the embryonic ventral nerve cord. Interestingly, these G2 cells retain MXC phosphorylation at the HLB, suggesting that Mute terminates RD-histone transcription at the end of S-phase by removing or blocking the CyclinE/CDK2 dependent phosphorylation of MXC. By generating genetically mosaic larval imaginal discs, we found Mute null cells have a severe proliferation defect, showing that limiting RD-histone expression to S-phase is critical for normal cell cycle progression and proliferation. As in the embryo, these *mute* null cells also display an uncoupling of histone gene transcription from S-phase. These data lead us to hypothesize that Mute restricts RD-histone expression to S-phase by removing or blocking CyclinE/CDK2 phosphorylation of MXC to repress histone gene expression as cells transition into G2. We are currently exploring whether misexpression of histone genes affects genome organization throughout embryogenesis using ATAC-Seq. This work enhances our understanding of the role of RD histone gene regulation in metazoans and provides insight into the mechanisms that govern the regulation of this highly conserved cellular process.

352 **Ectopic transcription due to inappropriately inherited histone methylation may interfere with the ongoing function of terminally differentiated cells** Monica Reeves, Juan Rodriguez, Eilleen Falkenberry, David Katz Emory University

C. elegans larvae that are double mutant for the H3K4 demethylase *spr-5* (LSD1/KDM1A in mammals) and the H3K9 methyltransferase *met-2* (SETDB1 in mammals) exhibit L2 developmental delay, chemotaxis defects, muscle defects and a failure to elongate the gonad. We found that these *spr-5;met-2* phenotypes are caused by the ectopic expression of germline genes in somatic tissues, which begins during embryonic stages. This provided the unique opportunity to determine how ectopic expression, due to inappropriate histone methylation, interferes with the invariant *C. elegans* embryonic lineage. Surprisingly, using automated lineage tracing, we find that *spr-5;met-2* mutants have no embryonic lineage defects through the 200-cell stage, despite the ectopic germline expression and the major phenotypes we observe one cell division later, in larvae. This suggested that the *spr-5;met-2* phenotypes are not due to development defects. Instead, they may be due to ongoing functional defects in terminally differentiated cells. To test this directly, we used RNAi to shut off the ectopic expression of germline genes in L2 *spr-5;met-2* larvae, which have a fully formed nervous system. Remarkably, we find that shutting off the ectopic germline expression rescues normal chemotaxis behavior in the same adult worms that previously had a chemotaxis defect at the L2 stage. This suggests that ongoing ectopic transcription due to the misregulation of epigenetic inheritance can block normal behavior in a fully intact nervous system. Interestingly, some of the *spr-5;met-2* phenotypes, such as the developmental delay and behavior abnormalities, broadly overlap with those observed in human Kabuki Syndrome-like patients, caused by mutations in *Lsd1* and other histone modifying enzymes. Our data in *C. elegans* suggest that it may be possible to rescue some of the defects in human patients by reverting the chromatin in adults. Similar to what we observe in *C. elegans*, we found that partially compromising LSD1 maternally in mice also results in inherited phenotypes that manifest postnatally, including perinatal lethality, developmental delay, craniofacial defects and altered behavior. We are currently using this new mouse paradigm to investigate whether some of the observed phenotypes are due to ongoing epigenetic defects in differentiated tissues.

353 **OVO Positively Regulates Essential Maternal Pathways by Binding Near the Transcriptional Start Sites in the *Drosophila* Female Germline** Leif Benner, Savannah Muron, Jillian G Gomez, Brian Oliver National Institutes of Health

Differentiation of female germline stem cells into a mature oocyte includes the expression of a number of RNAs and proteins that drive early embryonic development in *Drosophila*. We have little insight into what activates the expression of these maternal factors. One candidate is the zinc-finger protein OVO. OVO is required for female germline viability and has been shown to positively regulate its own expression, as well as a downstream target, *ovarian tumor*, by binding to the transcriptional start site (TSS). To find additional OVO targets in the female germline and further elucidate OVO's role in oocyte development, we performed ChIP-seq to determine genome-wide OVO occupancy, as well as RNA-seq comparing

hypomorphic and wild type rescue *ovo* alleles. OVO preferentially binds in close proximity to target TSSs genome-wide, is associated with open chromatin, transcriptionally active histone marks, and OVO-dependent expression. Motif enrichment analysis on OVO ChIP peaks identified a 5`-TAACNGT-3` OVO DNA binding motif spatially enriched near TSSs. However, the OVO DNA binding motif does not exhibit precise motif spacing relative to the TSS characteristic of RNA Polymerase II complex binding core promoter elements. Integrated genomics analysis showed that 525 genes that are bound and increase in expression downstream of OVO are known to be essential maternally expressed genes. These include genes involved in anterior/posterior/germ plasm specification (*bcd, exu, swa, osk, nos, pgc, gcl*), egg activation (*png, plu, gnu, wisp, C(3)g, mtrm*), translational regulation (*cup*, *orb*, *bru1, me31B*), and vitelline membrane formation (*fs(1)N*, *fs(1)M3*, *clos*). This suggests that OVO is a master transcriptional regulator of oocyte development and is responsible for the expression of structural components of the egg as well as maternally provided RNAs that are required for early embryonic development.

354 **Sexually dimorphic Argonaute structure and localization facilitate sex specificity of small RNA pathways in *C. elegans* germ cells** Acadia L DiNardo[1], Hannah Wilson[2], Rachael Giersch[2], Nicole A Kurhanewicz[2], Diana E Libuda[2] [1]Biology, University of Oregon, [2]University of Oregon

Germ cell proliferation and proper genome inheritance are critical to maintain fertility through generations. To promote proper germ cell development and fertility, small RNA pathways employ Argonaute proteins (WAGOs) to downregulate aberrant transcripts. WAGOs are largely housed within the germ granule, a cytoplasmic, phase separated compartment adjacent to nuclear pore complexes of germ cells. While previous work found that WAGO-1 post-transcriptionally regulates distinct sex-specific gene targets, the mechanism by which WAGO-1 achieves sexually dimorphic gene regulation is largely unknown. Here we show that WAGO-1 both responds to and regulates sexually dimorphic germ granule structure and function. During meiotic prophase I progression, we find that the structural germ granule components (PGL-1, PGL-3, and ZNFX-1) and the 21U small RNA regulator PRG-1 display dynamic and distinct localization patterns between egg and sperm development that elicit differential WAGO-1 localization and structure. Only during spermatogenesis, PGL-1, ZNFX-1, and WAGO-1 are encompassed within a shell of PRG-1 and a ring of PGL-3. These striking protein organizations encircling the germ granule suggest sex-specific roles of PGL-3 and PRG-1 in regulating germ granule structure. Moreover, we demonstrate that WAGO-1 is able to dimerize only during spermatogenesis when it resides within the PGL-3 and PRG-1 rings, which may facilitate the spermatogenesis-specific dimerization of WAGO-1. Further, we find that the N- and C-terminus of WAGO-1 play sex-specific roles in regulating the stability of germ granules. Additionally, our results indicate that disruption of the intrinsically disordered region of the N-terminus of WAGO-1 causes PGL-1 to lose phase separation only during spermatogenesis. Moreover, deletions of the PIWI-domain containing C-terminus causes complete sterility only in males. Together, our studies suggest that sexual dimorphisms in the structure and stability of the germ granule, where small RNAs are processed, may affect end-terminal interactions of Argonautes to enable sex-specific gene expression profiles required for fertility.

355 **A regulatory network of Sox and Six transcription factors initiate hearing regeneration in zebrafish** Sarah Hanson[1], Jeffrey Baffoe-Bonnie[2], Michelle Macurak[1], Braveen Joseph[2], Shawn Burgess[2], Erin A Jimenez[1] [1]Biology, Johns Hopkins University, [2]National Human Genome Research Institute, National Institutes of Health

Millions of people world-wide experience hearing or balance disorders due to the loss of hair cells in the inner ear. The hair cells are the mechanosensory cells used in the auditory and vestibular organs of all vertebrates and lateral line systems of aquatic vertebrates. In zebrafish and other non-mammalian species, hair cells turn over during homeostasis and regenerate completely after being destroyed or damaged by acoustic or chemical exposure, while in mammals, destroying or damaging hair cells results in permanent hearing loss or vestibular dysfunction.

To understand hearing regeneration, it is essential to understand how genes respond to injury and how those responses are controlled in the genome. To study this phenomenon closely, we previously performed a targeted ablation of the mechanosensory receptors in adult zebrafish auditory and vestibular organs and characterized the epigenome and transcriptome at consecutive time-points during regeneration. We identified unique, cell-specific transcription factor (TF) motif patterns in the chromatin that opened specifically during regeneration. We correlated this emergent enhancer activity with differential gene expression to identify key gene regulatory networks driving regeneration. We detected a clear pattern of overlapping Sox- and Six- family TF gene expression and binding motifs, suggesting a combinatorial program of TFs driving regeneration and cell identity.

Despite significant progress in identifying key genes involved in hair cell regeneration, there is still a gap in our knowledge regarding the role of the gene regulatory networks involved in this process. In this study, we investigated if Sox- and Six-TFs and identified regeneration-responsive regulatory regions containing Sox- and/or Six- binding motifs, were necessary in zebrafish hair cell regeneration by testing function through gene knockouts and mass mutagenizing putative enhancer regulatory regions. Using CRISPR/Cas9 guided mutagenesis, we phenotypically characterized TF mutants, singly and in

combinations, for defects or improvements in lateral line development and hair cell regeneration. To accelerate screening for hair cell regeneration phenotypes associated with enhancers containing either Sox, Six, or both motifs, we employed MIC-Drop (Multiplexed Intermixed CRISPR Droplets) to mass mutagenize putative regeneration-responsive regulatory regions and screened for hair cell regeneration defects using the lateral line as a proxy for large scale testing. Finally, we used fluorescent *in situ* hybridization to gain spatial resolution and determine the expression pattern of *sox* and *six* genes in the inner ear and lateral line. By combining knockout strategies, phenotypic analysis, and TF gene expression, we are beginning to understand the combinatorial "code" of TFs that initiate regeneration and instruct hair cell differentiation.

356 **Ketogenic diet and multiple loci drive diet-induced thermogenesis in mice** Alexandra Naron[1], Anna Salvador[2], David Threadgill[1] [1]Cell Biology and Genetics, Texas A&M University, [2]University of North Carolina-Chapel Hill

Precision nutrition is the customization of nutrition guidance through individualized plans based on unique metabolic characteristics to improve general health. However, there is still a significant lapse in knowledge of how genetics impacts diet. Genetically heterogenous mouse models have demonstrated significant variation in metabolism, activity, and body fat composition across different strains and diets. Genetic regulation of thermogenesis may contribute to the variation seen in response to diet. Investigating the role that genetics plays in individual consumption of energy, production of heat, and body composition will provide knowledge to better individualize nutritional approaches.

Previously C57BL/6J (B6), A/J, FVB/NJ (FVB), and NOD/ShiLtJ (NOD) mice were exposed to human comparable diets varied in macronutrient content, including an American (high fat, high carbohydrate) and ketogenic (high fat, no carbohydrate) diet to investigate the impact diet plays on thermogenesis rates.

We observed that the ketogenic diet increased rates of heat expenditure in A/J mice without a corresponding increase in activity relative to their A/J counterparts exposed to the American diet. B6 mice showed a more modest response to the ketogenic diet relative to the American diet with regards to thermogenesis rates. Percentage of body fat was also observed to have decreased in both A/J and B6 mice fed the ketogenic diet relative to their counterparts exposed to the American diet.

To further investigate genetic regulation of diet-induced thermogenesis, an F2 population of C57BL6/J x A/J was generated. F2s were genotyped at 7854 markers on Mouse Universal Genotyping Array (MUGA). Unconditioned linkage analysis was conducted with R/qtl2 and revealed several overlapping quantitative trait loci (QTL). QTL overlapping on Chr 7 were identified for heat expenditure and body fat gain. QTL overlapping on Chr 1 were identified for activity and heat expenditure. Allele effects showed AJ/AJ alleles driving higher heat expenditure at *Heatq2*, B6/B6 alleles driving higher activity at *Actq1*, and B6/B6 alleles driving higher percentage of body fat gain at *Bfgq3*. Investigation of an interaction between *Heatq2* and *Actq1* showed that F2 mice that are AJ/AJ at *Heatq2* and B6/B6 at *Actq1* show higher heat expenditure and lowest body fat gain.

To narrow the overlapping QTL of interest, we are generating a subconsomic line from chromosome substitution strains (CSS) for A/J Chr1 and Chr7. This will allow us to validate previously identified QTLs of interest and assist in the identification of genes regulating diet-induced thermogenesis.

357 **Nucleoporin complex NPP-14/24 shape perinuclear germ granule architecture and coordinate piRNA silencing** Kun Shi[1], Zhenzhen Du[1], Xinyu Fan[1], Jordan Brown[2], Ying Zhang[1], Heng-Chi Lee[2], Donglei Zhang[1,2] [1]Biochemistry and Molecular Biology, Huazhong University of Science and Technology, [2]Molecular Genetics and Cell Biology, University of Chicago

Germ granules are RNA-rich biomolecular condensates containing factors for the posttranscriptional regulation of gene expression and the development of germ cells [1]. In *C. elegans*, germ granules are associated with nuclear pore clusters [2]. Previous studies have shown that assembly of P granules in the perinuclear region is critical for the fidelity of piRNA-mediated gene silencing [3]. However, the mechanism by which germ granules associate with the nucleus and the functional relevance of such an association remain unknown. Here we showed that the conserved NPP-14/24 nucleoporin complex, which is localized on the cytoplasmic side of the nuclear pore complex, recruited various perinuclear germ granules to nucleus. Depletion of NPP-14/24 led to disaggregation of nuclear pore clusters and dissociation of most perinuclear germ granules. Additionally, germ granule components that originally localized in distinct P/Z/S/M foci merged into few remaining large condensates at the perinuclear region. Our results showed that poly(UG)-tailed RNAs, the RNA degradation intermediates, accumulated in the enlarged perinuclear condensates, suggesting that these granules are capable of RNA silencing. Interestingly, using a piRNA reporter, we found that piRNA-mediated gene silencing was enhanced in *npp-14/24* mutants. Notably, WAGO 22G-RNAs were specifically elevated at piRNA target sites across transcriptome, suggesting enhanced production of piRNA-dependent WAGO 22G-RNAs. On the other hand, we observed that *npp-14/24* mutants exhibited defects in siRNA-triggered transgenerational gene silencing, consistent with the hypothesis that the piRNA pathway antagonizes the inheritance of siRNA-mediated gene silencing [4]. Using proximity labeling, we further identified an uncharacterized P granule factor with intrinsic disordered

domains, GGO-1 (Germ Granule Organizer-1), associating with both NPP-14 and the P granule protein PRG-1. Remarkably, *ggo-1* mutants exhibited similar phenotypes as *npp-14/24* mutants, including merged perinuclear granules and enhanced piRNA silencing with elevated WAGO 22G-RNAs near piRNA target sites. Together, our results uncover the function of the NPP-14/24 complex in spatially organizing perinuclear germ granules and shed light on how organized germ granules function in fine-tuning the piRNA-based transcriptome surveillance and the inheritance of gene silencing.

[1] Voronina et al. 2011; [2] Updike et al. 2011; [3] Chen et al. 2022; [4] Shukla et al. 2021

358 **Germ granules modify the posterior pole promoting primordial germ cell formation**

Marcus D Kilwein[1], Elizabeth Gavis[2], Stanislav Shvartsman[1] [1]Molecular Biology, Princeton University & Simons Foundation, [2]Molecular Biology, Princeton University

Specification and segregation of the germline is one of the first events in metazoan embryogenesis. In Drosophila, the primordial germ cells (PGCs) exit syncytial development an hour before the soma, by precociously cellularizing at the posterior pole. This event depends on maternally deposited germ granules (GGs). We have known since the 1970s that transplantation of the germ granules is sufficient to induce PGC formation at new regions of the embryo. However, how germ granules promote PGC formation has remained unanswered. Our data show that GGs initiate PGC formation through local plasma membrane modifications that drive f-actin dynamics and precocious cell formation.

Among mRNAs found in germ granules or otherwise enriched at the posterior are mRNAs coding for actin regulatory and interacting proteins that could be involved in PGC formation. By live imaging using the f-actin sensors GFP-MoeABD and Lifeact, I found that f-actin becomes enriched at the posterior cortex of the embryo before nuclear cycle 5. This f-actin enrichment is dependent on GGs, as embryos lacking GGs through removal of the GG organizer Oskar, do not enrich f-actin.

Furthermore, GG transplantation induces f-actin formation at the new location in the recipient embryo and leads to formation of ectopic PGCs. I next sought to determine what actin polymerization factors organize the posterior enrichment, focusing on regulators of the ARP2/3 complex which is known to generate pushing force like that seen during PGC budding. The ARP2/3 activator WASp was indeed enriched at the posterior and localized to the bud-front during PGC formation. Injection of an inhibitor for ARP2/3 showed that ARP2/3 is essential both for the posterior f-actin enrichment and formation of the PGCs.

I then sought to determine how germ granules promote f-actin enrichment. Intriguingly, 7 of the 8 actin-related mRNAs found in germ granules contained binding domains for the membrane lipid PI(4,5)P2(PIP2). PIP2 has a well-established role in promoting f-actin formation. Using the PIP2 binding sensor PH-mCherry, I found enrichment for PIP2 at the posterior pole. GG transplantation induced PIP2 synthesis at the new location in the recipient embryo and formation of ectopic PGCs. Further, the PIP2 producing enzyme dPIP5K was enriched at the posterior pole, in a similar manner to PH-mCherry. Finally, injection of PIP2 at a new region of the embryo induced futile f-actin furrows at a new location.

359 **Homologous recombination is essential for DNA damage-induced regeneration of germline stem cells in the Drosophila testis niche**

Jasmine Grey[1], Salman Hasan[2], Janelle Bellot[1], Erika Matunis[1] [1]Cell Biology, Johns Hopkins University School of Medicine, [2]Johns Hopkins University School of Medicine

Germline stem cells (GSCs) transmit the genome to the next generation, and therefore understanding their DNA repair strategies is of particular interest. Several highly conserved DNA repair pathways sense and repair double strand breaks (DSBs), which are otherwise lethal events. This includes homologous recombination (HR), which uses the sister chromatid as a template to yield high fidelity repair, and non-homologous end joining (NHEJ), which is often mutagenic. Whether stem cells differentially require specific DSB repair pathways is not typically studied within tissues. Here, we use the *Drosophila* testis stem cell niche to study the responses of GSCs to DNA DSBs. We first established conditions to follow GSC loss and recovery after ɣ-irradiation (IR) *in vivo*. Exposing adult male flies to 75 Gy of IR causes approximately half of GSCs to become lost from the niche within 24 hours. Lost GSCs are replenished and their progeny (spermatogonia) return by one week, indicating GSC functionality. Unexpectedly, TUNEL staining and p35 overexpression show that GSC loss is not due to apoptosis. Instead, live imaging and clonal analysis show that IR causes single GSCs to detach from the niche and move toward the base of the testis, an event not seen in unirradiated testes. To identify the DNA repair pathway(s) at play, we assayed GSC loss and recovery in several mutant backgrounds. GSCs null for Chk2 or p53 persist in the niche after IR, consistent with a requirement for these factors in DSB sensing. Since the detachment of some GSCs from the niche is likely downstream of p53 activation, we analyzed GSC recovery in flies null for either NHEJ or HR pathway members. As expected, GSCs unable to perform NHEJ are partially lost and then replenished after IR exposure, as in wild type testes. Unexpectedly, GSCs unable to perform HR are not maintained within the niche. The GSC requirement for HR is cell autonomous, aligning with the germline's unique role in maintaining genomic integrity. We are now investigating the significance of the cell cycle phase on stem cell survival after IR. A deeper understanding of stem cell resistance to IR has implications in other radio-resistant stem cells, like cancer stem cells, which contribute to the regrowth of tumors after radiotherapy.

360 **An actomyosin network organizes niche morphology and responds to feedback from recruited stem cells** Bailey N Warder[1], Kara A Nelson[1], Justin Sui[2], Lauren Anllo[3], Stephen DiNardo[1] [1]Cell and Developmental Biology, University of Pennsylvania, [2]Department of Medicine, University of Pittsburgh, [3]Department of Biology, East Carolina University

Stem cells often rely on signals from a niche, which in many tissues adopts a precise morphology. What remains elusive is how niches are formed, and how morphology impacts function. To address this, we leverage the *Drosophila* gonadal niche, combining genetic tractability with live-imaging. This niche adopts a distinct morphology during embryogenesis, with a smoothened boundary between itself and adherent germline stem cells (GSCs). The niche plays key roles in regulating GSC behavior and it is thus vital to identify mechanisms of niche formation. We have found that the niche-GSC boundary is enriched for F-actin and Myosin II (MyoII). We therefore hypothesize that actomyosin contractility (AMC) shapes the niche, and makes it more efficient in guiding GSC behavior. Through transgenic and pharmacological manipulations, we show that AMC is required for generating a smoothened niche-GSC boundary and therefore a proper niche shape. Additionally, we have evidence that proper niche shape is crucial for its functions of sending self-renewal signals to a subset of germ cells, as well as regulating GSC divisions. Since AMC is therefore vital for forming a functional niche, our work further addresses mechanisms that robustly polarize MyoII in the niche. Interestingly, MyoII polarity can be regulated by mechanical forces exerted on a cell, and we have evidence that GSC divisions are required for MyoII polarity and niche morphogenesis. We therefore suspect that proper MyoII polarity in the niche is in part induced by forces inherent to GSC divisions. Our work unveils a unique feedback mechanism where stem cells shape the niche that guides their behavior. This work was supported by NIH grants F31HD105342 and T32GM007229 to BNW; T32 HD083185 and F31 HD111208 to KAN; GM125123 to LA; R35 GM136270 to SD.

361 **Autophagy in Meiotic Fidelity and Genome Integrity** Kaitlin Kosinski[1], Marilina Raices[2], Judith Yanowitz[3], Alicia Melendez[1] [1]Biology, Queens College/City University of NY, [2]Dept of OB/GYN/Reproductive Sciences, University of Pittsburgh School of Medicine, [3]Department of Obstetrics, Gynecology and Reproductive Sciences, University of Pittsburgh School of Medicine

Autophagy is a conserved cellular recycling process crucial for homeostasis. In this multistep process, cellular material destined for degradation is enclosed in the autophagosome, a double membrane-bound organelle that fuses with the lysosome for degradation. Reproduction is an energetically expensive process for living organisms, and the decision for an organism to invest in its offspring or survival thus requires the communication between the conditions in the environment and the germ line. Although typically upregulated in response to cellular stress conditions, basal levels of autophagy can also function as a quality control mechanism that serves to maintain cellular homeostasis in response to developmental and environmental cues. The role of autophagy in cellular homeostasis is well documented, but its function in the maintenance of genomic stability in the germline remains unclear. We recently described roles for BEC-1, the *C. elegans* ortholog of mammalian BEC-1/BECN1, and several other autophagy genes in germline stem cell homeostasis (Ames et al., 2017). Specifically, we found that BEC-1, as well as ATG-18 (in mammals, WIPI1/2), ATG-16.2 (ATG16L) and ATG-7 (ATG7), are required for the late larval expansion of germline stem cell progenitors during development. We have also reported a role for BEC-1 in the DNA damage response (DDR) to UV, where it exhibits crosstalk with CEP-1, the *C. elegans* ortholog of p53 (Hoffman et al., 2014). We have now found that autophagy genes are also required to maintain meiotic fidelity. In *bec-1, atg-7, unc-51* or *atg-18* mutants, the diakinesis oocytes display chromosomal abnormalities, defects in meiotic fidelity. CEP-1 is well known for its roles in promoting genomic integrity through the DDR, including cell cycle control, apoptosis, and DNA repair. CEP-1 also acts in meiosis, in the double-strand break formation and suppressing nonhomologous end-joining (NHEJ), to ensure the high-fidelity repair of double-strand breaks (DSBs) by the error-free homologous recombination (HR) pathway (Mateo et al., 2016). We are now investigating the mechanism(s) by which BEC-1 and autophagy genes promote DNA damage repair in germline development. Our current work seeks to elucidate which tissues require autophagy to regulate meiosis and germline proliferation and at which step of meiosis autophagy genes are required to regulate the DNA damage response during germline development.

362 **Epithelial migration speed modulates basement membrane mechanics to control the degree of tissue elongation** Mitch Anderson, Sally Horne-Badovinac University of Chicago

Basement membranes (BMs) are sheet-like extracellular matrices that line epithelia and other tissues to support their function. It is increasingly appreciated, however, that epithelia can also pattern the mechanical properties of their BM to control their own morphogenesis, but how this occurs is poorly understood. In this work, we use the *Drosophila* egg chamber to ask how a BM is patterned to control tissue elongation. An egg chamber is composed of a germ cell cluster surrounded by an epithelium of follicle cells; the entire organ is encased by a BM. Though initially spherical, egg chambers elongate throughout their development to produce an ellipsoid egg. This morphogenesis depends on a collective migration of the follicle cells across the BM. During this process, cell movement synergizes with new BM protein secretion to create an array of fibrils in the matrix, which stiffen the BM over the center of the egg chamber and allow it to act as a “molecular corset” to preferentially direct tissue growth along one axis. When follicle cell migration is blocked, as occurs with loss of *fat2*, the

BM corset fails to form, and the egg is much rounder than in wild type. Here, we leverage a different mutant condition, loss of *Sema5c*, to show that the mechanical properties of the BM can also be tuned to produce other morphogenetic outcomes. We previously showed that loss of *Sema5c* leads to slowed follicle cell migration and mildly round eggs. We have now found that the difference in egg shape between the two mutant conditions occurs because *Sema5c* egg chambers continue to elongate over a longer developmental time window than *fat2* egg chambers. We then explored the mechanical properties of the BM in *Sema5c* egg chambers by assaying its ability to resist rupture in response to acute osmotic swelling of the tissue. We found that *Sema5c* BMs become defective in this assay shortly before the defect in egg chamber elongation appears, and this phenotype is likely due to a reduction in BM fibrils. Restoring fibrils to the BMs of *Sema5c* egg chambers by changing the subcellular location of BM protein secretion suppresses the egg elongation defect. By contrast, reducing the levels of the primary BM component, Collagen IV, enhances the elongation defect without further disrupting cell migration. Altogether, these results suggest that the speed at which the follicle cells migrate affects BM remodeling and mechanics in a way that can be harnessed to generate a range of tissue shapes.

363 **The function of Bucky ball and the Balbiani body in oocyte polarity and germ cell development** Manami Kobayashi, Mary C Mullins University of Pennsylvania

Oocyte polarity is important for formation of the embryonic body axis and germ cells. The Balbiani body (Bb) is a large, membrane-less, mitochondrial-rich, electron-dense structure observed in the primary oocyte, which is conserved from insects to mammals, including humans. However, its function and the mechanisms regulating it are not fully understood. In frogs and fish, the Bb is postulated to establish oocyte polarity. mRNAs essential for body axis formation and germ cell formation localize to the Bb. As the Bb disassembles at the cortex in later stage oocytes, the Bb-localized transcripts and proteins become docked at the oocyte cortex. These vegetally-localized factors delivered by the Bb are postulated to specify the animal-vegetal (AV) axis. The Bb localized protein, Bucky ball (Buc), is the only gene known to function in Bb formation. Here, I established *buc* CRISPR mutant lines that are *buc* hypomorphic alleles, which differ to null alleles. In *buc* null mutants, AV polarity fails to form and the animal pole is expanded radially in the oocyte and embryo, which dies before 1 dpf. In *buc* hypomorphic mutants, embryos displayed normal AV polarity and survived to 1 dpf; however, many were severely ventralized. Those embryos with a WT phenotype failed to generate primordial germ cells and developed into sterile males. In *buc* hypomorphic oocytes, the mitochondria did not aggregate into the Bb and the Bb failed to form in early stage oocytes. Interestingly, in later stage oocytes, Buc and transcripts localized to the vegetal cortex, although in a reduced size domain. In these later stage oocytes the animally-localized mRNA, *cyclin B1*, was localized in an expanded animal pole domain. These results demonstrate the importance of Buc in germ cell formation and dorsal axis formation and suggest a Bb-independent mechanism of polarizing the oocyte.

364 **Dysfusion suppresses border cell recruitment and migration by attenuating Stat nuclear import** Anna C.-C. Jang[1], Jhen-Wei Wu[1], Chueh-Wen Wang[1], Ruo-Yu Chen[1], Liang-Yi Hung[1], Yu-Chen Tsai[2], Yu-Chiuan Chang[3] [1]Department of Biotechnology and Bioindustry Sciences, National Cheng Kung University, [2]Department of Life Science and Life Science Center, Tunghai University, [3]Institute of Biomedical Sciences, National Sun Yat-sen University

Collective cell migration, in which cells move as a group, is a pivotal process of embryonic development, wound healing and cancer dissemination. *Drosophila* Border Cells (BCs) escape from the neighboring cells, form a cluster and migrate through germ cells, serving as a good model to investigate cohesive cell movement. Jak/Stat signaling establishes follicle cell patterning in early oogenesis but induces BC migration at the later stage. The underlying mechanism governing such morphogenic switch remains to be explored. Here, we report that the spatiotemporal downregulation of *dysfusion* (*dysf*) escalates Jak/Stat activity, which thereby turns epithelial follicles into migratory BCs in egg chambers. Dysf protein is located on the inner nuclear membrane of all germline and follicle cells, but gradually reduced in BCs upon migration. When BCs reach the oocyte border, their Dysf staining becomes undetected. Overexpression of UAS-*dysf* severely impaired BC recruitment; conversely, *dysf* loss-of-function induced extra BCs. A similar phenotype of ectopic BCs caused by Jak/Stat hyperactivation can be suppressed by *dysf* overexpression. Furthermore, up-regulation of Dysf impeded the phosphorylation, transcriptional activity, and nuclear import of Stat protein, indicating that *dysf* negatively regulates Jak/Stat signaling. To further unfold Dysf-mediated nucleocytoplasmic translocation of Stat, we performed a biochemical screen to seek for proteins which interact with Dysf, and identified Pendulin (Pen), a member of the Importin-alpha protein family. GST pull-down assays revealed direct interaction of Dysf and Pen via the importin beta binding (IBB) domain. Elevating Pen expression counteracted the effect of *dysf* up-regulation to increase the flow of Stat into the nucleus. Therefore, we propose that *dysf* restricts Jak/Stat signaling activity to confine the size of BC clusters by constraining Stat nuclear transport. More importantly, we also demonstrated that the human homologue of Dysf, NPAS4, executes a similar task to prevent nuclear accumulation of STAT3 and impairs STAT3-induced migration in liver and colon cancer cell lines.

365 **Elucidating the molecular mechanisms of midbody reorganization during ring canal biogenesis** Kari L. Price, Ellery

Winkler, Kathleen Ayers, Yasmin Almazan, Lynn Cooley Yale School of Medicine

Animal gametes typically develop through some or all of gametogenesis as syncytia of cells attached by stable intercellular bridges called ring canals. Ring canals are important conduits allowing the movement of mRNAs, proteins, and organelles between sibling cells. Despite the conservation of germline ring canals across evolution, canonical cytokinesis is modified during germ cell division to produce ring canals has been poorly understood. Using time-lapse imaging of cytokinesis proteins in dividing germ cells in the Drosophila male germline, we previously showed that ring canal formation occurs via dramatic reorganization of the germ cell midbody – a structure classically associated with its function in recruiting abscission-regulating proteins in complete cytokinesis. However, unlike canonical midbodies, the germ cell midbody is unusually large, short-lived, and rapidly reorganizes to form a nascent ring canal. We identified a component necessary for germ cell midbody reorganization, the mitotic kinase and midbody organizing protein Citron kinase/Drosophila Sticky. Our recent structure-function analyses have revealed a role for the Citron-Nik1 Homology (CNH) Domain as over-expression of a *sticky-ΔCNH::GFP* cDNA construct dominantly affects ring canal formation. The CNH domain was previously shown to be necessary for Sticky function in completely dividing S2 cells[1], suggesting that it may function analogously during the incomplete divisions that generate ring canals. As Sticky contributes to the maintenance of RhoA at cleavage furrows in completely dividing cells, we examined the localization of RhoA with the RhoA sensor (Anillin Rho Binding Domain::GFP) and found evidence that RhoA is localized to ring canals throughout spermatogenesis. Furthermore, our preliminary results show that over-expression of dominant negative, but not constitutively active, RhoA in an otherwise wild-type background results in smaller ring canals on average, suggesting that RhoA-GTP may play a role in ring canal formation. To identify additional ring canal promoting factors, we performed a candidate RNAi screen targeting mitotic kinases and phosphatases, as well as enzymes with important roles in ubiquitin homeostasis. We have identified several genes, some of which are uncharacterized, that are required for proper ring canal architecture and/or size suggesting an important role for post-translational modifications of germ cell midbody proteins during ring canal biogenesis.

1. Bassi, Z.I., Verbrugghe, K.J., Capalbo, L., Gregory, S., Montembault, E., Glover, D.M., and D'Avino, P.P. (2011). Sticky/Citron kinase maintains proper RhoA localization at the cleavage site during cytokinesis. J. Cell Biol. *195*, 595–603. 10.1083/JCB.201105136.

366 **TGF-β Ligand Cross-Subfamily Interactions in the Response of *Caenorhabditis elegans* to Bacterial Pathogen** Emma Ciccarelli[1], Zachary Wing[2], Katerina Yamamoto[1], Cathy Savage-Dunn[1] [1]Queens College and the Graduate Center, CUNY, [2]Queens College, CUNY

Transforming Growth Factor-β (TGF-β) secreted signaling ligands play critical roles in a range of biological functions and their dysfunction in humans is associated with diseases including cancer, cardiovascular disease, and reproductive disorders. These ligands are divided into bone morphogenetic protein (BMP) and TGF-β/Activin subfamilies that predominantly signal through different signaling pathways. Many TGF-β ligands have context-dependent or concentration-dependent functions. While the core components of TGF-β signaling pathways have been identified for more than 25 years, how these pathways produce context-dependent outcomes remains poorly understood. In the nematode *Caenorhabditis elegans,* the BMP ligand DBL-1 is required for innate immunity. We tested the roles of all five *C. elegans* TGF-β ligands in survival on the pathogenic bacterium *P. luminescens.* Mutants for each of the five ligands had reduced survival, with loss of TIG-2 and TIG-3 showing the most severe defects. Furthermore, *tig3; tig-2* double mutants had a survival rate indistinguishable from each of the single mutants, suggesting that they function together in pathogen response. Joint action of TIG-2 and TIG-3 could be evidence of TIG-2/TIG-3 heterodimers, or the ligands could act together through a receptor clustering mechanism. To determine whether heterodimers of TIG-2 and TIG-3 are feasible, we performed structural modeling. Using the ColabFold implementation of AlphaFold, we generated strongly supported models for the TIG-2/TIG-3 heterodimer and for the TIG-2 homodimer. In contrast, the potential for TIG-3 to form homodimers was not well supported by ColabFold. The genetic evidence and structural modeling support the hypothesis that these ligands form a heterodimer, in spite of being from different sub-families (BMP and TGFβ/Activin). Heterodimers of BMP ligands are functionally required or outperform homodimers in a variety of physiological contexts, but cross-subfamily heterodimers have not, to our knowledge, been identified previously. Cross-subfamily interactions between TGF-β ligands may diversify biological outcomes, allowing differentiation of acute responses, such as host-pathogen response, from more ubiquitous signaling functions.

367 **Drosophila gut microbiome colonization specificity is driven by selective adhesion** Kevin Aumiller[1,2], Karina Gutierrez-Garcia[2], Ren Dodge[2], Sneha Agrawal[1], Ann Deng[1,2], Xincheng Yuan[1], William Ludington[1,2] [1]Johns Hopkins University, [2]Carnegie Institution of Washington

Animals form symbiotic relationships with resident gut microbiota that are both stable and host-specific. The current consensus in the field is that host specificity is achieved by environmental filtering, wherein the host gut provides a unique

set of growth conditions for symbiotic bacteria through metabolism and immunity. We propose a higher degree of biological sophistication, where specificity is further enhanced by specific receptor-ligand interactions that allow the host to recruit bacteria to spatially defined niches.

Lactobacilli are prevalent symbiotic bacteria that exhibit diverse host ranges that include mammals and insects such as *Drosophila melanogaster*. We isolated a strain of *Lactiplantibacillus plantarum* (LpWF) from wild *D. melanogaster* that establishes a spatial niche within the foregut. Using this system, we developed a model to identify the determinants of host-specific colonization through *in vitro* evolution of LpWF.

Through long-read sequencing, we identified a genomic island consisting of 27 genes that are deleted via homologous recombination during *in vitro* evolution, with these mutants exhibiting (I) a sharp decrease in colonization efficiency, (II) a lack of spatial specificity for the foregut niche and (III) an acute selective disadvantage when placed in competition with wild-type LpWF in the fly gut.

Phenotypic characterization of several evolved mutants revealed that a pair of serine rich repeat adhesins (SRRPs) encoded by the island drive selection for strong colonizers in the gut, but are rapidly lost when LpWF is evolved outside of the host environment.

Through biochemical characterization of recombinant SRRP binding domains, we found that these adhesins specifically bind to the luminal surface of the foregut. Ectopic expression and cell surface display of the binding domains in SRRP-deficient mutants and non-fly isolate *L. plantarum* strains demonstrated sufficiency of these proteins to promote attachment to the foregut, suggesting that adhesion plays a key role in specifying colonization of the commensal niche.

From our findings, we propose that ligands secreted into the gut epithelial barrier promote specificity of colonization by modulating bacterial adhesion. We aim to identify the *Drosophila*-expressed binding partners of the SRRPs to further investigate the mechanisms by which animals establish and maintain specific host-microbe associations.

368 **Metabolic consequences of chronic bacterial infection increase susceptibility to starvation in *Drosophila melanogaster*** Andrea M Darby[1,2], Scott Keith[1,2], Ananda A Kalukin[1], Brian P Lazzaro[1,2] [1]Entomology, Cornell University, [2]Cornell Institute of Host-Microbe Interactions and Disease

Infections induce systemic shifts in host lipid and carbohydrate metabolism, including reduction in triglyceride and glycogen stores to support the immune response. *Drosophila melanogaster* that survive systemic infection with the bacterium *Providencia rettgeri* sustain a chronic bacterial load, exhibit infection-induced gene expression of antimicrobial peptides (AMPs), and are more susceptible to starvation at 10-days post-infection. In this study, we asked whether increased starvation susceptibility in survivors is due in part to metabolic consequences of sustaining a chronic infection. Further, we asked whether severity of infection correlates with altered metabolic phenotypes that affect starvation survival. To address this question, we infected flies with pairs of high- and low-virulence strains of the Gram-negative bacteria *Serratia marcescens* and *P. rettgeri*, which are natural pathogens to *D. melanogaster* and establish a chronic infection by five days post-infection. Flies that survived infection were measured for bacterial load, AMP expression, starvation resistance, triglyceride and glycogen levels, and expression of genes involved in triglyceride and glycogen catabolism. We found that high-virulence bacterial strains established higher bacterial loads and increased starvation sensitivity. The high-virulence *P. rettgeri* infection resulted in increased induction of AMPs, however, there was no difference in AMP induction between high- and low-virulence *S. marcescens* strains. Susceptibility to starvation after high-virulence *S. marcescens* infection was associated with reduced triglyceride and glycogen stores and elevated expression of the lipase *brummer*, while high-virulence *P. rettgeri* infection only resulted in reduced glycogen stores. These results suggest that carrying a higher chronic bacterial load results in metabolic consequences that increase susceptibility to starvation. To further test whether carrying a higher chronic burden increases starvation sensitivity, we infected flies with a low or high dose for each low-virulence and high-virulence strain to generate a low and high chronic burden within each strain. For both *S. marcescens* strains, the higher dose resulted in higher bacterial load and increased sensitivity to starvation. Current experiments are in progress to test whether a higher dose of the *P. rettgeri* strains also results in higher bacterial load and increased starvation sensitivity, and to test within strains whether higher bacterial load correlates with depletion of metabolic stores.

369 **Deep homolog scanning of proteins involved in host-pathogen conflict** Meru Sadhu National Institutes of Health

The advent of deep mutational scanning, in which the effects of all possible single-amino acid changes are assayed in a protein of interest, has given researchers an exquisitely detailed view of the immediate evolutionary landscape available to a particular protein sequence. On the other hand, looking across species, the orthologs of a given protein explore even greater diversity. Studying species-scale functional diversity can help us understand how genetic differences between species underlie their

unique traits. We are using array-based oligonucleotide synthesis and yeast-based phenotypic screens to study the functional differences of hundreds to thousands of homologs of proteins of interest. I will discuss our work on proteins involved in pathogen defense to better understand the genetic basis of species' susceptibility to hosting particular pathogens. We typically focus on particular surfaces of host and pathogen proteins that interface in a manner that is critical for the success or failure of the infection, such as interaction surfaces in defense proteins, host receptors, and pathogen effectors. We then build genetic libraries to test the homologous surfaces from diverse sequences for their ability to mediate the interaction. We propose that deep homolog scanning will help expand our understanding of the compatibility between hosts and pathogens, and the molecular basis for that specificity.

370 **Parasite-driven mitochondrial remodeling reprograms the host metabolic state to support parasite propagation and vertical transmission** Shenlu Qin[1], Matthew Sieber[2] [1]Physiology, UTsouthwestern Medical Center, [2]Physiology, UT Southwestern Medical center

Interactions between microbes and their hosts are central to normal physiology and human disease. In particular, host-parasite interactions are known to play a role in gastrointestinal disorders, metabolic diseases, and even cancer, all of which are driven by defects in cellular metabolism and mitochondrial function. Despite this relationship between metabolic defects and parasite infection in human disease, very little is known about the mechanisms used by intracellular parasites and pathogens to reprogram host mitochondrial function. Our lab uses a multi-system approach featuring *Drosophila*, human cells, and mice, incorporating genetic and biochemistry techniques to systemically define the conserved mechanisms that drive mitochondrial remodeling in disease.

One of the major challenges in studying the metabolic relationships between host and intracellular parasites is that purely cell culture-based strategies create an artificial metabolic state in the host cell. In this study, we employed the intracellular bacteria known as *Wolbachia* and *Drosophila melanogaster* as a robust *in vivo* model to investigate the evolutionary conserved aspects of host-microbe metabolic interactions. We have discovered that *Wolbachia* infection blocks the reprogramming of mitochondrial metabolism during *Drosophila* oogenesis. Our data shows that *Wolbachia* alters host ovary mitochondria shape, activity, membrane potential, and movement during cellular quiescence. Furthermore, we found that *Wolbachia* physically interacts with host mitochondria and produces proteins that target host mitochondria to control host metabolic function. We have found these mechanisms create a metabolic state that supports parasite needs. Notably, we discovered that alteration in host NAD+ biosynthesis and the methionine cycle are required for *Wolbachia* parasitism and its vertical transmission to the next generation. We are currently examining mammalian host-parasite interactions to determine if mitochondrial remodeling redox metabolism represents a conserved node commonly tagged by parasites in models of human disease. Overall, this study provides a mechanistic platform to understand the remodeling of mitochondrial metabolism by intracellular parasites. This study also provides a framework to identify metabolic vulnerability caused by parasite infections that enhance disease progression.

371 **Alternative splicing of conserved lipase alters endocannabinoid production and host innate immune response upon bacterial infection** Francis RG Amrit[1], Julia A Loose[1], Laura Bahr[1], Abbe Vallejo[1], Ravi Sharma[2], Andreas Pfenning[3], Ramanathan Sowdhamini[4], Carles Sune[5], Carissa P Olsen[6], Hidehito Kuroyonagi[7], Arjumand Ghazi[1] [1]Pediatrics, University of Pittsburgh School of Medicine, [2]Amity Institute of Biotechnology, [3]Carnegie Mellon University, [4]National Centre for Biological Sciences, [5]LogoCab LogoIPBLN Instituto de Parasitología y Biomedicina, [6]Worcester Polytechnic Institute, [7]University of Ryukus

Lipids exert a profound influence on immune status providing bulk energy sources and mediating immune signaling. Indeed, host responses to microbiota and infection have immune and metabolic facets. But, mechanisms that govern immunometabolic remodeling are poorly understood and have been studied mostly in the context of transcriptional regulation. The role of post-transcriptional mechanisms such as Pre-mRNA splicing in host-bacteria conflict remains largely unknown. We have uncovered a novel, evolutionarily conserved and physiologically relevant mechanism by which alternative splicing of lipases alters endocannabinoid (eCB) production and shapes the host response to intestinal bacterial infection.

Previously, we identified the *Caenorhabditis elegans* protein, TCER-1, homolog of human splicing factor TCERG1, as a regulator of lipid remodeling that modulated longevity, and showed that it represses host immune response against multiple bacterial infections. We have now discovered that infection triggers global mRNA splicing changes, especially of lipid-metabolic genes controlled by TCER-1/TCERG1. TCER-1/TCERG1 controls the inclusion/exclusion of a single exon in DAGL-2, a diglyceride lipase responsible for biogenesis of 2 Arachidonyl Glycerol (2-AG), the most abundant mammalian eCB with key immunomodulatory roles. Our *in vivo* studies have revealed dynamic cell- and tissue- specific patterns of DAGL-2 alternative splicing upon infection. Importantly, DAGL-2 alternative splicing determines 2-AG levels and impacts the host response to bacterial infection. Computational structure-function modeling identified analogous exons in DAGLβ, the human homolog of DAGL-2. We found DAGLβ alternative splicing to be regulated by human TCERG1 and DAGLβ exhibits similar alternative splicing in peripheral

blood cells suggesting strong mechanistic conservation. Overall, this work establishes alternative splicing as a conserved regulatory feature of immunometabolism and host-bacteria conflict.

372 **The gut microbiome is a significant contributor to mouse model phenotypes contributing to a lack of reproducibility and masking of genetic drift** James Amos-Landgraf, Aaron Ericsson, Craig Franklin Veterinary Pathobiology, University of Missouri

The genetics community has long recognized that genetic background can modify phenotypes of animals. The reproducibility and translatability of genetically modified mouse models remain problematic for many models. Recent work by our group and others has highlighted that not only the host genome but also the host microbiome can significantly contribute to the phenotype but is often not controlled for between institutions, investigators, or experiments. We propose that a minimal characterization and reporting of the gut microbiome (GM) can enhance the rigor and reproducibility of mouse models. The Mutant Mouse Resource and Research Center at the University of Missouri has now examined six well-characterized mouse models of human disease and found quantitative differences in model phenotypes in animals harboring different vendor-derived specific pathogen-free (SPF) GMs. We have created CD-1 colonies that harbor the GMs of four major commercial vendors' SPF microbiomes that we use as surrogate dams for rederivation or transgenic mouse model production. While the resulting animals are SPF, 16s rDNA sequencing revealed unique taxa in each of the GMs and significant differences in relative abundances of various shared taxa. Using predictive algorithms and untargeted mass spectroscopy-based metabolomics we identified dramatic differences in the metabolic capacity between the most diverse and complex microbiome and the least. We examined phenotypes in the IL10$^{-/-}$, NOD/ShiLtJ, C57BL/6-*Apc*^{Min}, DSS-induced colitis, and infectious disease models, as well as the BTBR model of behavior, and found significant differences in phenotypes as determined by histology, quantitative tumor development, disease severity, and behavior tests. In one case, the influence of the microbiome masked genetic drift in the population and compromised the comparison of datasets. In addition to characterizing and controlling the microbiome, our group as well as others are also altering the mouse microbiome to enhance the translatability to human disease through human microbe transfer. Banking fecal samples prior to moving or rederiving animals as well as prior to, during, and at the completion of experiments can act as insurance if phenotype changes occur. This would allow ruling out the microbiome if it remains largely unchanged. We believe that simple characterization and documentation of the microbiome present during an experiment can provide valuable data to enhance the rigor and reproducibility of mouse models and we propose that minimal standards for reporting be adopted.

373 **Nurse cell lipid droplets regulate actin remodeling by multiple prostaglandin-dependent pathways** Michael Welte[1], Michelle S Giedt[2], Jonathon M Thomalla[1,3], Roger White[1], Tina L. Tootle[2] [1]University of Rochester, [2]Department of Biology, University of Iowa, [3]Cornell University

During oogenesis, LDs (lipid droplets) accumulate in developing oocytes from flies to humans. These LDs are a crucial energy source for the developing embryo, but it was unclear what roles - if any - they play during oogenesis. We recently discovered that LDs mediate a critical signaling function in *Drosophila* nurse cells: the LD-associated lipase ATGL/Brummer cleaves LD triglycerides to release arachidonic acid, the substrate for prostaglandin synthesis; prostaglandin signaling then regulates actin cytoskeletal remodeling to drive follicle morphogenesis. To identify additional components of this pathway, we examined flies mutant for Jabba, an LD protein particularly abundant in the female germ line and early embryo. We find that Jabba is indeed necessary for proper actin remodeling and acts in a prostaglandin-dependent manner. However, this pathway is independent of ATGL and substrate release from LDs. Rather, Jabba appears to act downstream of prostaglandins, as mutants unable to produce prostaglandins display defects in both Jabba localization and the relative expression of the different Jabba isoforms. In addition, the actin defects in these mutants are partially rescued by increased *Jabba* dosage. Intriguingly, we detect Jabba not only on mature LDs, but also enriched near the cell periphery, the site of both LD biogenesis and actin polymerization. This Jabba/actin co-enrichment is likely functionally important as disruption of F-actin with latrunculin disperses peripheral Jabba; in addition, Jabba overexpression in a wild-type background results in abnormally thick cortical actin and actin bundles. We propose that prostaglandin signaling regulates Jabba, which in turn directly or indirectly impacts actin remodeling necessary for follicle development. This work supports the emerging idea that LDs and their associated proteins play critical roles in controlling the actin cytoskeleton and can do so by distinct molecular mechanisms. Given the conservation of LDs, prostaglandin signaling, and actin remodeling in oocyte development, these findings have implications for fertility across organisms.

374 **ESCRTs mediate Notch signaling in the testis stem cell niche** Mara R Grace, Erika L Matunis Cell Biology, Johns Hopkins University

Stem cell niches are dynamic microenvironments that provide signals to ensure the maintenance and self-renewal of adult stem cell populations. Proper signaling dynamics within the niche are crucial to maintain homeostasis, while disruption

of this signaling can lead to tissue death or overgrowth. Although much is known about signaling from niche cells to stem cells, little is known about signaling in the opposite direction, from stem cells back to their niche. The testis stem cell niche of *Drosophila melanogaster* is an excellent model to investigate such signaling. Using this model, we have uncovered a role for the endosomal pathway in mediating signaling from somatic stem cells, the cell population that supports the germline, to niche cells. Endocytosis regulates a myriad of signaling pathways as well as cellular communication. The ESCRT complexes are involved in a variety of cellular processes, such as multivesicular body formation and particle budding, and are considered endocytic tumor suppressor genes due to their role in signal attenuation. Here, I show that knockdown of several different ESCRT members in somatic stem cells results in an enlarged niche, both in cell number and overall niche volume, thus suggesting that ESCRTs mediate signaling from somatic stem cells back to their niche to prevent niche hypertrophy. Additionally, niche cells, while normally quiescent, enter the cell cycle when ESCRT members are knocked down in somatic stem cells. While investigating signaling pathways that may be regulated by ESCRTs, I found that Notch activity is increased in somatic stem cells upon ESCRT knockdown. Furthermore, I have found that knockdown of Notch in somatic stem cells prevents niche overgrowth, whereas expression of activated Notch in somatic stem cells results in an enlarged niche, thus suggesting that Notch signaling mediates the niche hypertrophy caused by ESCRT loss. This leads to a model where loss of ESCRTs in somatic stem cells leads to an autonomous increase in Notch pathway activity which then non-autonomously triggers niche overgrowth. This work demonstrates an instance of stem cell to niche communication, and, as the previously quiescent niche cells are now entering the cell cycle, has implications for tumorigenesis.

375 **Distinct regulators of lipid asymmetry regulate extracellular vesicle budding** Lauren Pitts[1], Alissa Rumin[1], Tanner Chase White[1], Alexander Nguyen[1], Julia Frondoni[1], Dinah Loerke[2], Ann M Wehman[1] [1]Biological Sciences, University of Denver, [2]Physics & Astronomy, University of Denver

The P4-ATPase TAT-5 acts as a lipid flippase to maintain phosphatidylethanolamine (PE) asymmetry in the plasma membrane and inhibits extracellular vesicle (EV) release from the surface of *C. elegans* cells. TAT-5 is required for embryonic development and fertility, but how flippase activity regulates these processes was unclear.

To test how flippase activity regulates different processes, we generated mutations in the DGET motif of TAT-5 predicted to lead to a 3-fold (D to T) to complete (E to Q) loss in lipid transport. We discovered that *tat-5(E246Q)* mutants were sterile, while *tat-5(D244T)* mutants produced embryos that arrested during development. Using degron-based reporters and an automated EV detection algorithm, we found that EV release was increased >100-fold in both mutants and that phagocytosis was also disrupted. These data suggest that a low level of flippase activity can support fertility, while a higher level of flippase activity is required to inhibit EV release, allow phagocytosis, and carry out embryonic development.

As PE lipids are unlikely to be exposed in flippase mutants without the help of lipid scramblases that act as channels between leaflets of a membrane bilayer, we also investigated which scramblase proteins promote EV budding. Using a sensitized screen, we identified four scramblases where their knockdown leads to a 2-fold decrease in EV release from the plasma membrane. Intriguingly, these scramblases act at various membranes in cells, including the ER, intracellular vesicles, and the plasma membrane, suggesting that internal membrane asymmetry influences surface asymmetry.

As lipid localization can alter physical properties of the membrane, we also started determining the physical characteristics of the membrane that promote EV budding. Worms raised at 23˚C release significantly fewer EVs after a 4-hour shift to 20˚C and significantly more EVs after a 4-hour shift to 26˚C. These temperature shifts are consistent with changes in membrane fluidity altering plasma membrane budding and we are investigating this more directly using lipid probes. These studies on EV release are also likely to provide insight into other membrane budding and tubulation processes.

This work was funded in part by DFG WE5719/2-1.

376 **Lipids from a yeast-based diet mediate adaptation of *Drosophila melanogaster* to cold temperatures: a polyunsaturated plasmalogen tail.** Claudia Y Espinoza[1], Emily Behrman[2], Nan Chen[2], Daniel Milshteyn[3], Gudrun Ihrke[2], Jennifer Lippincott-Schwartz[2], Itay Budin[1] [1]Chemistry and Biochemistry, UCSD, [2]HHMI's Janelia Research Campus, [3]UCSD

Thermoadaptation is crucial for life to persist on our planet. Lipids are key molecular components for overcoming fluctuations of temperature, as they must be modified to maintain membrane fluidity and curvature as temperatures drop. Increasing the abundance of phospholipids with polyunsaturated chains (PUFAs) across cell membranes is a commonly observed strategy for animal cold adaptation. *Drosophila* cannot produce PUFAs *de novo* because they lack the required desaturase enzymes. It has thus been proposed that flies prefer plant-based diets in the cold, in contrast to yeast-based ones, as a dietary source of PUFAs. We collected wild *Drosophila melanogaster* during warm and cold periods of the year and found a predominance of associated PUFA-producing-yeast during colder months, suggesting yeast can also serve as a dietary source of PUFAs for flies. We found that the PUFA producing yeast *Lachancea kluyveri (L. k)*, prepared as a as laboratory diet, allows flies to maintain

activity down to 8°C. Flies fed with two *L. k.* strains that carry mutations in the desaturases *fad2* and *fad3,* and thus cannot produce any PUFAs, have lower activity, as do those fed non-PUFA producing yeast, like *Saccharomyces cerevisiae*. We also found that flies show egg laying and foraging preferences over PUFA-producing-yeast substrates at cool temperatures (18°C) that changes at warm temperatures (25°C). These processes depend on the olfactory system. GC-MS analysis identified isoamyl acetate as the main variant volatile in the WT and PUFA-mutant *L. kluyveri* strains, and behavioral assays showed that flies have a temperature-dependent feeding preference for the yeast-produced concentrations of isoamyl acetate. Lipidomic analysis identified the plasmalogen plasmenyl phosphatidylethanolamine, a structurally peculiar lipid containing a *sn*-1 vinyl ether linkage and *sn*-2 PUFA chain, to be differentially synthesized in flies fed with the different *L. k* diets. *D. melanogaster* null mutants for plasmalogen biosynthesis change the PUFA-dependent cold-activity phenotype. Finally, attraction towards isoamyl acetate is its affected in low plasmalogen mutants. These observations point to a complex symbiotic relationship between yeast and *Drosophila* that is influenced by PUFA exchange, volatile production, and ether lipid biosynthesis that allows *Drosophila* to adapt to cold temperatures

377 **Fascin controls nucleolar function and morphology during Drosophila oogenesis** Danielle E Talbot, Tina L Tootle Biology, University of Iowa

Prostaglandins (PGs) are locally acting lipid signaling molecules that regulate development, fertility, cardiovascular disease, and cancer. However, the underlying cellular mechanisms remain poorly understood. Using *Drosophila* oogenesis as a model, our lab has identified PGs as a novel regulator of the nucleolus. Loss of PGs results in a rounded nucleolar morphology, increased nucleolar transcription, and protein translation. These alterations to nucleolar structure and function are due to increased nuclear actin. Thus, PGs limit nuclear actin to control nucleolar function and structure. Here we address the question of how PGs regulate nuclear actin to control nucleolar functions. Actin binding proteins (ABPs), including the actin bundling protein Fascin, localize and function in the nucleus. As PGs regulate both the actin bundling functions and the nuclear localization of Fascin, and over-expression of Fascin in a PG synthesis mutant rescues nucleolar morphology, we hypothesize that PGs regulate Fascin to control nuclear actin and thereby, nucleolar function. We find that loss of Fascin results in a dispersed nucleolar morphology, decreases nucleolar transcription, and a loss of nuclear actin enrichment. This data leads to the model that Fascin promotes normal nuclear actin accumulation to maintain the appropriate level of nucleolar function. This model is at odds with Fascin's ability to rescue the loss of PGs, leading us to speculate this rescue is due to restoration of the actin cytoskeleton when PG signaling is lost. Together these data suggest Fascin has both an indirect (actin cytoskeleton) and direct role in regulating the accumulation of nuclear actin. Current work is focused on testing the indirect role of Fascin. By uncovering the mechanisms by which PGs and Fascin regulate the nucleolus, we hope to gain a greater understanding of how the dysregulation of these factors can disrupt development and fertility, and fuel disease pathogenesis.

378 **Oligomerization and feedback on membrane recruitment stabilize PAR-3 asymmetries in *C. elegans* zygotes.** Charles Lang[1,2], Alexander Anneken[3], Edwin Munro[2] [1]Molecular and Cellular Physiology, Stanford University, [2]Molecular Genetics and Cell Biology, University of Chicago, [3]University of Chicago

The PAR polarity network is a paradigmatic example of how systems of mutually antagonism interactions among peripheral membrane binding proteins allow them to form and maintain complementary polar domains in response to a transient polarizing cue. The oligomeric scaffolding protein PAR-3 has emerged as a keystone member of the PAR network in many different contexts. In early *C. elegans* embryos, PAR-3 is required for all other PAR asymmetries, and it can form stable unipolar asymmetries when its known inhibitors are absent and all other members of the PAR network are cytoplasmic or spatially uniform on the membrane. But how PAR-3 forms stable unipolar asymmetries absent mutual antagonism is unknown. Here we combine single particle analysis with quantitative modeling and experimental manipulations to determine how the dynamics of PAR-3 membrane binding, oligomerization and dissociation allow PAR-3 to maintain stable asymmetries in the one cell *C. elegans* embryo. We find that two forms of positive feedback contribute to sustaining PAR-3 asymmetries: First, a sharp size-dependent decrease in oligomer dissociation rates makes the effective dissociation rate of PAR-3 decrease sharply with its membrane density. Second, membrane-bound PAR-3 promotes additional binding of PAR-3 to the membrane. Through a combination of modeling and quantitative measurements, we show that these two feedback loops are sufficient to dynamically stabilize asymmetries of the magnitude observed in polarized *C. elegans* zygotes. These results establish a dynamic basis for stabilizing unipolar PAR-3 asymmetries and add to the growing body of evidence that point to a central role for oligomerization of peripheral membrane proteins in the establishment and maintenance of cell polarity.

379 **Lipase mediated gut-brain communication regulates insulin secretion in *Drosophila*** Kandahalli Venkataranganayaka Abhilasha[1], Alka Singh[2], Kathya R Acharya[3], Jairaj K Acharya[1], Usha Acharya[1] [1]Cancer and Developmental Biology Laboratory, National Cancer Institute, Frederick, [2]MCCB, UMass Chan Medical School, Worcester, [3]University of Cincinnati College of Medicine

Pancreatic beta cells synthesize and secrete insulin in response to elevated glucose to maintain blood glucose levels within the physiological range. Defective insulin secretion is causal in most forms of diabetes. While glucose is the primary stimulus for insulin secretion by the beta cells, it is known that lipids obtained from diet or generated intracellularly can amplify glucose-stimulated insulin secretion (GSIS). How the dietary lipid pool potentiates GSIS, the lipid signals and mechanisms involved in relaying the signals to pancreatic beta cells have not yet been well established. This is a challenging endeavor because maintenance of glucose homeostasis after a meal poses substantial complexity. It requires the coordination of digestion, absorption, relay of signals from other organs, and the final integration of these inputs at the beta cells to determine the extent of insulin release. Thus, inter-organ communication plays a vital role in glycemic control. *Drosophila* is increasingly being appreciated as a model to dissect mechanisms governing metabolism that involve inter-organ communication. Many metabolic pathways are conserved between flies and humans. This includes the insulin pathway and in *Drosophila*, there are eight insulin-like peptides, DILP1-8, of which DILP2 is most closely related to human insulin. DILP2 is synthesized and secreted from median neurosecretory cells called the insulin producing cells (IPCs) in the brain. Here, we show, a *Drosophila* secretory lipase, Vaha, is synthesized and secreted from the midgut in response to dietary fat. It moves to the brain, where it concentrates in the IPCs in a process requiring Lipid Transfer Particle, a *Drosophila* lipoprotein originating in the fat body. Our results demonstrate Vaha participates in fat amplified insulin secretion. Vaha mutant flies, flies with gut specific knockdown of Vaha or flies lacking Vaha lipase activity, all show decreased release of DILP2 from the IPCs upon feeding after fasting. Vaha mutant flies have reduced DILP2 in circulation and exhibit features of diabetes including hyperglycemia and hyperlipidemia. Our findings suggest Vaha functions as a diacylglycerol lipase in a gut-brain axis modulating DILP2 release to maintain glucose homeostasis in the adult fly.

380 **The stress response transcription factor Atf4 interacts with Ecdysone Receptor to maintain fat tissue homeostasis in *Drosophila*** Manuel H. Michaca[1], Lydia Grmai[1], Deepika Vasudevan[2] [1]Cell Biology, University of Pittsburgh, [2]University of Pittsburgh

The endoplasmic reticulum (ER) is the primary site of lipid synthesis and metabolism. Consequently, excess lipids or nutrient deprivation can cause highly metabolic cells, such as adipocytes and hepatocytes, to dysfunction. Such stresses trigger the ER stress response and induces the translation of the evolutionarily conserved ER stress response factor, Activating transcription factor 4 (Atf4). Atf4 restores cellular homeostasis through induction of stress-adaptive genes, or, alternatively, promotes apoptosis when homeostasis is irreparable. However, the molecular mechanism by which Atf4 specifies distinct suites of transcriptional targets under homeostasis versus ER stress conditions remains an open question. Here, I will use the *Drosophila melanogaster* third instar larva fat body as a platform to test the hypothesis that Atf4 interacts with nuclear receptors to switch between protective or deleterious transcriptional modes in metabolic tissues. My data show that homeostatic Atf4 transcriptional activity in the fat body is regulated by the nuclear hormone receptor, Ecdysone Receptor (EcR). Conversely, I also find that Atf4 is required for EcR transcriptional activity in the fat body. Loss of Atf4 has been demonstrated to result in overall reduced triacylglyceride content. Thus, I tested whether Atf4 and EcR coregulate lipid metabolism genes such as the triglyceride lipase, bmm. We found that loss of Atf4 or EcR results in increased expression of bmm in the fat body, suggesting that Atf4 and EcR repress *bmm* under homeostatic conditions. We next sought to examine if bmm is a direct transcriptional target of Atf4 and EcR. We next used the known Atf4 position weight matrix and found several Atf4 binding sites in the *bmm* genomic loci. Consistently with our *in vivo* data, we find that deleting Atf4 binding sites results in an enhancer-based reporter results in derepression of *bmm*. Surprisingly, this assay also revealed that Atf4 is required for induction of *bmm* under stress conditions. These data suggest that Atf4 has a dual role in *bmm* transcriptional regulation, as a repressor during homeostasis and an activator during stress. We are currently examining the role of EcR in Atf4-mediated regulation of bmm and extending this analysis to other lipid metabolism genes such as lsd1/2. Together, my data provide a mechanistic framework for understanding the dual protective and deleterious role of Atf4 in metabolic tissues.

381 **Glial KCNQ K^+ channels control neuronal output by regulating GABA release from glia in *C. elegans*** Bianca Graziano[1], Lei Wang[1], Olivia R. White[2], Daryn H. Kaplan[1], Jesus Fernandez-Abascal[2], Laura Bianchi[3] [1]University of Miami, [2]university of Miami, [3]Physiology and Biophysics, University of Miami

KCNQs (Kv 7) are voltage-gated K^+ channels expressed in the nervous system across species. In humans and mouse models, mutations in KCNQs have been linked to epilepsy and autism spectrum disorder (ADS). KCNQs are expressed both in neurons and glia. In neurons, KCNQs control neuronal excitability by setting the resting membrane potential and by regulating the firing rate. In glia though, the function of KCNQ channels is largely unknown. We used the model organism *C. elegans* to elucidate the function of KCNQ channels in glia and to determine their influence on neuronal function. In *C. elegans*, *kqt-1*, *kqt-2*, and *kqt-3* encode KCNQ channels homologs. Of these, *kqt-2* is expressed in the Amsh Sheath (Amsh) glia, a pair of glial cells that ensheath the dendrites of sensory neurons. Using behavioral assays, we found that *kqt-2* is needed in Amsh glia for response to the aversive odor octanol, suggesting that glial *kqt-2* is needed for neuronal output. Using in vivo Ca^{2+} imaging, we show that *kqt-2* is needed in glia for the activity of the L-type voltage gated Ca^{2+} channel *egl-19* and for Ca^{2+} transients in

response to octanol. Using the voltage sensor ASAP3, we show that *kqt-2* is required for setting the glial resting membrane potential and for voltage responses to octanol exposure. Using Ca^{2+} imaging, we show that loss of *kqt-2* in glia leads to the hyperactivity of the octanol sensitive neuron ASH, showing that neuronal hyperactivity is caused, not only by loss of KCNQ cannels in neurons, but also by their loss in glia. Finally, using optogenetics, genetic and pharmacological approaches we find that *kqt-2* is needed in glia for both tonic and phasic GABA release from glia. Importantly, all the *kqt-2* behavioral and cellular knockout phenotype are rescued by expression of the human KCNQ2 and KCNQ3 channels, supporting conservation of function across species. Finally, we show that loss of function (lof) and gain of function (gof) pathogenic KCNQ2 mutations reduce phasic and tonic GABA release respectively when expressed in Amsh glia. To conclude, our data point to the contribution of glial KCNQs to the expression of epilepsy and ASD phenotypes via reduction of GABA release from glia.

382 **A drug repurposing screen reveals novel biology and potential therapies for the rare disease DPAGT1-CDG** Hans M. Dalton, Alexys R. Berman, Kaylee A. Patterson, Sydney J. Peterson, Heather D. Evans, Clement Y. Chow Human Genetics, University of Utah

Glycosylation encompasses multiple biological pathways that affect essential sugar modifications of proteins. Mutations in glycosylation genes underlie Congenital Disorders of Glycosylation (CDGs) – ultra-rare disorders that cause seizures, developmental delay, and early mortality. Due to low CDG patient populations, it is challenging to conduct clinical trials for potential treatments. Consequently, there is a great need for alternative approaches to find therapies for these rare diseases. I use one such alternative – repurposing drugs by screening libraries of FDA/EMA-approved small molecules – to potentially speed up treatment development for CDG patients.

DPAGT1-CDG is caused by mutations in the gene *DPAGT1*, which encodes the first essential enzyme for N-linked glycosylation. Since total loss of *DPAGT1* is lethal, I created a model of DPAGT1-CDG in *Drosophila* via *DPAGT1* knockdown in the fly eye to cause a small, rough eye phenotype. This model can be screened for new therapies by quantitatively measuring improvements to its eye size. To find such therapies, I performed a drug repurposing screen by feeding flies 1,520 small molecules that are 98% FDA/EMA-approved. The top candidate drugs that rescue, resulting in a larger eye, were then validated by dose-response and genetic analyses.

I identified 40+ candidate drugs capable of rescuing the DPAGT1-CDG model eye size (Z-score ≥ 1.5). Top drug categories are dopamine receptor D2 (D2R) antagonists, acetylcholine-affecting drugs, COX inhibitors, and ion transporter-related drugs. Further genetic testing indicates that dopamine signaling is critical under *DPAGT1* loss. Overexpression of dopamine synthesis enzymes and knockdown of dopamine receptors rescued the *DPAGT1* model. This represents a potential new avenue for therapy - especially as seizures are common in DPAGT1-CDG patients. In addition, I genetically and pharmacologically validated rescue by an ion transporter inhibitor through its target *NKCC1*/*Ncc69*, as well as an acetylcholinesterase inhibitor through *ACHE*/*Ace* RNAi. All three pathways reveal novel biology related to *DPAGT1* mechanisms, and they may represent new therapeutic options for DPAGT1-CDG.

383 **Using *Drosophila* to understand the requirements of Alzheimer's risk genes in the central nervous system** Jennifer M Deger[1], Mingxue Gu[2], Shabab M Hannan[2], Oguz Kanca[2], Lindsey M Goodman[2], Ismael Al-Ramahi[2], Juan M Botas[2], Joshua Shulman[2], Hugo Bellen[2] [1]Neuroscience, Baylor College of Medicine, [2]Baylor College of Medicine

Alzheimer's disease (AD) risk is likely the amalgamation of many environmental and genetic factors. Thanks to data from genome-wide association studies (GWAS), we have new insights into genetic risk for AD. However, GWAS typically can't pinpoint which genes within susceptibility loci mediate association with disease risk. Furthermore, GWAS is limited by incomplete functional annotation of the genome. To address these limitations and extract actionable insights from AD GWAS, we have implemented a tiered, cross-species pipeline designed to dissect the functional genomic component of AD risk.

As of the summer of 2022, approximately 300 genes had been identified as AD GWAS loci. We prioritized these genes according to functional genomic evidence from human studies, i.e. the likelihood that the AD-associated variant alters the function and/or expression of the gene harboring it. In tandem, all 300 genes were included in an *in vivo* screen using *Drosophila* to find genetic modifiers of tau or amyloid-β (Aβ)-induced neurotoxicity. Elav-GAL4 driving UAS-human tau or Aβ induces a locomotor defect that worsens with age and can be enhanced or suppressed by RNAi-mediated knockdown of various genes. Together, our analyses identified 100 high-priority AD risk genes that were included in loss-of-function studies using *Drosophila* to characterize the requirements of these genes for central nervous system structure, function, and resilience to stress.

We generated Kozak or T2A-GAL4 alleles for 84 genes and crossed them to deficiencies. We determined that 40 high-priority AD genes were homozygous lethal in flies. For non-essential genes we used this same crossing strategy to create compound

heterozygous mutants to characterize loss-of-function phenotypes. For essential genes we crossed Kozak or T2A-GAL4 to two independent RNAi lines to create partial loss-of-function animals. These flies were aged and used for a battery of assays including histology to examine structural changes in the brain, electroretinograms to quantitatively measure neuronal function, and exposure to traumatic and heat stressors to assess neuronal resilience. Loss of approximately half of the genes tested thus far produce a defect in at least one assay. Our results provide insights into which genes with AD GWAS loci may be important for neuronal homeostasis. More broadly, these experiments allow us to assess potential functions for these genes and may help decipher the role of the genetic risk factors that have been identified for AD and other neurodegenerative diseases.

384 **Exploring glial induction of neuronal toxicity via the Draper pathway** Jayden Cyrus[1], Nina Sherwood[2], Emily Ozdowski[2] [1]Duke University, [2]Biology, Duke University

The *spastin* gene encodes a microtubule severing protein, and when mutated in humans leads to Autosomal Dominant Hereditary Spastic Paraplegia (AD-HSP), a neurodegenerative disease that impairs motor function in the legs. In *Drosophila*, *spastin* null larval neuromuscular junctions (NMJ) are characterized by a high synaptic bouton count with a "bunched" phenotype. In addition to neuronal proteins, glial proteins are also known to regulate synapses. One such protein is Pak3, a kinase that regulates actin polymerization and filopodial projections. Studies have shown that when *pak3* is deleted in *spastin* null *Drosophila*, neuronal structure and function are restored. While it is known that *pak3* deletion rescues the neurons by acting in subperineurial glia (SPG), the exact mechanism remains unclear. We hypothesize that Draper, an engulfment receptor in glia, may participate in this mechanism. Preliminary results indicate that, like *pak3* deletion, deleting *draper* and *spastin* rescues the *spastin* null phenotype, further demonstrating a requirement for glia in the pathology caused by loss of *spastin*. Additionally, although it is known that Draper functions in glia, the specific subtype of glia - wrapping, perineurial, or SPG - remains unknown. Therefore, my aim is to identify the specific subtype of glia in which Draper acts to cause the neuronal defects when *spastin* is lost. To do this, I will knock down Draper in a glial-specific manner using the UAS-GAL4 system to express draper-RNAi in a *spastin* null background. If a certain cell-type specific knockdown exhibits the same rescue as ubiquitous *draper* deletion, then Draper is likely working in these cells. My preliminary results indicate that Draper works in perineurial and wrapping glia, but not SPG. Interestingly, this implies that while Pak3 works in SPG, Draper acts in other glia, implicating four different cell types in this interaction: neurons, wrapping glia, perineurial glia, and SPG. Understanding the specific cell type(s) in which Draper acts will provide the first step in understanding how these proteins regulate neuronal structure and neuronal health, better our comprehension of how glia communicate with neurons and other glia, and shed light on the glial induction of neuronal toxicity.

385 **UNC-43/CaMKII regulates presynaptic assembly in *C. elegans*** Mizuki Kurashina, Kota Mizumoto Zoology, University of British Columbia

Neurons communicate via a specialized interface known as the synapse comprised of presynaptic and postsynaptic specializations. At the presynaptic specialization, the release of neurotransmitter is controlled by highly conserved proteins that reside at a protein-dense region called the active zone (AZ). AZ proteins control recruitment of neurotransmitter-containing synaptic vesicles (SVs) and their exocytosis for synaptic transmission. While the structural and functional components of the AZ are well characterized, less is known about how they assemble into a functional synapse. Here we found that *unc-43*, a sole ortholog of calcium/calmodulin-dependent protein kinase II (CaMKII), is integral for proper presynaptic assembly in *Caenorhabditis elegans*. To visualize synapses, we use a transgenic strain expressing GFP-tagged CLA-1, an AZ protein controlling SV clustering, and TdTomato-tagged RAB-3, a SV-associated small GTPase, In wild type animals, CLA-1 is localized as a single punctum at the tip of synaptic varicosity labeled with RAB-3. In *unc-43* loss-of-function (lof) mutants, we observed disorganized presynaptic structures characterized by an increased number of CLA-1 puncta with weaker fluorescence intensity, and diffuse localization of RAB-3 along the axon. This observation suggests that *unc-43* is required for proper presynaptic assembly. Consistently, *unc-43* gain-of-function (gof) mutants have 'overdeveloped synapses' with increased CLA-1 and RAB-3 fluorescence intensity. To determine whether *unc-43* controls the localization of other presynaptic proteins, we are examining the localization of endogenously tagged AZ proteins in *unc-43(lof)* mutants.

To examine the functional conservation between UNC-43 and human CaMKII in presynaptic assembly, we generated a *C. elegans* strain in which the endogenous *unc-43* locus was replaced with codon-optimized human CaMKIIA (*hCaMKIIA*). We found that *hCaMKIIA* fully replaces the functions of *unc-43* as *hCaMKIIA* animals exhibit wild type locomotion and have normal presynaptic structures judged by CLA-1 and RAB-3 localization. We then introduced recessive and dominant mutations that are found in the CaMKII genes of patients with intellectual disabilities. Indeed, these disease-associated mutations in hCaMKIIA resulted in presynaptic organization defects similar to those in the *unc-43(lof)* and *unc-43(gof)* mutants. These observations suggest the functional conservation between UNC-43 and human CaMKIIA in presynaptic assembly.

386 **SWI/SNF and PMK-1/p38 regulate the C-type lectin gene *clec-67* to modulate acute responses to alcohol** Laura Mathies[1], Tyler Crossen[1], Jonathan Lindsay[2], Andrew Hsiao[3], Andrew Davies[1], Jill Bettinger[1] [1]Pharmacology & Toxicology,

Virginia Commonwealth University, [2]Biology, Emory & Henry College, [3]Laboratoire MeLiS, UCBL - CNRS

Alcohol use disorder (AUD) is a significant societal problem, for which there are few pharmacological interventions. This is, in part, because of the complex pharmacology of ethanol. We use *C. elegans* to model the acute effects of ethanol on neuronal function to identify molecular targets of ethanol and determine the mechanisms underlying the development of tolerance to those effects. We have found that SWI/SNF genes are associated with alcohol dependence in human populations and are important for behavioral responses to ethanol in *C. elegans* (Mathies *et al.,* 2015). SWI/SNF chromatin remodeling complexes consist of multiple subunits that can be combined to generate functionally and molecularly distinct chromatin remodelers. Two major subfamilies of SWI/SNF are BAF (Brg1/Brm-associated factors) and PBAF (Polybromo-associated BAF). We found that different SWI/SNF complexes are required for two aspects of the acute response to ethanol: initial sensitivity and the development of acute functional tolerance (AFT). The BAF complex is required for normal initial sensitivity, while PBAF is required for AFT. A transcriptomic analysis identified 603 genes that are regulated by PBAF in adult neurons; innate immunity genes were overrepresented among these genes (Mathies *et al.,* 2020). We examined members of each innate immunity pathway to explore this overrepresentation. We found that the PMK-1/p38 mitogen-activated protein kinase (MAPK) pathway genes *tir-1, sek-1, nsy-1,* and *pmk-1* are all required for the development of AFT. PMK-1/p38 pathway genes are not among the SWI/SNF-regulated genes, and vice versa. Therefore, we sought to identify genes acting downstream of both pathways. A previous study identified genes regulated by *pmk-1* and *sek-1* (Troemel *et al.,* 2006). Nine genes are regulated in the same direction by *pmk-1, sek-1*, *swsn-1*, and *swsn-9*; these are candidate downstream mediators of the effect of SWI/SNF and PMK-1/p38 on AFT. We focus here on the C-type lectin gene *clec-67*, which has increased expression in PMK-1/p38 and SWI/SNF mutants. Loss-of-function mutations in *clec-67* do not alter acute ethanol responses, but they do suppress the AFT defect of both *pmk-1* and *swsn-9* mutants. In the nervous system, *clec-67* is expressed primarily in ADL sensory neurons (CeNGEN). We found that we can rescue *clec-67* mutants by expressing the gene specifically in ADL neurons. Together, our data support a model wherein SWI/SNF and PMK-1/p38 inhibit the expression of *clec-67* in ADL neurons to promote AFT. CLEC-67 is predicted to be a secreted protein, therefore ongoing experiments are aimed at identifying the molecular targets of CLEC-67. There is significant interest in the role of innate immune signaling in the development of AUD. Our studies in the simple model *C. elegans* can help to define the requirements of innate immunity genes in the nervous system response to alcohol.

387 **Neurogenomic profiles of schizophrenia and autism risk mutations defined through large-scale zebrafish phenotyping** Mary E.S. Capps-Lopez[1], Claire Conklin[2], Anna Moyer[1], Verdion Martina[2], Emma Torija[2], Ari Ginsparg[2], Morgan Klein[2], William Gannaway[2], Caleb Calhoun[2], Summer Thyme[1] [1]UMass Chan Medical School, [2]University of Alabama at Birmingham Medical School

Recent large-scale genomic studies have uncovered numerous genes linked to schizophrenia and autism. However, the specific impact of these genes on brain development and function remains unclear. Using optimized pipelines for high-throughput whole-brain activity mapping and behavioral profiling, we have established larval zebrafish phenotypes for 17 genes linked to autism, 6 to childhood-onset schizophrenia, and 16 to typical schizophrenia. The human mutations modeled in zebrafish are protein-truncating, amino acid substitutions, or copy number variants. The generated lines include five patient point mutations in the genes *deaf1*, *nsd2*, and *atp1a3*, which we compared to loss-of-function mutations to determine whether these protein-coding changes had a similar impact. Brain activity mapping revealed convergent phenotypes for several genes, as well as commonly affected brain areas. Behavioral changes included altered sensory processing and sleep behavior. For several lines, including loss-of-function and point mutation alleles, we performed RNA-sequencing at early developmental stages to define shared and distinct molecular mechanisms. Furthermore, beyond the larval screen, we discovered abnormal social interaction at 21 dpf for two of thirteen tested lines. Bulk RNA-sequencing of the adult brain for the *arid1b* line revealed disruptions to neuropeptide signaling, particularly to the relaxin-3 hormone previously found to be involved in social behavior in rodents. Ultimately, we expect in-depth studies of these zebrafish lines to nominate downstream targets of disease genes for rational drug development. In parallel to our zebrafish work, we have built a new computational method for *in silico* drug discovery. This method uses information from published structural data to guide predictions and has higher accuracy than commonly used docking methods. The exceptional sensitivity of larval whole-brain activity mapping, coupled with its potential throughput, makes this innovative approach well-suited for identifying molecules capable of mitigating mutant phenotypes. With these advancements, we aim to address the therapeutic challenges associated with these disorders, which currently lack effective treatments.

388 **Behavioral variation in psychomotor and incentive sensitization in Collaborative Cross mice** Lisa M Tarantino[1,2,3], Lauren S Bailey[3,4], Jared R Bagley[3,5], Ashley Charpentier[3,6], Troy Wilcox[3,6], Savanna Julian[3,6], Ashley Olson[3,6], Laura G Reinholdt[3,6], Leona H Gagnon[3,6], Vivek M Philip[3,6], Elissa J Chesler[3,6], James D Jentsch[3,5] [1]Department of Genetics, School of Medicine, University of North Carolina, [2]Division of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina, [3]Center for Systems Neurogenetics of Addiction, The Jackson Laboratory, [4]Behavioral Neuroscience, Binghamton University, [5]Psychology, Binghamton University, [6]The Jackson Laboratory

Substance use disorders are a significant public health concern with devastating consequences for affected individuals, families and society as a whole. Cocaine use and overdose deaths involving cocaine have been steadily increasing since 2015. Despite the prevalence of cocaine use disorder (CUD), no approved therapies currently exist. The lack of effective therapies is due, in part, to our limited knowledge about the complex etiology of these disorders. Not everyone who uses cocaine will go on to develop a CUD suggesting that individual differences, including genetic factors, play a role in increasing risk. Inbred mice have been useful for studying genetic and environmental mechanisms that impact addiction relevant behaviors from initial exposure to changes in the rewarding and reinforcing effects of drugs of abuse. However, much of the existing data have been collected in very few strains, limiting both the generalizability and translational value of the work. The Collaborative Cross (CC) is a genetically heterogeneous reference population derived from 8 inbred mouse strains. The CC provides an excellent platform on which to study mechanisms by which exposure to drugs of abuse results in a transition to compulsive drug seeking behavior. We have characterized cocaine-induced locomotor sensitization in the CC. Locomotor sensitization is the phenomenon whereby repeated exposure to the same dose of a psychostimulant results in an augmented locomotor response. Locomotor sensitization is thought to reflect long-lasting neuroadaptations in the brain that contribute to drug seeking behavior. However, direct comparisons of locomotor sensitization and changes in incentive-motivational processes that imbue drugs and drug-related stimuli with enhanced salience (incentive sensitization) are largely missing in the literature. We have captured significant phenotypic diversity in locomotor sensitization in 50 CC strains. Our data present a unique opportunity to establish the relationship between psychomotor and incentive sensitization in this well-characterized, genetically diverse and tractable experimental population. In fact, data from a limited number of CC strains suggests that behavioral sensitization does predict incentive sensitization, but the relationship between the two behaviors differs based on genetic background. These data will generate hypotheses regarding genetic and non-genetic mechanisms of addiction that can be explored in more targeted studies.

389 **Chance and genetics shape the diversity of individual cognitive behavior in *Drosophila melanogaster*** Riddha Manna[1], Johanni Brea[2], Tomislav Štampar[3], Gonçalo Braga[2], Ivan Tomić[2], Ana Marija Jakšić[2] [1]School of Life Sciences, École Polytechnique Fédérale de Lausanne, [2]EPFL, [3]TS Robotics

Genotype x environment interactions have been well studied for many phenotypes, including simple behaviours such as turn-bias and locomotion. However, studying how such interactions affect complex behaviors like cognition and give rise to behavioral individuality is hard. This is because complex behaviours show high intra- and inter-individual variability that changes dynamically throughout an individual's life. To study genetic basis of individual cognitive ability, we need to measure this behavior in a large number of individuals in highly controlled environments. Such studies have been so far technologically unattainable and usually used non-multiplexed assays inevitably introduce an entanglement of experimental noise with biological individuality. As a result, genetic and environmental effects on cognitive individuality have so far been experimentally highly confounded and poorly understood. To surpass this challenge, we developed a high-throughput, multiplexed platform for screening visual learning in *Drosophila melanogaster*. We use the platform with meticulous transgenerational environmental control to measure genetic effects on individual learning ability in more than 100 wild-type genetic backgrounds represented by more than 6400 individuals. This experimental design allowed us to partition the effects of genotype and environment on individuality in learning outcomes and learned behaviours, including decision-making, change in lateralization, and modulation of activity. Our results demonstrate there is a significant genetic influence on mean learning ability but also on intra-genotype variability in learning. We find that the extent of the intra-genotype variability in individual learning outcomes is shaped through the genotype-specific interactions with minimal environmental perturbations. These micro-environments experienced during learning have been usually ignored or written off as noise. Using the behavioural platform, we can, however, capture and measure them to show that minimal environmental perturbations are sufficient to induce massive behavioural variation that interferes with identifying fine-grained genetic effects on learning. To probe the limits of micro-environmental effects on learning behaviours that are, for humans, impossible to track manually we have developed and validated a robotic platform that autonomously performs the experimental setup. The robot handles the flies and phenotypes learning behaviour with high precision and repeatability. We use the behaviour assays performed by the robot to demonstrate the severity of micro-environmental effects on estimates of complex cognitive behaviours and the futility of behavioural genetic determinism beyond extreme experimental control.

390 **Chromosomal Inversion In(2L)t modulates behavior in a temperature specific manner and could enable *Drosophila's* seasonal adaptation** Benedict Lenhart[1], Alan O Bergland[1], Joaquin CB Nunez[2], Lynsey Blevins[1], Ben Riley[1] [1]Biology, University of Virginia, [2]Biology, University of Vermont

Drosophila melanogaster populations adaptively track to seasonal patterns in selection pressure, leading to cyclical changes in genotype and phenotype. However, we lack an understanding of the functional genetic architecture of this rapid evolutionary change. Inversions are a plausible genetic mechanism of this rapid evolutionary change of multiple phenotypes because they can accumulate linked variation at many genes and are thus likely to be pleiotropic. We have recently put forth evidence that

the cosmopolitan inversion In(2L)t mediates seasonal adaptation through linkage of adaptive alleles. Frequency of In(2L)t changes seasonally, and regions within the inversion are highly enriched with seasonal loci identified from temperature-based environmental models. When we examined phenotypic data from the DGRP -a *Drosophila* genomic panel- presence of In(2l)t is significantly associated with changes in traits related to behavior, morphology, and metabolism. These In(2L)t associated phenotypic changes could be due to linkage between functional polymorphism or the pleiotropic effect of individual genes within In(2L)t. To validate the phenotypic effect of In(2l)t, we quantified the impact of inversion karyotype on behavior within different environments. Using an automated tracking system to stimulate and record behavior, we show that the presence of In(2l)t reduced duration of sleep and the intensity of startle response compared to non-inverted flies. These reductions are sex specific to females. We quantified behavior in different thermal environments, and showed the differences between inverted and non-inverted karyotype were minimal at colder temperatures, and larger at warmer temperatures. To elucidate whether the impacts of In(2L)t derived from linkage or pleiotropy, we used complementation tests between genetic deficiency lines to analyze the impact of different regions within In(2L)t, and identified a genomic region near the distal breakpoint that impacts behavior. Future work seeks to identify pleiotropic genes near the distal breakpoint and test which genes could be contributing to seasonal evolutionary changes in a suite of highly correlated traits.

391 **Glial expression of a hydroxysteroid dehydrogenase underlies natural variation in hitchhiking behavior** Heeseung Yang[1], Daehan Lee[2,3], Heekyeong Kim[4], Daniel E Cool[3], Young-ki Paik[4], Erik C Andersen[3,5], Junho Lee[1,6] [1]Department of Biological Sciences, Seoul National University, [2]Department of Biological Sciences, Sungkyunkwan University, [3]Department of Molecular Biosciences, Northwestern University, [4]Yonsei Proteome Research Center, Yonsei University, [5]Biology Department, Johns Hopkins University, [6]Research Institute of Basic Sciences, Seoul National University

Phoresy is a type of species interaction in which organisms disperse by attaching themselves to more mobile and usually larger animals. Hitchhiking species have evolved specific traits for physical contact and successful phoresy, but little is known regarding the evolution of such traits or the regulatory mechanisms involved. The nematode *Caenorhabditis elegans* displays a hitchhiking behavior, nictation, during its stress-induced developmental stage called dauer. Nictation involves the nematode standing and waving its body to enhance its chance of riding another organism. Dauer-specific nictation behavior has an important role in natural *C. elegans* populations, which experience boom-and-bust population dynamics. By hitchhiking onto carrier animals such as isopods and slugs, dauer larvae can disperse to a new favorable habitat where they can resume their reproductive growth. Here, we investigated the species-wide natural variation found in nictation behavior of 137 *C. elegans* strains sampled throughout the world. We performed genome-wide association mapping and found a quantitative trait locus (QTL) for natural variation in nictation behavior. We then attempted to specify the locus at the gene level and found that sequence variation in the promoter of a hydroxysteroid dehydrogenase, *nta-1*, underlie differences in nictation. The absence of *nta-1* expression in certain glial cells (GLRs), attributable to promoter variation, enhances nictation. This implies that the steroid metabolism in glial cells may regulate hitchhiking behavior. Furthermore, population genetic analysis of 550 strains and their geographic distribution suggest that two *nta-1* promoter haplotypes existed prior to the global expansion of *C. elegans* and have been maintained by long-term balancing selection. *nta-1* confers a trade-off between dispersal and post-dauer reproduction, and therefore provides the potential for balancing selection.

392 **Cell type differences underlying color vision diversification in *Heliconius* butterflies** Wei Lu[1], Nicholas VanKuren[2], Marcus Kronforst[2] [1]Ecology and Evolution, University of Chicago, [2]University of Chicago

Animals exhibit a rich diversity of behaviors and perceptual capacities to interact with the complex environment. With the benefit of minimizing pleiotropic effects, modifications on the peripheral sensory system appear to be a more frequent target for rapid behavioral adaptations. Mate preference is one such rapidly evolving adaptive behavior during the speciation process. Closely related but reproductively isolated species often evolve unique mating cues and the mate preference for conspecific mating cues.
Heliconius butterflies represent a classic example of adaptive radiation with extraordinary within species divergence and between species convergence in wing color pattern. These diverse wing colorations are also used as mating cues for male mate choice. Previous studies have shown that *Heliconius* males with divergent mate preference differ at multiple layers of the peripheral visual system, including photosensitive rhodopsin and inter-photoreceptor connections. However, we still do not know the transcriptomic changes underlying color vision diversification, which precludes a complete understanding from genetic variants to final behavior differences.
To better understand the regulatory network changes underlying color vision diversification, we conducted single-nuclei RNAseq (snRNAseq) and profiled more than 80,000 nuclei from both adult male and female *Heliconius* butterflies, spanning from polymorphic population to species of subgenus-level divergence (~14 Mya). We recovered all photoreceptor cell types including the most basally positioned butterfly R9 photoreceptor(homologous to Drosophila R8), which is usually inaccessible through antibody staining or in-vivo recording due to its position and small size. We also found that while most cell type abundances are similar across species and sex, a group of pigment cells is highly variable in males and the abundance is

associated with inter-photoreceptor connection variation. Surprisingly, this pigment cell type is marked by sens-2 expression, which is a candidate gene for male mate preference in *Heliconius*.
Overall, our snRNAseq results provide a comprehensive cell atlas for butterfly retina and enable us to identify cell type abundance and regulatory network changes in a group of butterflies undergoing rapid mate preference evolution. Compared to *Drosophila*, *Heliconius* butterflies have expanded color vision and our results provide insights into the conservation and evolvability of peripheral visual system.

393 **Convergent reduction of olfactory genes and olfactory bulb ratio in mammalian species at altitude** Allie M Graham[1], Elysia Seputra[2], Bogdan Kirilenko[3], Jason Presnell[1], Arianna Harrington[4], Chad Huff[5], Michael Hiller[3], Nathan Clark[2] [1]Human Genetics, University of Utah, [2]University of Pittsburgh, [3]LOEWE Centre for translational biodiversity genomics, [4]Southern Utah University, [5]University of Texas MD Anderson Cancer Center

Life at high altitude presents unique challenges. Species specialized for life there have evolved phenotypic changes in response, many of which are convergent among unrelated high-altitude lineages. We present evidence that mammalian species living at altitude repeatedly evolved a reduced palette of olfactory receptor genes (ORs) and apparently lower olfactory acuity. This convergent decrease of ~19% of ORs was discovered through an unbiased scan of pseudogenization events scored in the genomes of 27 high-altitude mammalian species as compared to 45 low-altitude species. Accordingly, reduction of olfaction is apparently a consistent response to long term colonization of high-altitude habitats. In contrast, receptor gene families involved in pheromone detection and taste were not lost. In agreement with OR gene loss, cranial endocast measurements show that the brains of high-altitude species have ~16% smaller olfactory bulbs relative to lowland relatives. Together, these repeated evolutionary outcomes suggest a general relaxation of constraint on olfaction at altitude, perhaps due to reduced odorant diversity in high-altitude niches or reduced effectiveness of mammalian olfactory physiology in thin, dry, or cold air.

394 **Sensory receptor expansion and neural accommodation between flies and butterflies** Ke Gao[1], Cara Genduso[2], Michael Perry[1] [1]Cell & Developmental Biology, University of California, San Diego, [2]New York University

The evolution of larger and more complex brains required existing neurons and neural circuits to accommodate new inputs. The genetic and developmental basis of how neural accommodation occurs is largely unknown. Relative to other insects such as Drosophila, butterflies have evolved more complex retinal mosaics and expanded color vision through the addition of a second R7-type photoreceptor per ommatidium (unit eye). We investigated the developmental basis of this change in the retina and how butterfly brains accommodate an expansion in sensory receptor input. We identified four differences in transcription factor expression during retina development between flies and butterflies and tested the genetic relationships between each. Modifying *Drosophila* retinas to have butterfly-like expression produces flies that recruit the “mystery cell” as a second R7, in the same position as in butterflies. These ommatidia have two R7s and each makes an independent stochastic choice, like butterflies, leading to three stochastically distributed ommatidial types instead of two. In *Drosophila*, the main target of each R7 is a single Dm8 neuron per retinotopic medulla column, and we asked how additional R7s impact Dm8 number and position. We show that in the presence of extra R7s, additional Dm8 cells are retained during development and that two Dm8s can now target the same medulla column. We propose a model in which an excess of Dm8 cells provided developmental flexibility that helped immediately accommodate an increase in sensory receptor input. Neurons like Dm8, which are made in excess during development to help accommodate population-level variability in input types, could provide increased developmental flexibility and enable broader neural evolution.

395 **Comparative population genomics reveals convergent signatures of adaptation in avian brood parasites** Ekaterina Osipova[1], Christopher Balakrishnan[2], Jeff DaCosta[3], Michael Sorenson[4], Wesley Warren[5], Tim Sackton[6] [1]Harvard University, [2]East Carolina University, [3]Boston College, [4]Boston University, [5]University of Missouri, [6]Harvard Univ

About 1% of all bird species are obligate brood parasites, in which where females lay their eggs in the nest of another species. This behavior has evolved independently seven times across the avian tree of life, and presents a particularly appealing opportunity to study the molecular correlates of a convergently evolved behavioral trait. To study patterns of recent adaptation associated with avian brood parasitism, we have generated population-scale resequencing data (n = 10-31 individuals per species) from five species of obligate brood parasite (representing three independent trait origins) along with nesting outgroups. These include the parasitic cuckoo finches and wydahs, the parasitic greater honeyguide, and the parasitic brown-headed cowbird. Using a comparative population genetics framework, we detect signatures of recent adaptation at multiple time scales in both nesting and parasitic species. Using McDonald–Kreitman tests, we find evidence for repeated adaption on proteins involved in spermatogenesis and sperm function in multiple parasitic clades, but not nesting sister clades. This is consistent with evidence for increased male-male competition in parasitic lineages associated with reduced parental investment. Furthermore, using methods to detect recent selective sweeps, we find evidence for putative positive selection on genes with neurological function in some parasitic lineages, and we assess evidence for a role of selection on noncoding

regions of the genome in transitions to brood parasitism.

396 **Identification of regulators of early CEPsh glia development in *Caenorhabditis elegans* by single-cell RNA sequencing** Simin Liu, Shai Shaham The Rockefeller University

Astrocytes are the most abundant glial cells in the vertebrate central nervous system, and play important roles in development, homeostasis, and plasticity of the brain. Astrocytes are a heterogeneous population with remarkable diversity in their morphology, molecular signatures, and physiological functions. While some transcription factors and signaling pathways have been implicated in astrogliogenesis, the precise mechanisms governing the specification and generation of distinct astrocyte subtypes remain not fully understood. The *Caenorhabditis elegans* CEPsh glia resemble astrocytes in their elaborate shapes, development from radial-glia-like precursors, postembryonic transcriptomes, and physiological functions. Despite similarities in morphology and molecular signature, the four CEPsh glia of each animal undergo distinct developmental processes and serve varied physiological functions. Therefore, they provide an excellent model system for uncovering the elusive factors contributing to the generation of diverse astrocyte subtypes. Using single-cell RNA sequencing, we profiled the transcriptome of newly generated ventral CEPsh glia, their direct progenitor cells, and their close relatives, which include other neuronal and glial cell types. Differential gene expression analysis reveals early CEPsh glia-specific molecular signatures, as well as genes shared with another glial cell type. Through a functional RNAi screen, we identified transcription factors that regulate the expression of marker genes in CEPsh glia, implicating their involvement in the acquisition of CEPsh glia fate. Our study provides a comprehensive lineage- and time-resolved transcriptomic atlas of early developing ventral CEPsh glia and the close relative cell types around the period of their generation. Given the similarities between CEPsh glia and astrocytes, we are excited about the possibility that vertebrate homologs of CEPsh glia fate regulators we identify will also direct astroglia fate acquisition in mammals.

397 **The nonsense-mediated decay pathway for RNA surveillance is necessary for the complete hypoxia response by *C. elegans*** Calista Diehl, Robert Horvitz MIT/HHMI

All aerobic organisms require oxygen to survive and have developed adaptive mechanisms to sense and respond to conditions of hypoxia (low O_2). Hypoxia drives many physiological stress responses and is a prevalent feature in numerous human pathologies including cancer, myocardial infarctions, and ischemic stroke. The major hypoxia-response pathway is evolutionarily conserved from worms to mammals and is driven by the transcription factor HIF-1, which is negatively regulated by the O_2-dependent prolyl-hydroxylase EGL-9 (EGLN/PHD in mammals). In *C. elegans*, increased HIF-1 activity, caused by either hypoxia or an *egl-9(lf)* mutation, induces numerous adaptive responses, including the retention of eggs in the uterus (the Egl phenotype), decreases in locomotion and defecation rates, and increased resistance to both hypoxia and other stressors, such as ER stress, oxidative stress and bacterial infection. Despite substantial progress in understanding the EGL-9/HIF-1 pathway, much remains to be learned about downstream effectors of the EGL-9/HIF-1 pathway and how they mediate adaptive responses to hypoxia. In this study, we utilized the striking Egl phenotype of *egl-9(lf)* mutants to screen for suppressors of the hypoxic stress response. We discovered that loss-of-function mutations in the conserved nonsense-mediated decay (NMD) pathway suppress the *egl-9(lf)*-induced changes in egg laying, indicating that functional NMD is required for a complete hypoxia response. NMD, which was originally identified in yeast and worms, is an RNA surveillance mechanism that degrades aberrant mRNA transcripts with premature termination codons and maintains cellular homeostasis in response to transcript errors. We found that some, but not all, of other *hif-1*-dependent responses are affected by NMD-pathway mutations, indicating that NMD modulates specific aspects of the HIF-1-dependent hypoxia response. Overall, our findings show that the link between the hypoxia response and NMD extends beyond egg laying and likely reflects a major integration of these two important and evolutionarily conserved stress-response pathways. Moving forward, we plan to identify the population of transcripts that are degraded by NMD in hypoxic conditions, with the hope of determining which, if any, aberrant transcripts provide the link between NMD and the hypoxia response.

398 **A recessive-by-dominant Dobzhansky Muller incompatibility causes embryonic lethality in *Caenorhabditis* hybrids** Dongying XIE, Yiming Ma, Pohao Ye, Gefei Huang, Yiqing Liu, Tongwen Wen, Zhongying Zhao Hong Kong Baptist University

Postzygotic Hybrid incompatibility (HI), such as hybrid lethality, is pivotal in speciation because it precludes gene flow and creates reproductive barriers. HI is typically the result of a negatively epistatic interaction between at least two genes following hybridization, i.e., the so-called Bateson–Dobzhansky–Muller incompatibility (DMI). Despite tremendous efforts to understand the genetic mechanism of speciation over the past decades, only a handful of DMI genes have been molecularly identified across taxa, which inhibits the interpretation of the processes driving speciation. Using *C. briggsae* and its sibling species *C. nigoni* as a model, we previously identified tens of HI loci between the two and mapped a hybrid lethality locus to the right arm of *C. briggsae* ChrIV. With a combination of high-resolution genetic mapping, targeted mutagenesis, and

complementation tests, we established the molecular identity of the hybrid lethality locus, which fits well with a recessive-by-dominant type of DMI. The DMI involves a recessive allele *shls-1* (Species Hybrid Lethality Suppressor) in *C. briggsae* and a dominant allele *shel-1* (Species Hybrid Embryonic Lethality) in *C. nigoni*. We first found that *shls-1* encodes for an enzyme indispensable in a conserved biogenesis pathway, perturbation of which caused embryonic arrest in both nematodes. Hybrid lethality is suppressed when *Cni-shls-1* is present. However, its absence leads to complete hybrid embryonic arrests. This suggested a potential recessive deleterious interaction between *Cbr-shls-1* and a dominant *C. nigoni* allele, which is masked by *Cni-shls-1* in the hybrids. We subsequently mapped the dominant allele, *Cni-shel-1*, through genome-wide screening and found that it is also located on the *C. nigoni* ChrIV, in close proximity to a *C. nigoni*-specific *shls-1* paralog. The characterization of the molecular identity of *Cni-shel-1* is still ongoing. We proposed that the recessive-by-dominant DMI was potentially initiated by a gene duplication event, and subsequently manifested through species-specific evolution of *shls-1*, driven by complex genome rearrangements between the two nematode species. Our results will establish the first DMI gene pairs in *Caenorhabditis* interspecies hybrid and provide novel insights into how duplicated genes can invoke negative epistasis, interrupt crucial biological functions and ultimately reinforce the species boundary.

399 **All animals are equal, but some tetraploids are more equal than others** Mara Schvarzstein[1,2] [1]Biology, Brooklyn College at the City University of New York, [2]Biology & Biochemistry programs, The Graduate Center at The City University of New York

Polyploidization or whole genome doubling (WGD) is the process of inheriting more than the two copies of each chromosome inherited normally in diploid cells. WGD is central to normal development, repair and regeneration, adaptation and speciation, cancer development and evolution, and crop domestication. Tetraploidy is the most common type of WGD in nature and is found in more than 30% of cancers where it promotes oncogenesis, metastasis, and drug resistance. Our lab developed a strategy to rapidly generate multiple independent tetraploid *C. elegans* strains from nearly any diploid strain. To aid in establishing *C. elegans* as a model for polyploidization and its effects at the cellular, organ, and animal levels we have compared the physiology and development (e.g., intracellular, cellular, and organ scaling, as well as cell division dynamics, self-fertility, and developmental timing) between isogenic diploid and tetraploid strains. Here I report that we observe variability between animals in established tetraploid strains and that we observed differences between independently derived isogenic tetraploid strains. For instance, we have seen that isogenic tetraploid strains have diverse levels of self-fertility and effects in intracellular scaling, and we observe distinguishable developmental timing effects between non-isogenic tetraploid strains. Together, these findings are exciting because they suggest that each independent tetraploidization event produces similar, but not identical, tetraploids, and that evolution is observable in tetraploid strains in relatively short periods of time. However, it also highlights the need to use at least two independently derive isogenic tetraploid strains for studies using this model.

400 **Sexual dimorphisms in meiotic chromosome structures drive heat induced male infertility in *C. elegans* and *D. rerio*** Cori Cahoon, Colette Richter, Amelia Dayton, Diana Libuda University of Oregon

Many of the developmental processes critical for the genome stability of developing sperm and egg are directly altered by environmental stressors, such as temperature, toxins, and pH. In contrast to egg development, developing sperm are incredibly sensitive to changes in temperature with heat exposure strongly linked to genome instability, infertility, and cancer. Despite these detrimental consequences of heat on male reproductive health, the mechanisms behind heat-induced male infertility are unknown. Here we show in *Caenorhabditis elegans* and *Danio rerio* (zebrafish) that differences in the temperature sensitivity between sperm and egg development are due to sexual dimorphisms in the synaptonemal complex (SC), a conserved, meiosis-specific chromosome structure required for meiotic genome stability and fertility. We find that only the spermatocyte SC in both *C. elegans* and zebrafish is destabilized and fragmented following acute heat exposure. Concurrently, heat exposure also causes an increase in double strand DNA breaks in both *C. elegans* and zebrafish. To establish the sexually dimorphic features rendering the SC temperature sensitive, we developed novel imaging tools for sex comparative live imaging studies in *C. elegans* and identified several sexual dimorphisms in SC composition and dynamics without heat exposure. We also uncover functional roles for these sex-specific differences in SC composition where individual SC proteins regulate specific steps of meiotic DNA repair differently in each sex. Finally, we performed a forward genetic screen and identified mutants that both suppress and enhance the sex-specific mechanisms regulating heat sensitivity of the SC. Cytological analysis of these mutants suggest sexual dimorphisms in SC assembly and disassembly may contribute to the heat sensitivity of the complex. Together, these studies reveal the sexual dimorphisms within the SC and provide insights into how developing sperm and eggs adapted similar chromosome structures to differentially regulate and execute meiotic stress responses to temperature.

401 **Pervasive sublethal effects of agrochemicals as contributing factors to insect decline** Lautaro Gandara[1], Richard Jacoby[1], François Laurent[2], Nikolaos Vlachopoulos[1], Noa Borst[1], Matteo Spatuzzi[1], Gülina Ekmen[1], Clement Potel[1], Martin Garrido-Rodriguez[1], Antonia Böhmert[3], Natalia Misunou[1], Bartosz Bartmanski[1], Xueying Li[1], Dominik Kutra[1,1], Jean-Karim Hériché[1], Christian Tischer[1], Maria Zimmermann-Kogadeeva[1], Victoria Ingham[3], Mikhail Savitski[1], Jean-Baptiste Masson[2],

Michael Zimmermann[1], Justin Crocker[1] [1]EMBL, [2]Pasteur Institute, [3]Universitätsklinikum Heidelberg

Insect biomass is declining across the globe at an alarming rate. Climate change and the widespread use of pesticides have been hypothesized as two underlying drivers. However, the lack of systematic experimental studies across chemicals and species limits our causal understanding of this problem. Here, we employed a chemical library encompassing 1024 different molecules—including insecticides, herbicides, fungicides, and inhibitors of plant growth—to investigate how insect populations are affected by varying concentrations of pesticides, focusing on sublethal doses. Using a controlled laboratory pipeline for *Drosophila melanogaster*, we found that 40% of these chemicals affect the behavior of larvae at sublethal concentrations, and an even higher proportion compromises long-term survivability after acute exposure. Consistent with these results, we observed that exposure to chemicals at doses orders of magnitude below lethality induced widespread phosphorylation changes across the proteome. The effects of agrochemicals were amplified when the ambient temperature was increased by four degrees. We also tested the synergistic effects of multiple chemicals at doses found widely in nature and observed fitness-reducing changes in larval developmental time, behavior, and reproduction. Finally, we expanded our investigation to additional fly species, mosquitos, and butterflies and detected similar behavioral alterations triggered by pesticides at sublethal concentrations. Our results provide experimental evidence that strongly suggests sublethal doses of agrochemicals coupled with changes in environmental temperatures are significantly contributing to the global decline in insect populations. We anticipate that our assays can contribute to improving chemical safety assessment, better protect the environment, secure food supplies, and safeguard animal and human health, as well as understand our rapidly changing world.

402 **Single nuclei multiome ATAC and RNA sequencing reveals the molecular basis of thermal acclimation in *Drosophila melanogaster* embryos** Thomas S O›Leary[1], Emily E Mikucki[1], Sumaetee Tangwancharoen[1], Seth Frietze[2], Sara Helms Cahan[3], Brent L Lockwood[3] [1]University of Vermont, [2]Biomedical and Health Sciences, University of Vermont, [3]Biology, University of Vermont

Plasticity enables organisms to extend their tolerance limits. But often the physiological constraints that influence plastic responses are not well characterized, which hinders our ability to make predictions about tolerance limits. Here, we demonstrate that *Drosophila melanogaster* embryos undergo rapid thermal acclimation, on the timescale of hours, that extends their upper thermal limit. Given the speed of this response and the fact that early development is coordinated by changes in chromatin state and gene activation, we set out to characterize the molecular basis of embryonic thermal plasticity by performing single nuclei multiome ATAC and RNA sequencing on embryos that were acclimated to different temperatures. We found coordinated changes in chromatin state and the transcriptome in response to thermal acclimation. Overall, cool-acclimated embryos exhibited thermal compensation to the cold through increased chromatin accessibility and gene expression. Specifically, cold-acclimated embryos had higher chromatin accessibility of transcription factor binding motifs of global transcriptional activators, such as Zelda, and higher expression of genes encoding ribosomal proteins and enzymes involved in oxidative phosphorylation. Although most of these shifts were common to all cell types, many significant changes were cell type specific. For example, increased expression in the cold-acclimated embryos was particularly prominent in tracheal primordial cells, presumably to prepare for increased gas exchange to support a higher metabolic rate. On the other hand, we observed modestly higher expression of genes involved in cell migration and cell adhesion in warm-acclimated embryos, particularly in ventral nerve cord primordia, suggesting a potential role for locomotor and sensory development in embryonic heat tolerance. Overall, our results indicate that thermal plasticity is largely mediated by shifts in the epigenome and transcriptome that, at least in part, regulate the speed of development and that may impose metabolic costs that constrain upper thermal limits.

403 **Drivers of DNA Damage Tolerance in *Drosophila melanogaster*** Mitch McVey[1], Varandt Khodaverdian[2], Tokio Sano[2], Mai Tran[2], Lara Maggs[2], Alice Witsell[2], Nina Benites[2], Natalie Danzinger[2], Ana Dias[2], Rita Gyurko[2], Sofia Lombana Rengifo[2], Kian Sahani[2], Alexander Schmidt[2], Hanna Slutsky[2], Gina Tomarchio[2] [1]Biology, Tufts University, [2]Tufts University

DNA damage tolerance mechanisms allow for the completion of DNA replication in the presence of base and nucleotide damage. Experiments conducted largely in yeast and mammalian cells have identified translesion synthesis, repriming, and template switching as the major damage tolerance mechanisms. However, few studies have examined how multicellular organisms prioritize these strategies to ensure their survival, and the consequences that result when one or more are inactivated. To address this, we have conducted a systematic survey of Drosophila possessing mutations in genes involved in damage tolerance, and the response of these mutants to exogenous alkylation damage.

Based on results from genetic screens and reverse genetic analyses, we report five main findings: (1) homologous recombination/template switching is not the primary damage tolerance mechanism in Drosophila; (2) translesion synthesis, mediated largely by polymerases zeta and eta, is a central component of damage tolerance in rapidly dividing imaginal disc tissues; (3) Rev1 plays a critical role in tolerance by recruiting translesion polymerases and through its deoxycytidyl transferase

activity; (4) the SLX1/4 structure-specific endonuclease and the Drosophila ortholog of Ttf2 (transcription termination factor 2) become important for damage tolerance when translesion synthesis is impaired, and (5) collectively, these responses prevent the accumulation of double-strand breaks and catastrophic chromosomal shattering that lead to cell and organismal death. Together, our findings establish Drosophila as a versatile system in which to study tolerance strategies and discover novel mechanisms that promote organismal survival when replicating damaged DNA. Furthermore, they may provide insight into mechanisms that cancer cells use to survive conventional chemotherapeutic treatment.

404 **Asynchronous DNA synthesis establishes epigenetic asymmetry at sister centromeres and regulates both de-differentiation and re-differentiation in a stem cell lineage** Rajesh Ranjan[1], Xin Chen[2] [1]Biology, Howard Hughes Medical Institute, [2]Howard Hughes Medical Institute

Many stem cells utilize asymmetric cell division (ACD) to produce a self-renewed stem cell and a differentiating daughter cell. How non-genetic information could be inherited differentially to establish distinct cell fates is not well understood. We reported a series of spatiotemporally regulated events that ensure differential enrichment of the centromere-specifying component CENP-A between sister chromatids for their biased attachment and segregation during ACD of *Drosophila* male germline stem cells (GSCs). Our results provide the cellular basis for partitioning epigenetically distinct sister chromatids during stem cell ACDs.

However, the mechanisms that establish asymmetric sister centromeres between genetically identical sister chromatids is not well understood. Using Super-Resolution Chromatin Fiber (SRCF) assay, I found asymmetric recycling of pre-existing (old) CENP-A during DNA replication. Further, I found that CAL1, the chaperone for CENP-A, is required for asymmetric recycling of old CENP-A in S-phase GSCs. Compromising CAL1 not only abolishes CENP-A asymmetry between sister chromatids, but also results in mis-determination of germ cell fate, shown by both GSC loss and early-stage germline tumor phenotype. Furthermore, we found that DNA polymerases involved in lagging-strand synthesis, such as Polα and Polδ, are expressed at reduced levels in stem cells compared to non-stem cells in the same germline lineage. Interestingly, compromising either Polα or Polδ using heterozygotes is sufficient to recapitulate stem cell-specific asymmetric sister centromeres in symmetrically dividing progenitor cells. I hypothesize that the asynchrony between leading and lagging strand synthesis biases the pre-existing CENP-A recycling by the leading strand and helps establish asymmetric sister centromeres. To further understand the biological significance of induced epigenetic asymmetry in non-stem cells, I tested these cells for their de-differentiation and re-differentiation abilities *in vivo*. I found that under both physiological condition during aging or with genetic ablation of stem cells, the non-stem cells with enhanced epigenetic asymmetry behave more like *bona fide* stem cells, manifested by their more efficient restoration of stem cell-unique features and activities.

Together, these results illuminate the molecular mechanisms establishing asymmetric epigenetic information and highlight the important role of DNA replication in this process for cell fate determination in multicellular organisms.

405 **Transcriptional coupling of telomeric retrotransposons with the cell cycle** Mengmeng Liu[1], Xiao-Jun Xie[2], Xiao Li[3], Xingjie Ren[4], Jasmine Sun[1], Zhen Lin[5], Rajitha Udakara Sampath Hemba-Waduge[1], Jun-Yuan Ji[1] [1]Biochemistry and Molecular Biology, Tulane University School of Medicine, [2]Department of Molecular and Cellular Medicine, Texas A&M University Health Science Center, [3]Lewis-Sigler Institute of Integrative Genomics, Princeton University, [4]Department of Neurology, University of California, San Francisco, [5]Department of Pathology, Tulane University School of Medicine

Dipteran species employ a distinctive mechanism to safeguard chromosome ends, relying on the transposition of telomeric-specific retrotransposons (TRs), including *HeT-A*, *TART*, and *TAHRE* in *Drosophila*, rather than telomerases. While the role of TRs in generating tandem repeats at chromosome ends is established, the mechanism controlling TR transcription remained unclear. This study elucidates novel regulators of TR transcription and telomere length in *Drosophila*, identifying multiple subunits of the transcription cofactor Mediator complex, along with the transcriptional factors Scalloped (Sd) and E2F1-Dp. Depletion of multiple Mediator subunits, Dp, or Sd increases TR expression and telomere length, while overexpressing E2F1-Dp or depleting the E2F1 regulator Rbf1 stimulates TR transcription. Notably, Mediator and Sd affect TR expression through E2F1-Dp. Our CUT&RUN analysis revealed direct binding of CDK8, Dp, and Sd to telomeric repeats. These findings highlight the essential role of the Mediator complex in maintaining telomere homeostasis by regulating TR transcription through E2F1-Dp and Sd, revealing the intricate coupling of TR transcription with the host cell-cycle machinery for chromosome end protection and genomic stability during cell division. Additionally, this study reveals how *Drosophila* synchronizes the initial step in the TR life cycle with the cell cycle through factors such as E2F1-Dp to safeguard chromosome integrity.

406 **A sperm-killing selfish X chromosome in Drosophila exhibits female meiotic drive** Graeme L. Keais[1,2,3], Chadi M. Saad-Roy[4,5], Emmanuel Gonzalez[6], Ryan M.R. Gawryluk[1], Pauline van den Driessche[7], Benjamin Loppin[6], Steve J. Perlman[1] [1]Department of Biology, University of Victoria, [2]Department of Botany, University of British Columbia, [3]Biodiversity Research Centre, University of British Columbia, [4]Miller Institute for Basic Research in Science, University of California,

Berkeley, [5]Department of Integrative Biology, University of California Berkeley, [6]Laboratoire de Biologie et Modelisation de la Cellule, Ecole Normale Superieure de Lyon, [7]Department of Mathematics and Statistics, University of Victoria

Meiotic drivers are selfish genetic elements that bias gene transmission in their favor during meiosis or gamete development. These elements play a powerful role in centromere and genome evolution. Meiotic drive occurs through both males and females, but sex differences in gametogenesis circumscribe the mechanism of drive in the two sexes: Male meiotic drivers kill gametes that do not inherit them, while female meiotic drivers preferentially segregate to the egg cell during meiosis. We have discovered an X chromosome in *Drosophila testacea* that is capable of meiotic drive through both sexes. As previously reported, male carriers transmit the driving X to over 80% of offspring through a sperm-killing mechanism. We now report significant distortion of the driving X through females heterozygous for this chromosome. We find that both the adult offspring and embryos of heterozygous females inherit the driving X significantly more than the wild-type X. We also find that heterozygous females maintain normal fecundity, suggesting that distortion occurs during meiosis itself. To support this notion, we use microscopy to reveal that the driving X has undergone extensive elongation near the centromere, which may be related to the mechanism of drive in females. Male and female drive of this chromosome therefore appear to use different mechanisms. Overall, our results show that the driving X of *D. testacea* is not only a novel case of female meiotic drive, but the first example of a driving X capable of meiotic drive through both sexes since their discovery nearly 100 years ago and a striking example of collaboration between different meiotic drive elements. Meiotic drive through both sexes has major implications for the origin and evolutionary dynamics of the driving X in this species, and in other systems where female drive may be present but unnoticed.

407 **The synaptonemal complex plays multiple roles in establishing the recombination landscape across chromosomes** Katie Billmyre Genetics, University of Georgia

One of the top factors associated with aneuploidy is the disruption of meiotic crossing over. Interestingly, we know from extensive work in humans and model systems that meiotic segregation is not a uniform process for all chromosomes and instead a variety of mechanisms ensure segregation. However, the mechanisms underlying recombination and segregation of specific chromosomes are not understood. Here we use a model of chromosome-specific meiotic defects in *Drosophila melanogaster* to investigate the mechanisms that govern meiotic events on individual chromosomes. We find that small in-frame deletions in the transverse filament protein of the synaptonemal complex (SC), a key component of the meiotic machinery, result in fragmentation of the SC. These mutants also exhibit chromosome-specific defects where pairing and crossing over are lost on the X chromosome but not the autosomes. However, how the SC alters the recombination landscape on the X chromosome but not the autosomes is unclear. We used genomics to examine the relationship between the SC, double-strand breaks, and recombination on the X chromosome and the autosomes. Our sequencing results showed that in a partial loss of SC background, double-strand breaks can be repaired as non-crossover gene conversions, even when they are unable to be repaired as crossovers on the X chromosome. This work will help us better understand the mechanisms that regulate meiotic events on individual chromosomes to ensure proper inheritance.

408 **Mechanisms of ring chromosome lethality** Adam Lin, Mary Golic, Hunter Hill, Kate Lemons, Kent Golic School of Biological Sciences, University of Utah

We generated circular forms of sex chromosomes and autosomes in *Drosophila melanogaster*. Each of these ring chromosomes exhibits significant dominant zygotic lethality. In mitotic divisions the ring chromosomes show frequent misbehavior. Double bridges resulting from sister chromatid exchange and catenated sister rings were the most frequent anaphase aberrations. We also observed instances of mitotic nondisjunction, mitotic recombination between the ring and its homolog, and ring chromosome breakage. The frequent occurrence of catenated rings suggested that lethality could be ameliorated by overexpression of Topoisomerase II. Crossing ring males to females carrying additional copies of *Top2* significantly rescued ring-bearing offspring, while crossing to heterozygous *Top2*$^{+/-}$ mutant females resulted in complete lethality. We conclude that the normal level of maternal Top2 is not sufficient to regularly resolve catenated rings and is a major contributor to ring chromosome lethality. The DNA Damage Response also contributes to ring lethality: *chk2* and *p53* mutants show strong maternal rescue of ring-bearing progeny but with different phenotypes suggesting that Chk2 and P53 are detecting different aberrations. Finally, we saw many cases of homolog capture in mitosis, where a "sticky" connection between a ring chromosome and its linear homolog produced an anaphase bridge. We hypothesize that these represent remnants of somatic homolog pairing. This further suggests that somatic chromosome pairing is not merely homologs lying side by side, but that chromosome pairs are entwined by Top2-mediated passage of one chromosome through its homolog during interphase.

409 **Identification of UTR sequences involved in post-transcriptional gene regulation of vertebrate embryonic development** Jayesh Kumar Sundaram, Miler Lee Biological Sciences, University of Pittsburgh

The development of a fertilized egg into an adult organism with different specialized cell types requires precise gene regulation. After transcription, mRNA expression is influenced by factors that bind the untranslated regions (UTRs), which can influence stability, translation, and sub-cellular localization. These factors often bind to mRNAs by recognizing short regulatory sequences in the UTRs. To better understand post-transcriptional gene regulation during vertebrate development, we developed a novel method to perform unbiased identification of short UTR sequences that have dynamic prevalence in the transcriptome during development of six chordate species - zebrafish, medaka, Xenopus tropicalis, Xenopus laevis, axolotl, and amphioxus. We reasoned that developmental stage-specific changes in the transcriptome-wide abundance of a given sequence could reflect the activity of a stage-specific post-transcriptional regulator that binds to that sequence. For example, we observe a strong depletion of specific sequences corresponding to targets of the microRNA miR-430/miR-427 during gastrula stages, which is consistent with the known role of these microRNAs in regulating maternal mRNA clearance during the maternal-to-zygotic transition. We have also identified several other sequences of interest with significantly differential abundance during development, both species-specific and shared across vertebrates, which remain to be further characterized. Of note, across vertebrates, polypyrimidine sequences in the 5'UTR increase in abundance over time, which is consistent with the emergence of 5' TOP sequence-mediated regulation only later in development. We also found conserved enrichment of U-rich 3'UTR sequences in early stages in contrast to later stages, suggesting conserved roles for maternal mRNA regulation. The novel methods and findings in this study will help us better understand post-transcriptional gene regulation during embryonic development and beyond.

410 **Differential H3K4me2 distinguishes two enhancer classes at zygotic genome activation** Matthew D Hurton, Miler T Lee Biological Sciences, University of Pittsburgh

Early animal development requires dramatic gene regulatory changes, as an initially silent zygotic genome gains transcriptional competency and assumes developmental control from maternally deposited factors during the maternal-to-zygotic transition. In zebrafish embryos, maternal pluripotency factors Nanog, Pou5f3, and Sox19b (NPS) play critical roles in orchestrating zygotic genome activation, in part by opening condensed chromatin at distal regulatory elements, i.e. enhancers, and mediating the acquisition of activating histone modifications. However, some embryonic gene activation still occurs in the absence of NPS activity, suggesting the existence of other mechanisms regulating zygotic genome activation. To identify chromatin signatures of these unknown pathways, we profiled the histone modification landscape in zebrafish embryos using CUT&RUN, focusing on modifications associated with active regulatory sequence in other systems. Our regulatory map identified two subclasses of enhancers distinguished by presence or absence of H3K4me2. Further investigation revealed that enhancers lacking H3K4me2 require NPS for activation, while enhancers bearing H3K4me2 seem to be NPS-independent. Rather, these H3K4me2+ enhancers appear to be epigenetically bookmarked in a manner previously described for embryonic promoters. Together, these data implicate a parallel pathway for zygotic genome activation that does not depend on NPS pioneering, which likely has implications for understanding how pluripotency induction and transcriptome reprogramming are regulated in other species and contexts

411 **Conserved enhancers control notochord expression of vertebrate *Brachyury*** Cassie L. Kemmler[1], Jana Smolikova[2], Hannah R. Moran[1], Brandon J. Mannion[3], Dunja Knapp[4], Fabian Lim[5], Anna Czarkwiani[4], Viviana Hermosilla Aguayo[6], Vincent Rapp[7], Olivia E. Fitch[8], Seraina Bötschi[9], Licia Selleri[6], Emma Farley[5], Ingo Braasch[8], Maximina Yun[4], Axel Visel[3], Marco Osterwalder[7], Christian Mosimann[1], Zbynek Kozmik[2], Alexa Burger[1] [1]Pediatrics, University of Colorado, [2]Institute of Molecular Genetics of the ASCR, [3]Environmental Genomics and Systems Biology Division, Lawrence Berkeley National Laboratory, [4]CRTD Center for Regenerative Therapies Dresden, Technische Universität Dresden, [5]Department of Medicine, University of California San Diego, [6]Department of Orofacial Sciences, University of California San Francisco, [7]Department for BioMedical Research (DBMR), University of Bern, [8]Department of Integrative Biology and Ecology, Michigan State University, [9]University of Zürich

Brachyury/T/TBXT genes encode T-box transcription factors that are critical regulators of notochord development, the defining feature of the chordate body plan. The notochord stabilizes the embryonic axis, secretes signaling molecules to guide neural tube patterning, and forms the template for spine development. Although anomalies in notochord patterning and spine formation are major contributors to disabilities worldwide, how *Brachyury* expression is controlled in normal and pathological conditions is unknown. The gene-regulatory enhancer elements that drive *Brachyury/T/TBXT* gene expression in the mammalian notochord have long remained elusive. Here, we combine genomic data from human chordoma tumors, evolutionary conservation analysis, cross-species transgenic reporter assays, and mouse knockouts to define three notochord-specific enhancer elements in the human *Brachyury/T/TBXTB* locus. Using transgenic assays in zebrafish, axolotl, and mouse, we establish the shared versus species-divergent activities of the three *Brachyury*-controlling notochord enhancers *T3*, *C*, and *I* in the human, mouse, and marsupial genomes. Acting as Brachyury-responsive, auto-regulatory shadow enhancers, deletion of all three elements in mouse abolishes Brachyury/T/TBXTB expression selectively in the notochord. We document enhancer dose-dependent trunk and neural tube defects downstream of Brachyury/T activity without impact on gastrulation

or tailbud formation. Surprisingly, the three *Brachyury/T/TBXTB*-driving notochord enhancers are conserved beyond mammals in the *brachyury*/*tbxtb* loci of fishes, dating their origin to the last common jawed vertebrate ancestor. Our data define an evolutionary ancient, essential enhancer combination dedicated to notochord control of *Brachyury/T/TBXTB* that advances our understanding of how this central transcriptional regulator is controlled in development and disease. Supported by the NIH, NSF, CHCO Foundation, and CU Anschutz.

412 **Decoding mitochondrial-nuclear interactions: Unraveling mechanisms of postzygotic isolation in Danionin fish species** Trevor J Chamberlain, Francisco Pelegri The Laboratory of Genetics, UW-Madison

Barriers to successful interbreeding arise as mechanisms of selection act on diverging species. One possible barrier is postzygotic isolation, in which mating and fertilization occur but embryos remain inviable. Members of the cyprinid subfamily Danioninae, which includes zebrafish, comprise a model phylogeny for studying biological mechanisms including postzygotic isolation by examining hybrid and nucleocytoplasmic hybrid (cybrid) embryonic development in a well understood developmental genetics framework. A suspected source of postzygotic species isolation lies in incompatibilities between the mitochondrial genome (mtDNA) of one species and the nuclear genome of another. To begin to study mito-nuclear incompatibilities, we sequenced mtDNA from zebrafish (*Danio rerio*) and related species *D. aesculapii*, *D. kyathit*, *D. nigrofasciatus*, *D. tinwini*, *D. albolineatus*, *D. margaritatus*, *D. erythromicron*, *D. choprae*, *Devario sondhii*, *D. aequipinnatus*, and *Microdevario kubotai*, assembled their mitochondrial genomes, and identified single amino acid variants (SAVs) among mitochondrial proteins. We performed analyses which showed episodic diversifying selection in *Danio albolineatus* mitochondrial respiratory complex I, and in complex IV proteins in species belonging to *Devario* and *Microdevario* genera. We also examined mitochondrial proteins for increased rates of amino acid divergence above neutral and found sites that experience positive selection, suggesting functional change. Leveraging the high degree of mitochondrial protein conservation among vertebrates, we then used 3D protein modeling to identify interacting nuclear-encoded gene candidates for further functional variant and positive selection analyses. These studies will determine co-evolving mitochondrial and nuclear genes that underly mechanisms of species isolation and provide targets for mitochondrial fitness assays in hybrids and cybrids.

413 **Zebrafish scales: a new model of skin appendage evolution and development** Andrew J Aman, David M Parichy Biology, University of Virginia

Vertebrate skin is endowed with a variety of skin appendages, a morphologically diverse class of protuberances and invaginations that includes teeth, hairs and glands in mammals, feathers in birds, keratinous scales in squamate reptiles, and calcified scales in non-tetrapod fishes. Did skin appendages evolve multiple times or do all skin appendages share common ancestry? Evolutionary relationships among these diverse appendages are contentious because of widely varying morphology, histology and extracellular matrix composition. Using developmental genetics, live imaging, and single cell transcriptomics, we have found striking similarities in the signaling networks that regulate zebrafish scale development and development of terrestrial skin appendages. Additionally, we found that zebrafish scale matrix is deposited by an epithelium that produces an enamel-like matrix and condensed mesenchyme that produces an elasmoid matrix that is distinct from other vertebrate mineralized tissues such as dentin or bone. Together, our work suggests a single, common origin of all vertebrate skin appendages and establishes zebrafish skin as a study system that will prove useful for discovering general mechanisms underlying skin appendage patterning and morphogenesis.

414 **Unraveling the role of evolutionary capacitors that obscure cryptic genetic variants in fish** Hannah A Grunwald[1,2], Matthew Harris[1,2], Clifford J Tabin[1] [1]Genetics, Harvard Medical School, [2]Orthopedic Surgery Research, Boston Children's Hospital

Imagine a school of fish—a group of extremely similar individuals, all the product of a large, outbred population. These individuals, despite phenotypic homogeneity, harbor extensive genetic variation. Why is this variation not apparent? Why isn't there a 1:1 relationship between genotype and phenotype? This disconnect has potentially profound consequences in the studies of ecology, evolution, and human health. It has been proposed that cells can use molecular "capacitors" to buffer cryptic genetic variation such that the phenotypic outcome of these variants is obscured. The most famous of these is Hsp90, a chaperone that stabilizes and aids in protein maturation for a diverse array of kinases, chromatin remodelers, and signal transducers. Inhibition of Hsp90 is sufficient to reveal cryptic variants in many animals and plants, however the specific mechanism(s) by which this buffering occurs, the extent of buffered systems, and the impact on evolution remains to be elucidated.

Hsp90-buffered variants are thought to play a crucial role in eye loss during the evolution of the blind Mexican cavefish, *Astyanax mexicanus*, and it was previously shown that inhibition of Hsp90 in these fish produces individuals with

a wider range of eye-sizes than untreated siblings. However, it has not been determined which specific genetic variants are responsible for changes in eye-size, and the feasibility of Hsp90 capacitance to accelerate or materially impact evolution has not yet been investigated. By combining datasets of Hsp90 clients with genes associated with eye-loss in existing QTL studies in *Astyanax*, we have identified a short list of 19 candidate genes that may explain Hsp90-dependent eye-loss in these fish. Using a variety of genetic tools in the zebrafish, including CRISPR knock-out and knock-in models and transgenic expression of dominant negative Hsp90 alleles, we are able to model and perturb Hsp90 buffering to investigate chaperone role in eye development and determine which specific Hsp90 clients may have played a role in *Astyanax* evolution.

415 **Functional validation of the albino *OCA2*^{NW273KV} polymorphism identified in a Caribbean Native American population in zebrafish** Thaddeus Harbaugh, Kathryn Early, Jessica Christ, Victor Canfield, Keith Cheng, Khai Ang Pathology, Penn State Hershey College of Medicine

Our interest in the genetic determinants of major population differences in human skin pigmentation led us to explore the contributions of genetic ancestry to human light skin color in a mixed Caribbean population of primarily Native American and African genetic ancestry residing in the Kalinago Territory of the Commonwealth of Dominica. Skin pigmentation phenotype measured by reflectance spectroscopy and expressed as the Melanin Index (MI) ranged from 20 to 80 units, averaging 45.8. Three albino individuals with light skin, hair, and eye color, and nystagmus were identified during fieldwork. Exome sequencing of an albino individual and an obligate carrier revealed a 4bp inversion, *NW273KV,* in the *OCA2* gene in all three albino individuals; these mutations were heterozygous in all obligate carriers. A second mutation in the *OCA2* gene, *R305W*, was also found in all three albino individuals. However, this was not the causative variant as two non-albino individuals were also found to be homozygous for this mutation. In further support of this conclusion, one individual who was homozygous for *R305W* but homozygous ancestral for *NW273KV* had an MI of 72, which was among the darkest in the entire population. The MI values of the three albino individuals were 20.7, 22.4, and 23.8, which were the lowest values among the Kalinago. The *NW273KV* polymorphism had a single allele effect size of -8 melanin units. The zebrafish (*Danio rerio*) model organism is ideal for the study of human pigmentation disease phenotypes given the conservation in function between species. Here, we used CRISPR-Cas9 to knock-in the *OCA2*^{NW273KV} polymorphism into a zebrafish model to functionally validate the albino allele. Wild-type zebrafish of the AB strain were crossed to produce embryos for microinjection of the CRISPR-Cas9 knock-in construct. These embryos were injected at the single-cell stage and raised to adulthood as the F_0 generation. Preliminary confirmation of the desired knock-in was qualitatively verified through the appearance of a mosaic albinism phenotype. We also performed allele-specific PCR to confirm successful knock-in of the *OCA2* allele. F_0 fish were then crossed, producing F_1 offspring that displayed a total loss of pigment. These results validate *OCA2*^{NW273KV} as the polymorphism responsible for albinism in the Kalinago population and highlight the value of zebrafish as a model for testing pigment phenotypes of human pigmentation alleles.

416 **Genomic factors shape metabolic niche breadth across an entire subphylum** Chris Todd Hittinger[1], Dana A. Opulente[1], Abigail Leavitt LaBella[2], Marie-Claire Harrison[2], John F. Wolters[1], Xiaofan Zhou[2], Xing-Xing Shen[2], Marizeth Groenewald[3], Antonis Rokas[2], Y1000+ Project Consortium[1] [1]University of Wisconsin-Madison, [2]Vanderbilt University, [3]Westerdijk Fungal Biodiversity Institute

Organisms, including yeasts, vary greatly in ecological niche breadth, from quite narrow (specialists) to quite broad (generalists). Paradigms proposed to explain this variation invoke either trade-offs between performance efficiency and breadth or underlying extrinsic or intrinsic factors. Here, we generated and assembled genomic (1,154 yeast strains from 1,051 species), metabolic (quantitative growth measurements in 24 conditions), and ecological (using a hierarchical environmental ontology) data from essentially all known species of the ancient yeast subphylum Saccharomycotina to examine niche breadth evolution. Using evolutionary genomic, machine learning, and network analyses, we found that large interspecific differences in carbon breadth stem from intrinsic differences in genes encoding specific metabolic pathways, but we found limited evidence for trade-offs or extrinsic factors. These comprehensive data argue that intrinsic factors drive yeast niche breadth variation. This unprecedented genomic, metabolic, and ecological dataset shows how metabolic diversity and niche breadth are encoded in yeast genomes and how these traits have evolved during more than 400 million years of yeast evolution. A preprint is available at https://www.biorxiv.org/content/10.1101/2023.06.19.545611.

417 **Genetic network rewiring between distantly related eukaryotes** Vanessa Pereira[1], Rohan Dandage[1], Elena Kuzmin[1,2] [1]Department of Biology, Centre for Applied Synthetic Biology, Centre for Structural and Functional Genomics, Concordia University, [2]Department of Human Genetics, Rosalind & Morris Goodman Cancer Institute, McGill University

Synthetic lethality represents an extreme example of a genetic interaction that occurs when a combination of mutations in different genes results in lethality, which would not be expected from the combined effects of individual viable single mutants. The extent of genetic interaction network conservation differs from genome sequence conservation between species. Two

distantly yeast species, *S. cerevisiae* and *S. pombe*, diverged ~500 Mya and despite 75% genome conservation, they display 29% genetic interaction network conservation. Other distantly related eukaryotes such as *C. elegans* and *H. sapiens* diverged ~600 Mya. Here, we investigate genetic network rewiring by studying the genetic interactions that underlie conditional essentiality of single mutants between *S. cerevisiae, S. pombe, C. elegans*, and *H. sapiens*, whereby a gene is essential (ES) in one species but nonessential (NES) in another. We identified 2853 *S. cerevisiae – S. pombe* orthologs, where ~15% are conditional ES. From 269 conditional NES *S. cerevisiae* genes (*S. pombe* ES*, S. cerevisiae* NES), we identified 124 cases which are rewired by synthetic lethal digenic interactions that modify conditional NES single mutants to synthetic lethal double mutants. Genetic interaction degree and phenotype rate of rewired conditional NES genes are higher than conserved NES genes suggesting that they are central on these networks. However, the lower phenotype rate of rewired relative to nonrewired conditional NES suggests that they are less pleiotropic. This finding is consistent with conditional NES genes being rewired by few synthetic lethal interactions, with most interactors modifying one conditional NES gene. To further understand the functional relationship between conditional NES genes and their rewiring synthetic lethal interactions, we overlapped them with common functional standards and found that they were co-expressed, co-localized, co-annotated, shared protein-protein interactions and showed similar phenotypic profiles suggesting that genetic rewiring of conditional NES genes is local. We extend these findings to *C. elegans* and *H. sapiens,* where ~21% of *H. sapiens – S. cerevisiae* orthologs, ~23% of *C. elegans – S. cerevisiae* orthologs, and ~14% *H. sapiens – C. elegans* orthologs are conditional ES. Mapping how conditional ES genes are rewired by genetic interactions will provide insight into genetic network rewiring and should reveal principles of genetic network conservation.

418 **Spindle architecture constrains karyotype in budding yeast** Jana Helsen[1], Md Hashim Rez[2], Gavin Sherlock[3], Gautam Dey[1] [1]EMBL, [2]Jawaharlal Nehru Centre for Advanced Scientific Research, [3]Stanford University

The eukaryotic cell division machinery must rapidly and reproducibly duplicate and partition the cell's chromosomes in a carefully coordinated process. However, chromosome number varies dramatically between genomes, even on short evolutionary timescales. We sought to understand how the mitotic machinery senses and responds to karyotypic changes by using a set of budding yeast strains in which the native chromosomes have been successively fused. Using a combination of cell biological profiling, genetic engineering, and experimental evolution, we show that chromosome fusions are well tolerated up until a critical point. However, with fewer than five centromeres, outward forces in the metaphase spindle cannot be countered by kinetochore-microtubule attachments, triggering mitotic defects. Our findings demonstrate that spindle architecture is a constraining factor for karyotype evolution.

419 **Proteome-wide alanine scanning with mistranslating tRNAs to identify functionally important residues across the proteome** Matthew D Berg, Alexis Chang, Kyle Hess, Ricard A Rodriguez-Mias, Judit Villén Genome Sciences, University of Washington

While DNA sequencing has identified millions of natural genetic variants that alter protein sequence, determining the functional impact of these variants remains challenging. Traditional mutagenic approaches are not scalable for millions of variants and high-throughput approaches such as deep mutational scanning are limited to investigating one protein per experiment. Recently, our lab established Miro – a high-throughput proteomic technology to enable functional annotation of thousands of missense mutations across entire proteomes simultaneously. In this approach, stochastic errors in protein synthesis are induced to create amino acid substitutions throughout all expressed proteins within a cell. Biochemical selections are applied to the collection of protein variants that probe general protein properties like solubility, thermal stability, ligand binding, protein-protein interactions and posttranslational modifications. After selection, variants are quantified by mass spectrometry to determine the functional impact of each mutation on the measured property. In this work, we harness a collection of engineered alanine tRNAs that mis-incorporate alanine at almost all non-alanine codons to determine the impact of thousands of alanine substitutions proteome-wide in yeast. By applying thermal stability and solubility assays to the alanine substituted proteomes, we identify functionally important residues and protein regions. Our work represents the first proteome-wide alanine scan and provides insight into various aspects of protein biology including the structural and functional context underlying mutational sensitivity.

420 **Copy number variation alters local and global mutational tolerance** Pieter Spealman[1], Grace Avecilla[2], David Gresham[1] [1]Biology, New York University, [2]BioBus

Copy number variants (CNVs), duplications and deletions of genomic content, contribute to evolutionary adaptation, but can also confer deleterious effects and cause disease. Whereas the effects of amplifying individual genes or whole chromosomes (i.e., aneuploidy) have been studied extensively, much less is known about the genetic and functional effects of CNVs of differing sizes and structures. Here, we investigated Saccharomyces cerevisiae (yeast) strains that acquired adaptive CNVs of variable structures and copy numbers following experimental evolution in glutamine-limited chemostats. Although beneficial in the selective environment, CNVs result in decreased fitness compared with the euploid ancestor in rich media. We used

transposon mutagenesis to investigate mutational tolerance and genetic interactions in CNV strains. We find that CNVs confer novel mutational tolerance in amplified essential genes and novel genetic interactions. We validated a novel genetic interaction between CNVs and BMH1, which we identified in multiple strains. We analyzed global gene expression and found that transcriptional dosage compensation does not affect the majority of genes amplified by CNVs, although gene specific transcriptional dosage compensation does occur for approximately 12% of amplified genes. Furthermore, we find that CNV strains do not exhibit previously described transcriptional signatures of aneuploidy. Our study reveals the extent to which local and global mutational tolerance is modified by CNVs with implications for genome evolution and CNV associated diseases, such as cancer.

421 **Sc2.0: Design and build a synthetic eukaryotic genome in yeast from scratch** Yu Jeremy Zhao[1], Camila Coelho[1], Amanda Hughes[2], Luciana Lazar-Stefanita[1], Sandy Yang[1], Leslie Mitchell[1], Joel Bader[3], Giovanni Stracquadanio[4], Lars Steinmetz[2,5], Yizhi Cai[6], Jef D. Boeke[1] [1]Institute for Systems Genetics, NYU Langone Health, [2]European Molecular Biology Laboratory, [3]Department of Biomedical Engineering, Johns Hopkins University, [4]School of Biological Sciences, The University of Edinburgh, [5]Department of Genetics and Stanford Genome Technology Center, Stanford University, [6]Manchester Institute of Biotechnology, The University of Manchester

Rapid advances in DNA synthesis technology enable transitioning from genome reading and editing to genome writing. The synthetic yeast project (Sc2.0) is building a designed synthetic genome in yeast from scratch. We have accomplished a significant milestone with the complete assembly of all individual synthetic chromosomes and consolidated seven of them into one yeast cell through endoreduplication intercross. This strain, with its genome more than half synthetic, carried ~6000 designer modifications and still grows similarly to the wild type. Here, we describe the next-generation consolidation strategy called chromosome substitution to combine all remaining synthetic chromosomes to build the ultimate strain with an entirely artificial genome. Using an innovative CRISPR-based genome scanning method, we discovered an unexpected genetic interaction that links transcriptional regulation, inositol metabolism, and tRNA abundance.

Synthetic chromosomes in Sc2.0 carry thousands of loxPsym sites, which enables a genome-wide shuffling system with an inducible Cre recombinase, a means to rearrange the synteny of protein-coding genes on demand. We are pioneering this evolutionary platform to answer a fundamental question: What constitutes the minimal gene set for eukaryotic cell growth? In addition, synthetic genomes represent a revolutionary approach to metabolic engineering. Our engineered Sc2.0 strain already showed improved isobutanol production. This observation inspired us to consider constructing the second designer genome of the premiere industrial yeast, *Kluyveromyces marxianus* (Kmarx2.0). This initiative aims to address the global environmental challenge of biofuel production directly.

422 **Visual impairment cell non-autonomously dysregulates canonical integrated stress response brain-wide** Shashank Shekhar[1], Katherine J Wert[2], Helmut Krämer[3] [1]UT Southwestern Medical center, [2]Opthalmology, UT Southwestern Medical Center, [3]UT Southwestern Medical Center

Recent statistical findings have pointed to an aspect of blindness that has garnered little attention in the past: blindness is a significant risk factor for dementia, a devastating set of diseases impacting more than 3 million people in the U.S. each year [1]. While highly intriguing [2], this finding currently lacks any mechanistic foundation.

Starting with 6 different Drosophila models of blindness, we observed the cell non-autonomous induction of stress granules (SGs) deep in the brain, and their reversal upon restoration of vision. These SGs contain cytosolic condensates of p62, ATF4 and XRP1 and are marked by the presence of RNA-binding proteins Caprin and dFMR1. This cytosolic restraint of the ATF4 and XRP1 transcription factors dampens their activity during integrated stress response (ISR). Brain-wide propagation of ISR dysregulation depends on specific lamina neurons as their thermogenetic manipulation triggered the reversible formation of SGs deep in the brain. We also demonstrate the evolutionary conservation of blindness-induced proteostasis dysregulation in mammalian brains. In the thalamus and hippocampus of congenitally blind vsx2 mice, or degenerative blind RhoP23H retinitis pigmentosa mice, we observed increased cytosolic condensates of p62 and ATF4.

In summary, we have discovered a functional interplay between the ISR and the formation of SGs in the brain as a strategy to prevent cell death under chronic stress. Our data reveal a previously unknown mechanism cell non-autonomously regulating protein quality control and provide mechanistic insight into blindness-induced proteostasis dysregulation deep in the brain. Malfunctioning of the proteostasis network is associated with a wide range of human diseases, especially neurodegeneration including dementia.

423 **Splice variants of the actin nucleator Arp2 functionally diverge in fertility and development** Jordan Powell, Courtney M Schroeder Pharmacology, UT Southwestern Medical Center

The Arp2/3 complex is highly conserved throughout eukaryotic evolution and plays an essential role in branched actin nucleation. Interestingly, most eukaryotes encode two splice variants of Arp2 that differ merely by five amino acids in the unstructured D-loop, which is critical for Arp2/3 activation. Although the length of the alternative exon is largely conserved from flies to humans, the sequence is not. We investigated whether the *Drosophila* Arp2 splice variants functionally diverge by replacing *Arp2* in *D. melanogaster* with the coding sequence of either the short ('Arp2S') or long ('Arp2L') variant, each under the control of the Arp2 promoter. We expected minimal phenotypic differences because the splice variants are 99% identical in sequence. While both Arp2S and Arp2L fully rescue the *Arp2*-knockout lethality phenotype, we surprisingly found that *Arp2L*-expressing flies develop significantly slower than *Arp2S*-expressing flies. Furthermore, the *Arp2L*-expressing females are subfertile with a striking reduction in egg production, and males exhibit defects in actin cones, which are testis structures that separate syncytial sperm. Because the alternative exon in Arp2L differs in sequence between vertebrates and insects, we tested whether sequence or length contributes to these phenotypes by substituting the exon with five glycine residues. Surprisingly, the mutant exhibited normal development and fertility, suggesting that the alternative exon's sequence, not length, is disadvantageous in specific tissues, including the germline. We compared the motility of Arp2S- versus Arp2L-generated actin structures by live imaging the movement of cones, which are powered by actin polymerization. While Arp2S-generated cones move consistently down sperm tails at a speed similar to WT cones, Arp2L-generated cones move inconsistently, varying in speed within and across testes, suggesting the five additional residues alter actin polymerization kinetics. Overall, our data reveal that Arp2 splice variants are functionally nonequivalent due to the alternative exon's sequence, and we hypothesize that evolution shaped the Arp2L D-loop to tune actin polymerization kinetics for tissue- and species-specific roles.

424 **The splicing regulator Acn moonlights as a cytosolic activator of autophagy in a Tor-independent pathway to suppress neurodegeneration** Nilay Nandi[1], Leonard Yoon[2], Jeffery Kelly[2], Helmut Kramer[3] [1]Neuroscience, Univ of TX Southwestern Medical Center, [2]Scripps Research, [3]Neuroscience, UNIV OF TEXAS SOUTHWESTERN MEDICAL CENTER

To remove cellular debris and maintain homeostasis, neurons employ basal autophagy, a process that is positively regulated by Acinus (Acn) protein [1]. In Drosophila and mammalian cells, Acn is a primarily nuclear protein. The ASAP complex, formed by Acn together with Sap18 and RNPS1, binds to spliceosomes and regulates a subset of alternative splicing [2, 3], suggesting that Acn may stimulate autophagy through its function in alternative splicing. To test this, we generated the Acn^{ASAP} mutant that interrupts its binding interface with Sap18 and RNPS1 and, as predicted, interferes with ASAP-mediated alternative splicing. However, the Acn^{ASAP} protein is primarily cytosolic and enhances autophagy indicating that this mutant separates the regulatory functions of Acn in splicing and autophagy. Further support for a splicing-independent, non-nuclear role of Acn came from expression of a membrane-enriched myristoylated Acn that robustly enhanced autophagy. Moreover, an Acn^{NES} mutant that enhanced nuclear occupancy reduced autophagy, whereas an Acn^{NLS} mutant with reduced nuclear occupancy enhanced autophagy. These results are consistent with a model that, despite its primarily nuclear localization, Acn must exit the nucleus to induce autophagy. Because wild-type Acn is degraded in the cytoplasm [1], we reasoned that modifications that stabilize Acn would promote its function in autophagy. Acn stability is enhanced by phosphorylation of a highly conserved $Serine^{437}$, which is regulated by the balance of the activities of Cdk5-p35 kinase complex and the metal-dependent Nil phosphatase. Consistent with the importance of this modification, the phosphomimetic Acn^{S437D} mutation partially suppressed neurodegeneration and extends life expectancy compared to wild-type flies. Moreover, a drug obtained from an unbiased screen for mTor-independent autophagy activators can trigger Acn-S437 phosphorylation, enhance neuronal autophagy and suppress neurodegeneration in Drosophila models of Alzheimer's disease.

425 **Calcium imbalance underlies PS-deficiency induced mitochondrial damage** Yifan Zhou[1], Xiao Yang[2], Xun Huang[1] [1]Institute of Genetics and Developmental Biology, Chinese Academy of Science, [2]Shandong First Medical University

Orchestrated phospholipid composition is essential for cellular homeostasis. It is well known that phosphatidylserine (PS) is an important component of cellular membrane. Beyond its structural function, comparatively little is known about the regulatory function of PS. Here we uncovered a conserved, robust link between PS metabolism and Ca^{2+} homeostasis. In *Drosophila*, we identified Ca^{2+} signaling as a critical player downstream of PS-dependent mitochondrial integrity. We show that PS deficiency impairs mitochondrial function through triggering mitochondrial Ca^{2+} overload. The inositol trisphosphate receptor (IP3R) channel is involved in this process, forming clusters in response to PS deficiency. Mechanistically, reduced PS biosynthesis reshaped PE species profile and inhibited the activation of SREBP signaling. Correcting the lipid composition suppressed mitochondrial defects and formation of IP3R clusters. In mammalian cells, IP3R-dependent Ca^{2+} signals were sensitized by disease-associated status of PS synthesis: in the context of PS deficiency, IP3R activation elicited long-lasting Ca^{2+} spikes, with increased frequency and reduced duration of peaks as compared to the wild-type cells. While in the Lenz-Majewski syndrome (LMS)-causative mutant cells, where PS is overproduced, IP3R activation induced higher amplitude of Ca^{2+} transient than that in the wild-type cells. Our data suggest that balanced Ca^{2+} signal allows cells combat against disorders induced by aberrant PS metabolism.

426 **Dual role of PP2A in Hippo signalling and growth regulation** Aashika Sekar[1], Elodie Sins[2], Alberto Rizzo[2], Paulo Baptista-Ribeiro[2] [1]Barts Cancer Institute, Queen Mary University London, [2]Barts Cancer Institute

The Hippo pathway integrates multiple environmental signals to regulate tissue growth and homeostasis. Previously, we demonstrated that the apical-basal polarity protein Crumbs inhibits Hippo signalling by promoting CK1α kinase-dependent phosphorylation and degradation of upstream Hippo activator, Expanded. Here, using *in vitro* biochemical approaches in *Drosophila* S2 cells and *in vivo* approaches in the larval wing disc, we provide evidence that PP2A activates Hippo signalling by (1) antagonising Crumbs-mediated phosphorylation and degradation of Expanded and (2) stabilising basal Expanded levels in the absence of Crumbs stimulus. This occurs independently of the PP2A-containing STRIPAK complex, which inhibits the Hippo pathway by dephosphorylating Hippo. Importantly, we also show that distinct PP2A complexes are involved in the regulation of basal and Crumbs-mediated stabilisation of Expanded, thereby suggesting that Crumbs directs the interaction between PP2A and Expanded. Furthermore, we observed similar PP2A-mediated regulation of FRMD-6, the human orthologue of Expanded, in *Drosophila* S2 cells. Overall, our work characterises a novel Hippo-activating role for PP2A in the stabilisation of Expanded and provides insight into how PP2A tightly controls Hippo pathway in response to polarity stimuli.

427 **New A.I. behavioral annotation system MAFDA reveals that Fruitless robustly controls interaction social behaviors by guiding lipid metabolism.** Jie Sun[1], Wen-Kan Liu[1], Calder Ellsworth[1], Qian Sun[2], Yu-Feng Pan[3], YICHUN HUANG[1], Wu-Min Deng[1] [1]Tulane University School of Medicine, [2]Louisiana State University, [3]Southeast University

Pheromones are chemical signals used for communication between members of the same species. To increase fitness, animals use both internal (pheromone perception) and external states (pheromone production) to coordinate multiple physiological behaviors. In *Drosophila*, the male-specific isoform of Fruitless (Fru), FruM, is known as a master neuro-regulator of innate courtship behavior to control perception of sex pheromones in sensory neurons. Here we show that the non-sex specific Fru isoform (FruCOM) is necessary for pheromone biosynthesis in hepatocyte-like oenocytes for sexual attraction. Loss of FruCOM in oenocytes resulted in adults with reduced levels of the cuticular hydrocarbons (CHCs), including sex pheromones, and show altered sexual attraction and reduced cuticular hydrophobicity. We further identify evolutionarily conserved *Hepatocyte nuclear factor 4 (Hnf4)* as a key target of FruCOM in directing fatty acid conversion to hydrocarbons in adult oenocytes. *fru*- and *Hnf4*-depletion disrupts lipid homeostasis, resulting in a novel sex-dimorphic CHC profile, which differs from *doublesex*- and *transformer*-dependent sexual dimorphism of the CHC profile. Thus, Fru couples pheromone perception and production in separate organs for precise coordination of chemosensory communication that ensures efficient mating behavior. In addition, we developed a novel machine-learning-based automatic fly-behavioral detection and annotation (MAFDA) system, which allows us to visualize behavioral phenotypes under a temporal and spatial overlay, and to quantifiably compare behavioral index across different genetic backgrounds. This artificial intelligence system allows us to annotate social behaviors more accurately and digitize them, clustering them for a better comprehensive assessment of health indices. This system has been used in the behavioral assessment of liver injury models and cancer models, revealing the close relationship between disease ecology and interactive social behaviors.

428 **Glut1 functions in insulin-producing neurons to regulate organismal lipid storage in *Drosophila*** Matthew Kauffman, Justin DiAngelo Penn State Berks

Obesity continues to prevail as one of the largest health problems in the world. Obesity arises from excess storage of triglycerides (TAG); however, the full complement of genes important for regulating TAG storage is not known. The *Glut1* gene encodes a *Drosophila* glucose transporter that has been identified as a potential obesity gene through a buoyancy screen. However, the mechanism by which Glut1 acts in different tissues to affect the metabolism and storage of carbohydrates

and lipids is not fully understood. In this study, we characterized the role of Glut1 specifically in the fly brain. We decreased neuronal Glut1 levels by inducing RNAi in all neurons using *nSyb-Gal4* and measured the levels of TAG in adult flies. *Glut1-RNAi* flies had a decrease in TAG, and this was not due to changes in food consumption. A group of hormones that regulate metabolism and are expressed in the fly brain are *Drosophila* insulin-like peptides (Ilps) 2, 3, and 5. Since the secretion and expression of certain Ilps are also regulated by sugar, we hypothesized that decreasing *Glut1* in all neurons would result in a defect in the secretion and/or expression of these Ilps. Interestingly, we observed a decrease in the expression of *Ilp3* in *Glut1-RNAi* flies, suggesting that Glut1 functions in insulin-producing neurons (IPCs) to regulate organismal TAG. To test this hypothesis, we induced *Glut1-RNAi* specifically in the IPCs and measured TAG. We saw a decrease in the organismal storage of TAG in these flies as well as a decrease in the expression of *Ilp3*, indicating Glut1 functions in IPCs to regulate insulin-like peptide expression and whole-organism nutrient storage. If this decrease in *Ilp3* expression results in decreased TAG storage, we predict that genetically decreasing *Ilp3* would result in this same phenotype. To test this hypothesis, we measured TAG storage in *Ilp3* mutants and observed a decreased lipid phenotype, suggesting that the decreased *Ilp3* expression observed in *Glut1-RNAi* flies is responsible for the decreased TAG phenotype we observed in these flies. Together, these data suggest that Glut1 functions as a nutrient sensor in the insulin-producing cells, controlling TAG storage and regulating organismal energy homeostasis.

429 **Polarized recycling of cell-cell adhesion proteins facilitates scarless wound healing** Sofia Mendez Lopez, Kate MacQuarrie, Katheryn Rothenberg, Rodrigo Fernandez-Gonzalez University of Toronto

Following myocardial infarction, wound healing causes the formation of scar tissue, which limits cardiac output and can lead to heart failure. In contrast, embryos have a striking ability to repair wounds rapidly, with no inflammation or scarring. We are investigating the mechanisms of scarless wound repair in the Drosophila embryo, which is amenable to live imaging, as well as genetic, pharmacological and biophysical manipulations. In embryos, wound repair is driven by the collective movement of the cells around the wound to draw the wound closed. Upon wounding, the cells adjacent to the wound polarize the cytoskeletal protein actin and the molecular motor non-muscle myosin II, forming a supracellular cable at the wound edge that creates tension and coordinates cell movements. In parallel, adherens junction proteins, including E-cadherin, are depleted from former bicellular junctions (BCJs) at the wound edge and accumulate at former tricellular junctions (TCJs) around the wound. The reorganization of cell-cell adhesions is necessary for rapid wound healing. E-cadherin is removed from BCJs at the wound edge via polarized endocytosis, but the mechanisms by which E-cadherin accumulates at TCJs around the wound are unclear. To examine whether protein recycling contributes to E-cadherin reorganization during wound closure, we manipulated the activity of the small GTPase Rab11, which marks vesicles for slow recycling. Reducing Rab11 activity by overexpressing a dominant-negative form (Rab11DN), slowed down wound closure by 29%. While myosin polarization occurred normally in Rab11DN embryos, the accumulation of E-cadherin at TCJs decreased by 33%. Together, these results indicate that Rab11 is partially responsible for the remodeling of cell-cell adhesions during wound repair, and that cell-cell adhesion rearrangements control the rate of wound healing independent of cytoskeletal polarity. We are currently investigating the contribution of other protein trafficking pathways to embryonic wound healing, including rapid recycling (Rab8) and exocytosis (Sec5). Together, our results will pave the way for understanding the mechanisms of scarless wound repair, and may reveal novel therapeutic targets to prevent scarring and reduce the likelihood of heart failure following myocardial infarction.

430 **Genetic Quality Control for Mouse-Based Research: The Experience of the MMRRC** Matthew W Blanchard[1,2], Jennifer Brennan[1], James Amos-Landgraf[3], Renee Araiza[4,5], Laura Reinholdt[6], Brandon Willis[4,5], Dominic Ciavatta[1,2], Leonard W McMillan[7,8], John S Sigmon[7,8], Chidima Ahulamibe[9], Sam Ardery[2], Timothy A Bell[2], Pablo Hock[2], Caroline E.Y. Murphy[9], Joyce Woo[9], Fernando Pardo Manuel de Villena[2,8,10] [1]Genetics, Mutant Mouse Resource and Research Centers, University of North Carolina at Chapel Hill, [2]Genetics, University of North Carolina at Chapel Hill, [3]Mutant Mouse Resource and Research Centers, University of Missouri, [4]Mutant Mouse Resource and Research Centers, University of California at Davis, [5]Mouse Biology Program, University of California at Davis, [6]Mutant Mouse Resource and Research Centers, The Jackson Laboratory, [7]Computer Science, University of North Carolina at Chapel Hill, [8]Mutant Mouse Resource and Research Centers, University of North Carolina at Chapel Hill, [9]University of North Carolina at Chapel Hill, [10]Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill

The Mutant Mouse Resource and Research Centers (MMRRC) is the premier repository and distributor of spontaneous and induced mutant mice and cell lines for the US National Institutes of Health. As part of our commitment to optimize the rigor and reproducibility of biomedical research using mouse models, the MMRRC has implemented standardized Genetic Quality Control (GQC) for the models it distributes. This GQC process is used to update, validate, supplement, and correct information provided by strain donors, in a consistent, objective, and genome-wide manner. For each strain, the MMRRC Genetics Committee leverages MiniMUGA genotyping data from two independent mice from the MMRRC colony to update the MMRRC Strain Detail Sheet (SDS) in a section named MMRRC Genetic QC. This new section provides a detailed summary of the genome-wide makeup of the strain (including the Y Chromosome, the mitochondria, and the vendor origin for popular

substrains), the level of inbreeding and congenicity, and constructs present. We present real-world examples of curated MMRRC strains, detail the resulting SDS changes, and show how GQC provides more accurate and objective information for users. We will discuss how GQC may provide actionable recommendations that will improve experimental design and increase rigor and reproducibility. Currently we have genotyped 245 strains and completed the MMRRC GQC strain review in 41. At least a quarter of strains reviewed require an update or correction, involving strain name changes, overestimated level of congenicity and inbreeding, Y Chromosome origin discordant with naming, complex genetics, and the presence of unexpected constructs. We provide a summary of MMRRC strains with significant updates or corrections. For a subset of these strains, we will propose specific actions to address the impact(s) of the GQC findings including changing the suggested control mice, breeding out undesired constructs or Y Chromosomes, and adjusting experimental sample size to account for genetic heterogeneity in the line. Finally, we introduce two MMRRC-produced video tutorials, one designed to familiarize non-expert users with the MiniMUGA genotyping platform and a second explaining MMRRC GQC and how to interpret the relevant sections of the SDS.

431 **What's new in Mouse Genome Informatics (MGI)?** Carol J Bult, Martin Ringwald, Cynthia Smith, Richard Baldarelli, Joel Richardson The Jackson Laboratory

The Mouse Genome Informatics (MGI) consortium maintains multiple integrated community knowledgebases that are united by a common mission to facilitate the use of the laboratory mouse as an experimental model for understanding the genetic and genomic basis of human health and disease. MGI is the authoritative source for key data types and annotations including: official nomenclature for mouse genes, alleles, and strains; phenotype annotations; functional annotations, developmental gene expression; and mouse models of human disease.

Content and user interfaces are constantly evolving at MGI in response to community needs and to the rapidly changing data landscape. Likewise, the infrastructure that supports expert curation of information from the scientific literature is changing with advances in machine learning and artificial intelligence. This presentation will highlight some of the latest enhancements to MGI and plans for the near future.

Among the new features to be highlighted are:

- New methods and interfaces for mapping mouse phenotype terms to equivalent human phenotype ontology terms
- Visualization and interaction with genome annotations from multiple inbred mouse strains and other species (including human)
- Enhanced annotation of mouse genome variation
- Enhanced representation of regulatory genome features and alleles in the mouse genome
- Enhanced representation of the pseudoautosomal region (PAR) in the mouse
- Implementation of machine learning algorithms to improve efficiency of literature curation

MGI is supported by NIH HG000330, HD062499, CA089713, HG012212 432 ***The panoramic view of organismal aging at single-cell resolution*** Zehao Zhang, Chloe Schaefer, Weirong Jiang, Wei Zhou, Junyue Cao The Rockefeller University

Aging is a multifaceted biological phenomenon characterized by intricate changes in diverse cell populations throughout the entire organism. The identification and characterization of these cell types, especially those undergoing substantial alterations during the aging process, represent a crucial step in developing targeted interventions to mitigate or reverse aging-related degeneration. Despite remarkable advancements in single-cell genomics, existing methodologies face challenges in capturing rare yet pivotal cell types involved in aging at the organismal level. In this study, we developed a high-throughput genomic analysis platform that is suitable for organismal-scale single-cell transcriptome profiling. With this platform, in one study, we profiled more than 20 million high-quality single-cell transcriptomes across 13 distinct organs from a sex-balanced mice cohort, yielding the most extensive catalog of aging-associated cell types (i.e., 230 distinct cell populations that undergo significant expansion or depletion), each characterized by its unique gene expression profiles and cell state dynamics. Notably, the scalability of our platform has effectively mitigated batch effects that typically arise when integrating various single-cell datasets in conventional consortium-level studies. This panoramic assessment of aging has revealed four temporally structured, dynamic aging waves that are organ-specific and lineage-specific. Additionally, we have explored the aging-related alterations in immune cell populations and their interplay with other cell types. The experimental and computational resources outlined here are expected to enhance our understanding of aging, fostering innovative methodologies to extend healthy

lifespans and address age-related diseases.

433 **Generation of knock-in rodent models using AAV-mediated DNA delivery with 2-cell embryo CRISPR-Cas9 electroporation** Daniel Davis, James McNew, Bhanu Telugu, Elizabeth Bryda University of Missouri

Complex animal models with targeted DNA insertions or substitutions (knock-ins) are essential for a variety of applications. In many cases these knock-ins are required to be large in size, which has been shown to reduce gene editing efficiency and limit capabilities of successfully creating the desired model. Numerous technical refinements have been developed to increase CRISPR-Cas mediated genome editing pertaining to creating targeted knock-ins via the homology-directed repair (HDR) pathway. In this study we have merged four promising approaches to come up with a highly effective pipeline to generate knock-in mouse and rat models. The four combined methods include: AAV-mediated DNA delivery, single-stranded DNA donor templates, 2-cell embryo modification, and CRISPR-Cas ribonucleoprotein (RNP) electroporation. Using this optimized approach, we have successfully produced targeted knock-in mouse and rat models carrying insertion of DNA sequences up to 3.0 kb in size with efficiencies of over 90%. Our modified AAV-mediated DNA delivery with 2-cell embryo CRISPR-Cas9 RNP electroporation technique has proven to be highly effective for generating both knock-in mouse and knock-in rat models.

434 **Algorithmic prioritization of genetic background for improved rare disease model generation** Robyn L Ball[1], Gaurab Mukherjee[1], Alexander Berger[1], Sara Davis[2], John Bluis[2], Robert Duggan[1], Mathew Gerring[1], Tim Holland[2], Beena M Kadakkuzha[1], Guy Karlebach[2], Peter Robinson[2], Elissa J Chesler[1] [1]The Jackson Laboratory, [2]JAX Genomic Medicine

Mouse models for rare disease research are often generated by modeling human genetic variants through genome editing of a small handful of widely used background strains, often chosen without insight into the susceptibility of the strain to the disease in question. Even single gene perturbations (i.e., rare, Mendelian disease variants) function in the context of biological networks. Some networks are highly robust and are able to buffer the effect of deleterious alleles readily. Others are molecular networks and are vulnerable to the effects of allelic variation. Some mouse strains have more deleterious allele in these networks than others, and we posit that these cumulative effects influence vulnerability to rare variants, resulting in variable penetrance and impact of disease mutations. Such strains may show mild patterns of network level dysfunction. These strains are detectable through the manifestation of similarity to disease associated phenotypic or transcriptional states. By imputing these states from molecular and physiological phenomes in all extant mouse resources, we can identify those strains that most resemble people with disease vulnerability and thus identify the ideal background strains in which to model disease. We present the application of our software pipeline for prioritization of these strains. Several examples are presented in rare and common disease, along with considerations for background strain selection from the prioritized results. The JAX Center for Precision Genetics Bioinformatics Core Strain Recommender uses molecular and phenotypic signals of disease to recommend mouse backgrounds likely to be susceptible (and resistant) to the disease and treatment. This work is supported by NIH JCPG grant number, NIH DA028420 and by The Jackson Laboratory, The Cube Initiative Program Fund.

435 **The NIH Comparative Genomics Resource (CGR)** Terence D Murphy, Nuala O›Leary, Sanjida Rangwala, Francoise Thibaud-Nissen, Tom Madden, Aron Marchler-Bauer, Valerie Schneider NCBI/NLM, NIH

Comparative genomic analyses are a powerful tool for scientific discovery. CGR is an NIH-funded, multi-year NLM project to establish an ecosystem to facilitate reliable comparative genomics analyses for all eukaryotic organisms in collaboration with the genomics community. The project's vision is to maximize the biomedical impact of eukaryotic research organisms and their genomic data resources to meet emerging research needs for human health. To achieve this, NCBI will provide high-value data and assorted tools compatible with community-provided resources. This presentation will give an overview of CGR resources of interest to the TAGC community, including genome contamination screening and annotation tools, new methods to access genome and gene sequence and metadata, Comparative Genome Viewer (CGV) for pairwise analysis of genomes, and improvements to BLAST and domain analysis to aid in exploring protein function and conservation across the tree of life.

436T **Identification and verification of proximity interactors of the polycystin complex in cilia and extracellular vesicles** Elizabeth desRanleau[1], Inna Nikonorova[2], Katherine Jacobs[2], Joshua Saul[2], Jonathon Walsh[2], Juan Wang[2], Maureen Barr[2] [1]Genetics, Rutgers University, [2]Rutgers University

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a devastating genetic disorder characterized by fluid-filled cysts that

accumulate in the kidneys, leading to renal failure. ADPKD is caused by mutations in the polycystin complex, encoded by PKD1 and PKD2. The polycystins localize in cilia of kidney cells and human urinary extracellular vesicles (EVs), but their function in EVs remains unexplored.

In C. elegans, like in humans, polycystins may act in cilia and EVs. In the worm, the polycystins are male-specific and are necessary for mate sensing by males. The polycystin complex, LOV-1 and PKD-2, is expressed in the tail ray neurons (RnBs) and cephalic male sensory neurons (CEMs). When either polycystin is mutated, male worms are mating deficient. With whom the polycystins interact in cilia and EVs is not known. Here, we used proximity labeling to identify interactors of the polycystin complex that colocalize into ciliary EVs. The objective of this work is to validate candidate cargo of polycystin-carrying EVs in *C. elegans* with endogenous genome-engineered fluorescent reporters.

Here, we focused on two novel PKD-2-proximity interactors: the polycystin-associated transmembrane lectins PAML-1 and PAML-2. When tagged with fluorescent reporters, we found that these proteins colocalize with PKD-2 in cilia and EVs. PAML-1 and PAML-2 are male-specific and are expressed in non-overlapping *pkd-2* expressing neurons. In L4 larval males, *paml-2* is expressed in all ray neurons then declines in ventral neurons during sexual maturation. In contrast*, paml-1* expression is limited to the ventral ray neurons. We discovered that although PAML-2 is initially present in all *pkd-2* expressing neurons, PAML-2 localizes to the cilia of dorsal rays and CEMs, whereas PAML-1 localizes to the cilia of ventral rays. When *lov-1* is mutated, neither PAML-1 nor PAML-2 are delivered to the cilium from the cell body, which suggests that LOV-1 is required for the transportation of these proteins to the ciliary tip. Our data shows that PAML-1 and PAML-2 are markers of dorsal and ventral EVs, where association with the polycystin complex might act as the factor that determines dorsal versus ventral transport of these lectins to the ciliary tip.

437T **Getting stressed out – iron induced stress response in *C. elegans*** Anna Gremme[1], Zainab Al-Timimi Safa Flaih[1], Bernhard Michalke[2], Julia Bornhorst[1] [1]Food Chemistry with focus on Toxicology, University of Wuppertal, [2]Helmholtz Munich

As an essential trace element, the general population mainly takes up iron (Fe) in form of various Fe species through food, food supplements and drinking water. The redox capacity between the oxidation states Fe^{2+} and Fe^{3+} turns Fe into an important key player in many biological processes. In addition, the adequate formation of reactive oxygen and nitrogen species (RONS), e.g. by Fe via Fenton reaction, is necessary for different signaling pathway cascades. However, an enormous Fe-induced RONS formation upon Fe overdosage lead to oxidative stress and is supposed to be a risk factor of various diseases.

Since little is known about the consequences and underlying mechanisms of overdosing different Fe species, we treated the nematode *C. elegans* with iron (III) ammonium citrate (FAC), iron (II) gluconate (FeGlu), and iron (II) chloride ($FeCl_2$) for 5 and 24 hours. We quantified the Fe by inductively coupled plasma-optical emission spectroscopy (ICP-OES) and observed overdosing in the worm by all Fe species. Increased superoxide dismutase (SOD) activity and MitoTracker™ red CM-H_2Xros fluorescence indicate the formation of RONS by all Fe species, with SOD activity altering in a species-specific manner. While the Fe-species have no effect on the mRNA expression of the genes *daf-16* (human *FOXO*) and *skn1* (human *NRF2*), measured *via* Taqman qPCR, a species-specific increased translocation of DAF-16 in the nucleus can be observed in a DAF-16:GFP *C. elegans* mutant. Since glutathione is an important molecule of the antioxidant system, we measured reduced (GSH) and oxidized (GSSG) glutathione *via* liquid chromatography–tandem mass spectrometry (LC-MS/MS). While no changes could be observed after FeGlu and $FeCl_2$ treatment, FAC shows increased GSH levels. Measurements of mRNA expression of *gcs-1* (human *GCLC*) and *gst-4* (human *HPGDS*) *via* Taqman qPCR indicate reduced gene expression by treatment with all Fe species after 24 hours. In this context we were interested in consequences of Fe overdosing in a worm model with depleted GSH. GSH depletion was achieved by diethyl maleate (DEM) after FAC incubation and verified *via* LC-MS/MS analysis.

In this study, we can show that the stress response after Fe overdosage in *C. elegans* is species-specific in some oxidative stress endpoints. This is an important finding to better assess mechanistic effects in a species-specific way. Further consequences and underlying mechanisms of Fe overdosage, also in combination with GSH depletion, are the subject of current studies.

438T **Investigating the role of a conserved 14-3-3 protein, FTT-2, in contractility of smooth muscles** Mustafi Raisa Amin Biology, Northeastern University

Cell contractility is vital for the maintenance and regulation of several biological systems, including the circulatory, respiratory, and digestive systems, etc. To study cell contraction, we use the *C. elegans* spermatheca, a contractile tube composed of smooth muscle-like cells, that stores sperm and is the site of oocyte fertilization. Regulated spermathecal contraction is needed to push the embryo into the uterus. Spermathecal cell contraction is regulated by actin and myosin, and is activated, in part, by the phospholipase, PLC-1. Previous studies have shown that the heterotrimeric G-protein alpha subunit, GSA-1/Ga_s, and protein kinase KIN-1/PKA-C are involved in ovulation and Ca^{2+} release. However, the upstream regulators of these pathways are still unknown. The spermatheca is not under neuronal control. So, how do the spermathecal cells know when to

contract? In order to identify novel regulators of spermathecal contractility, we performed a candidate RNAi screen to look for genes that caused an increase in the number of occupied spermathecae. One of the candidate genes, *ftt-2*, is one of the two putative 14-3-3 encoding genes in C. elegans. The 14-3-3 proteins have been implicated in a growing number of cell biology processes, however not much is known about their involvement in regulation of cellular contraction. Hence, study of the FTT-2 gene may identify a novel function of the 14-3-3 proteins in general.

439T **The acyl-CoA dehydrogenase ACDH-11 is required for *C. elegans* lysosomes-related organelle biogenesis** Madeline Daniel, Frances Parrott, David Nhek, Frances Courtemanche, Greg Hermann Lewis & Clark College

Gut granules are lysosome-related organelles (LROs) that coexist with conventional lysosomes within *C. elegans* intestinal cells. Gut granules contain conspicuous crystalline and autofluorescent material and function in lipid metabolism, cell signaling, and heme and micronutrient storage. The formation of gut granules requires evolutionarily conserved proteins that broadly function in LRO biogenesis. We screened *C. elegans* Million Mutation Project strains for mutants with altered LRO dynamics and identified a role for the ACDH-11 acyl-CoA dehydrogenase in gut granule formation and morphology. We show that *acdh-11(-)* mutant embryos exhibit enlarged gut granules and defects in the steady-state localization of the gut granule protein LMP-1. The morphology of conventional degradative lysosomes, lipid droplets, and yolk granules are unaltered in *acdh-11(-)* mutants. Gut granule numbers are unchanged in *acdh-11(-)*, suggesting that ACDH-11 activity impacts trafficking to/from gut granules rather than organelle fusion. ACDH-11 has been shown to inhibit the expression of the lipid desaturase FAT-7 in adult intestinal cells. We find that *acdh-11* is likely expressed embryonically and that FAT-7 becomes expressed in embryonic intestinal cells in *acdh-11(-)* mutants. The removal of *fat-7* activity in *acdh-11(-)* mutants reduces gut granule size and the overexpression of FAT-7 in *acdh-11(-)* results in gut granule enlargement, showing that FAT-7 activity promotes the expansion of gut granules in *acdh-11(-)*. Ectopic expression of FAT-7 in *acdh-11(+)* did not increase gut granule size, indicating that other processes altered in *acdh-11(-)* synergize with FAT-7 activity to promote gut granule enlargement. FAT-7 promotes the generation of unsaturated fatty acids to increase membrane fluidity. Consistent with increased membrane fluidity promoting gut granule enlargement, gut granules in *acdh-11(-)* mutants are significantly smaller at 15C compared to 22C. We will present work that investigates how ACDH-11 functions to regulate gut granule biogenesis.

440T **Enzyme kinetic characterization of wild-type *C. elegans* IDH-1 and the G98N & R133H mutants** Melissa A. Bouchard, Anne McAllister, William Wolfe, Katherine M. Walstrom Div. Natural Sciences, New College of Florida

The *C. elegans* ortholog of human cytosolic isocitrate dehydrogenase (IDH1) is called IDH-1. Isocitrate is reversibly converted to α-ketoglutarate (αKG) by both enzymes. Because some mutations linked to human malignancies can decrease the normal activity of IDH-1 and introduce a neomorphic enzyme activity that converts αKG to 2-hydroxyglutarate (2HG), this enzyme is of particular interest for cancer and genetics research. This experiment began with the overexpression and purification of wild-type IDH-1 as well as two mutants, G98N and R133H, which correspond to the human G97N and R132H mutations, respectively, to investigate whether IDH-1 may be a trustworthy model system to investigate the cellular abnormalities caused by IDH-1 mutations. During our initial characterization of wild-type IDH-1 using spectroscopic assays to detect NADPH, we found that the enzyme had increased activity in the presence of Mn^{2+} compared to $Mg^{2+}$and a strong preference for $NADP^+$ compared to NAD^+. In comparison to the previously published K_M values for αKG with the human R132H mutant, the experimental K_M for αKG for the *C. elegans* R133H mutant was lower (14 ± 2 μM). The findings of other experiments demonstrated that, in the forward reaction, human wild-type IDH1 and its R132H mutant shared traits with wild-type IDH-1 and the R133H mutant respectively. However, the G98N mutant had a higher forward enzyme activity than the human G97N mutant. LC-MS was used to measure the amounts of 2HG and isocitrate (ICT) produced by the enzymes in the reverse reactions, and the evidence indicated that the R133H mutant produced a larger ratio of 2HG per reaction (80 ± 20 2HG/ICT) than the G98N (13 ± 1 2HG/ICT) and wild type (1.5 ± 0.3 2HG/ICT) enzymes. (The first three authors contributed equally to this research project.)

441T **Actomyosin fibers in the spermatheca are under tension** Seyedeh-Fereshteh Sadeghian-Kiadehi[1], Erin Cram[2] [1]Bioengineering, Northeastern University, [2]Biology, Northeastern University

The proper control of contractile and relaxation processes is crucial for the functionality of tubular structures within organisms. In the case of *C. elegans*, the spermatheca, the site of fertilization, is comprised of cells that exhibit properties similar to smooth muscle. As oocytes pass through the spermatheca, the process involves several cycles of stretching and contracting. Within the spermatheca, actin structures take on a characteristic form, with parallel, basal bundles resembling stress fibers aligned along the cellular long axis. In order to gain a more comprehensive insight into how mechanical forces are transmitted within the spermatheca, we measured the tension exerted on these fibers employing a strain sensor named STReTCh. The STReTCh system consists of two components: SpyTag and SpyCatcher. SpyTag is an epitope tag integrated into a mechanosensitive domain, while SpyCatcher serves as a fluorescently labeled binding partner. SpyCatcher can only interact

with SpyTag when the mechanosensitive domain is in an unfolded state. In the context of *C. elegans*, we customized this technique by integrating the sensor into mechanosensitive sections of DEB-1/vinculin and FLN-1/filamin. Our observations revealed that SpyCatcher and DEB-1/vinculin::SpyTag, as well as SpyCatcher and FLN-1/filamin::SpyTag, coincide in the spermatheca when animals are subjected to *mel-11/MYPT* RNAi treatment and *plc-1/phospholipase C* RNAi treatment, respectively. Furthermore, we assessed the tension on the fibers through laser ablation. In animals expressing ACT-1::GFP, we employed a SpectraPhysics Spirit laser operating at 1040 nm, with 400 fs pulses at a frequency of 1 kHz and approximately 500 mW power, to sever the fibers, allowing us to observe the rates of fiber retraction. Protein kinase A, which consists of the catalytic subunit KIN-1/PKA-C and the regulatory subunit KIN-2/PKA-R, plays a pivotal role in controlling calcium release and contractility within the *C. elegans* spermatheca. Initial findings indicate that KIN-1/PKA has an influence on the tension of the fibers. The combined results from these methods point towards the presence of tension in the actomyosin fibers within the spermatheca. Our upcoming plan involves mapping tension distribution throughout the spermatheca and elucidating the role of PKA in regulating contractility.

442T **Mechanisms of Lamp1 non-cell autonomous regulation of endo-lysosomal acidification** Jonathan Chandler Handy[1], Aliza Kass[1], Gustavo MacIntosh[2], Andreas Jenny[1] [1]Developmental and Molecular Biology, Albert Einstein College of Medicine, [2]Biochemistry, Biophysics and Molecular Biology and Plant Sciences Institute, Iowa State University

Proteostasis is critical for the maintenance of cellular homeostasis especially during aging. Disruption of proteostasis results in the accumulation of toxic and insoluble protein aggregates associated with diseases like Alzheimer's Disease (AD) and Parkinson's Disease (PD). Lysosomes are the major degradative organelle in cells and are responsible for degrading macromolecules including proteins. The degradation activity of acid hydrolases within lysosomes is highest at pH 4.5. Alterations in lysosomal pH are frequently linked to lower degradative capacity and thus intrinsically to aberrant proteostasis and neurodegenerative diseases. Lysosomal membrane integrity is protected from acid hydrolases by lysosomal associated membrane proteins, the most abundant of which are LAMP1 and LAMP2. Mounting evidence suggests that LAMP proteins associate with other lysosomal membrane proteins to regulate lysosomal acidification, though the mechanisms by which this happens remain unclear. *Drosophila melanogaster Lamp1* encodes the LAMP1/2 homolog, and data from our lab suggest deletion of functional Lamp1 protein leads to an accumulation of acidic vesicles in the endo-lysosomal compartment of fat bodies (FBs; akin to liver and adipose tissue), termed excessive endo-lysosomal acidification (EELA). Intriguingly, when individual *Lamp1* mutant FB cells are induced in mosaics of an otherwise *Lamp1* heterozygous fly, EELA is not seen. This finding suggests that *Lamp1* is either required in a tissue other than FB to prevent EELA or that *Lamp1* expression in neighboring FB cells is sufficient to rescue EELA in FB cells lacking *Lamp1*. We thus have identified an unprecedented non-cell autonomous function of Lamp1 in regulation of endo-lysosomal pH. We will report on the characterization of the pH and endo-lysosomal identity of the acidic vesicles and on the identification of tissues in which *Lamp1* is required and/or sufficient to regulate endo-lysosomal pH in the FBs. To date, we have determined that expression of *Lamp1* in FBs and neurons of *Lamp1*-deficient larvae are sufficient to suppress EELA.

Our approach to address Lamp1 function will provide much needed insight into the regulation of endo-lysosomal acidification critical for proteostasis. It will therefore significantly advance our understanding of how dysfunction of the endo-lysosomal system underlies disease, ultimately leading to the development of novel treatment strategies to improve healthspan.

443T **The Role of the ER Integral Protein Jagunal in Regulating "Stemness" of Neuroblasts During Asymmetric Cell Division.** Judy Especial Abuel, Blake Riggs Biology, San Francisco State University

Cell division is a fundamental process in all living organism as it is essential in the development of all multicellular organisms. This development is accomplished through an unequal asymmetric partitioning of cellular components during cell division. However, the regulation and mechanism which allows for asymmetric cell division (ACD) to lead to a diverse generation of cells is poorly understood. A recent study shows that asymmetric partitioning of the endoplasmic reticulum (ER), an essential organelle involved in a host of cellular events, may be involved in the adoption of cell fate and cell diversity through a highly conserved ER transmembrane protein called, Jagunal (Jagn). Cell fate determination is normally controlled by cell fate determinants and transcription factors that drive the intrinsic and extrinsic signaling pathways that allow genes to be turned on and off. Our preliminary data illustrates that the presence of Jagn is crucial in maintaining cell diversity and cell fate determination. We believe that the disruption of ACD due to lack of Jagn leads to a direct consequence of changes in the fate of the two daughter cells. Previous studies showed that Jagn is involved in the proper partitioning of the ER in pro-neural cell populations and our preliminary data revealed an increase of the NB population in Jagn-deficient larval brains, suggesting that Jagn is involved in ACD and in the correct localization of cell fate determinants. To determine whether Jagn regulates proper NB development, I will examine programed NB quiescence during embryonic development in Jagn-deficient embryos to distinguish whether this event happens prior to cell fate selection. I will incorporate the thymidine analog 5-ethynyl-2-deoxyuridine (EdU) in late-stage embryos and then fix the tissue in order to observe whether Jagn-deficient embryos bypass

quiescent state and instead allow NBs to actively divide during embryonic-to-larval transition. I hypothesize that Jagn is involved in cell fate decisions during mitosis, establishing a differentiated cell population. This study will determine if an ER-specific protein has a role in cell fate selection and ACD. Furthermore, our findings will shed light on important questions related to cell specification and signaling transport during cellular organization and partitioning of cell fate determinants, polarity establishment, and regulation of the ACD.

444T **Non-canonical dFOXO regulation in Drosophila larval oenocytes under starvation** Peiduo Liu, Hua Bai Iowa State University

The Forkhead box O (FOXO) transcription factors are the key regulators of metabolic homeostasis and aging. It is well known that upon nutrient deprivation, insulin signaling decreases and FOXO is dephosphorylated and translocated into the nucleus to activate the transcription of a large number of metabolic genes, including those in lipid metabolism pathways. Unexpectedly, we find that Drosophila dFOXO protein is localized to the nucleus of larval oenocytes under normal fed conditions, while starvation reduces nucleus-localized dFOXO. The non-canonical response to starvation suggests a unique dFOXO regulation in Drosophila larval oenocytes, the specialized hepatocyte-like cells. Consistent with this notion, our genetic analysis shows that oenocyte-specific knockdown of Akt does not alter the nuclear shuttling of dFOXO under fed and starvation conditions. To further dissect the nutritional signals that regulate the non-canonical dFOXO activation in larvae oenocytes, we examine the effects of macronutrient refeeding on starvation-induced dFOXO nuclear depletion. Interestingly, refeeding of proteins, but not sugar, can attenuate the starvation-induced dFOXO nuclear depletion, which suggests that amino acid deficiency is a key underlying mechanism for non-canonical dFOXO regulation in larval oenocytes. Lastly, we screen a panel of amino acids and find that a deficiency of lysine and phenylalanine, but not branching amino acids, is required for starvation-induced dFOXO nuclear depletion. It is known that, unlike other larval tissues, Drosophila oenocytes accumulate fat upon starvation, similar to hepatic steatosis in the mammalian liver. Our findings indicate that Drosophila larval oenocytes may activate distinct metabolic programs via non-canonical dFOXO regulation to maintain metabolic homeostasis during nutrition deprivation.

445T **Rcp, a regulator of G-protein-coupled receptor signaling, controls the polarized deposition of basement membrane proteins in epithelial cells** Lindsey Price[1], Rebecca Brnot[1], Trent Davids[1], Alejandro Salas[1], Tracie Yiqing Kong[2], Trudi Schüpbach[2], Olivier Devergne[1] [1]Northern Illinois University, [2]Princeton University

Epithelia are organized in sheets of tightly adherent cells that are polarized along an apical-basal axis. Epithelial cells rely on their cellular organization for their structure and functions. The apical-basal polarity is characterized by the cytoplasmic and surface organization of individual cells in apical, basal, and lateral domains. The establishment and maintenance of these different domains rely on the transport and sorting of newly synthesized or recycled proteins to their correct locations. A key component of this organization is the basement membrane (BM), a specialized sheet within the extracellular matrix. The BM lies along the basal side of epithelial cells and is essential for the establishment and maintenance of epithelial cell structure and functions, tissue organization, and organ morphogenesis. The loss of integrity and misregulation of the BM leads to epithelial defects which can cause changes in signaling and cellular communication and has been associated with carcinomas and tumor metastasis. The BM components are produced within the epithelial cells and are secreted to the basal side through a dedicated pathway. Despite the BM's important roles in epithelial organization, the process of the secretion of BM proteins is poorly understood. To study BM protein deposition, we use the follicular epithelium (FE) of the *Drosophila* ovary as a model system. In a genetic screen looking for new genes involved in the proper placement of BM proteins, we identified a new gene, *Rcp* (Receptor component protein), which has been shown to be involved in G-protein signaling. Our data show that the loss of *Rcp* leads to an apical mislocalization of BM proteins without primarily affecting the general polarity, indicating that *Rcp* specifically controls the proper placement of BM proteins. Interestingly, *Rcp* is the first component of a signaling pathway implicated in BM polarity. In the FE, Rcp assumes cytoplasmic and nuclear localizations, this data paired with Rcp's protein structure suggests a role of Rcp in gene regulation. Finally, we also showed that Rcp genetically interacts with other known members of the pathway dedicated to the polarized deposition of BM proteins such as PIP2, and the GEF Stratum. Altogether, our data indicate a specific role for *Rcp* in epithelial organization by regulating the polarized deposition of BM proteins, a process that is critical for the establishment and maintenance of epithelial cell polarity.

446T **Characterizing the epithelial sheath as a barrier to professional phagocytes during apoptosis in the ovary** Max C Wertheimer, Alexandra Chasse, Kim McCall Biology, Boston University

In Drosophila, when cells die they are typically removed by phagocytic hemocytes. However, the ovaries inhibit hemocyte infiltration even when signals are released during cell death events. The signals released typically attract phagocytic cells to break down developing egg chambers and recycle nutrients but while hemocytes have been seen on the periphery, they do not enter the ovarioles. The epithelial sheath, which lines the surface of ovarioles, may be responsible for inhibiting hemocyte infiltration via septate junctions which control the diffusion of signals across tissues and may physically inhibit hemocytes

themselves. Eleven septate junction genes were identified as candidates and, using RNAi, knocked down to determine if they play a role in barring hemocyte entry into the epithelial sheath. The ovaries were dissected, stained and imaged with confocal microscopy to visualize any potential phenotypes. Findings show that many of the selected genes have adverse effects on fecundity and suggest the possibility of increased cell death in the ovaries. Some genes show severe phenotypes ranging from large gaps between eggs, tight bunching of the epithelial sheath, bunching of early stage eggs, and stretched stalk cells between eggs. These atypical phenotypes suggest excessive cell death, improper relaxation of the epithelial sheath, and abnormal cell signaling. Some of the knockdowns also affect hemocyte invasion into the ovariole. Discovering the gene(s) responsible for epithelial sheath permeability can be key for understanding the immune response in other immune privileged organs and potentially develop targets for therapy.

447T **Mutagenesis and characterization of the putative HAD-domain phosphatase CG11291 in *Drosophila melanogaster*** Veronica Gomes[1], Jennifer Kennell[2] [1]Vassar College, [2]Biology, Vassar College

Phosphoglycolate phosphatase (PGP) is an enzyme that plays an important role in DNA damage repair in bacterial and mammalian cells, is involved in producing glycerol in mice and worms, and breaks down toxic side-products of glycolysis in human and yeast cells. So far, PGP has only been studied in a few organisms, and very little is known about its function in Drosophila. Therefore, this study attempts to characterize the gene, *CG11291*, which is one of the predicted orthologs of *PGP* in *Drosophila melanogaster*. Studying this ortholog could tell us more about the function of the enzyme in fruit flies, and whether it has evolved to perform novel functions in this organism. *CG11291* is a small gene (~1.87kb) located on the positive strand of the second chromosome of *Drosophila melanogaster*. This gene is predicted to encode a member of the HAD-domain phosphatase family and has been found to be expressed during the larval, pupal, and adult stages of development, mostly in the testes of adults. To learn about the role of *CG11291* in the metabolism or development of *Drosophila melanogaster*, we have mutated the gene in this species. Transgenic flies were generated that expressed two guide RNAs targeting *CG11291* under the control of the UAS enhancer to induce CRISPR-Cas9-mediated mutations in *CG11291*. After conducting controlled crosses of transgenic flies, two mutant lines with unique frameshift mutations were selected to be phenotyped. Currently, the mutant lines are being tested for their sensitivities to ethylene glycol, salt, and oxidative stress, as well as fertility. Additionally, *CG11291* has been annotated in nine different species of *Drosophila* to learn more about the evolution of this gene by comparing the levels of similarity of its gene structure, protein sequence, and genomic neighborhoods between the various species.

448T **Regulation and function of GAGA factor mitotic retention in the early *Drosophila* embryo** Annemarie E Branks, Marissa Gaskill, Hope Hawthorn, Kerstin Hurd, Olivia Ward, Melissa Harrison University of Wisconsin-Madison

Development is driven by cell division and differentiation, which is controlled by gene expression. Once established, this gene-expression program must be maintained to ensure development proceeds. A major challenge to the maintenance of a robust gene-expression profile is mitosis. During mitosis, the chromatin condenses, transcription arrests, and most transcription factors dissociate into the cytoplasm. Despite these substantial disruptions, the gene expression profile is rapidly and robustly re-established in the daughter nuclei. The essential mechanisms needed to preserve cell identity across mitotic divisions are poorly understood. A subset of transcription factors remains associated with mitotic chromosomes, suggesting that these proteins may function to maintain cell fate. However, for many transcription factors the functional relevance of this mitotic retention is unclear. To better understand how developmental programs are stably propagated through the mitotic divisions, we focus on GAGA factor (GAF). GAF is required in the early *Drosophila* embryo to promote the establishment of both the active and silent genomes. Live-imaging experiments demonstrate that GAF is retained on the mitotic chromosomes, but this retention is developmentally regulated. GAF is evident at the pericentric heterochromatin during the rapid and synchronous early mitotic divisions, but at gastrulation GAF is no longer mitotically retained. Furthermore, GAF retention at euchromatin has been suggested to be instrumental in facilitating memory of the transcriptional state through mitosis. We identified protein domains important for GAF mitotic retention and individual amino acid residues that, when mutated, result in increased mitotic retention. Mutations of these serine residues result in the persistence of GAF mitotic retention into gastrulation. Our data support a model in which phosphorylation of serine residues in the DNA-binding domain weaken the affinity of GAF for chromatin and mutating these residues increases mitotic retention at both heterochromatin and euchromatin. To determine whether this increased retention of mutated GAF changes the gene-expression profile of the embryo, we made endogenous mutations in GAF and will present data on the impact of these mutations. Our studies of the essential transcription factor GAF provide insights into the functional relevance of mitotic retention in maintaining a robust gene-expression program.

449T **Monitoring fatty acid trafficking in follicles reveals a critical role for the triglyceride synthase DGAT1 in protecting mitochondrial integrity** Roger P White, Michael A Welte BIOLOGY, University of Rochester

During Drosophila oogenesis, LDs (lipid droplets) accumulate in nurse cells (NCs), but the mechanism of how lipid metabolism

contributes to follicle development is unknown as these LDs might simply provide energy reserves for the future embryo. To address this question, we treated explanted mid-stage follicles with CPT1 inhibitors to block uptake of long-chain fatty acids (FAs) into mitochondria. We monitored mitochondrial membrane potential (MMP) in NCs using the dye TMRE and found that within 30 mins levels of MMP dropped by nearly half. MMP was also reduced upon germ-line knockdown of several enzymes involved in fatty acid oxidation (FAO). These observations suggest that NC mitochondria rely to a substantial extent on FAO for energy production. Because MMP of NCs is also reduced in mutants for the triglyceride lipase ATGL, we hypothesize that the triglycerides (TAGs) in LDs are the source of FAs for FAO. To directly monitor FA trafficking, we exposed follicles to fluorescently labeled FAs (FLFAs) or fed FLFAs to flies. With *ex vivo* incubation or short-term feeding, fluorescent signal predominately appears in LDs. In mutants for the TAG synthesis enzyme DGAT1, LDs are not produced and FLFAs accumulate in mitochondria. We find that *DGAT1* mutant NC mitochondria display increased levels of mitochondrial ROS and take on a toroidal morphology often associated with oxidative stress. They also are functionally impaired as the mutant follicles display lower oxygen consumption rates and decreased ATP levels. Finally, *DGAT1* mutants arrest in stage 9 of oogenesis. We propose that in the absence of LDs unrestrained influx of FAs damages mitochondria which in turn causes developmental arrest. Indeed, when we throttle mitochondrial FA import with CPT1 inhibitors, mitochondrial ROS is reduced and some follicles advance up to stage 10B. Lipophorin receptors LpR1 and LpR2 are responsible for facilitating the uptake of exogenous lipids into follicles, and we have found that reducing their dosage in *DGAT1* mutants increases the frequency of follicles that advance to stage 10B. To specifically test the role of FA import into mitochondria, we are in the process of analyzing *CPT1 DGAT1* double mutants to see if the morphological and bioenergetic defects are rescued and if follicle progress beyond stage 9. In summary, we find that LDs in NCs are critical for pacing the import of FAs into mitochondria and to protect mitochondria from FA overload.

450T **Heat shock alters nucleolar morphology in *Drosophila* nurse cells** Anna S Ramsey, Danielle E Talbot, Tina L Tootle Biology, University of Iowa

The nucleolus is a membraneless organelle that plays a critical role in cell signaling and has many functions, including ribosome biogenesis, organizing heterochromatin, regulating the cell cycle, and activating the cellular stress response. Using *Drosophila* oogenesis, our lab found inhibition of RNA polymerase I (RNAPI) and loss of prostaglandin synthesis result in two distinct nucleolar morphologies. Nucleolar morphology is deeply connected to nucleolar function; changes in morphology indicate altered function. Therefore, we wanted to explore how other stimuli affect nucleolar morphology and focused on the effects of heat shock. In amniotes, the nucleolus contains three compartments: the fibrillar center (FC), dense fibrillar component (DFC), and granular component (GC). It is currently unclear how many nucleolar compartments are present in *Drosophila* nurse cells. To explore this question, we used GFP-tagged protein lines to assess the localization of various nucleolar proteins and to determine how heat shock alters their localization in Stage 10 follicles. We find Fibrillarin (present in the DFC in amniotes) goes from smooth localization throughout the nucleolus to a speckled pattern with heat shock. The extent of the Fibrillarin speckling is time dependent, with longer heat shocks resulting in more penetrant speckling. Similarly, Nopp140 (present in the DFC in amniotes) exhibits speckled staining in heat shocked follicles. Whereas Modulo (present in the DFC and the GC in amniotes) and Nucleostemin1 (present in the GC in amniotes) also localize throughout the nucleolus but exhibit holes inside the nucleolus. These holes decrease in size in heat shocked follicles. These data suggest the presence of two distinct compartments in *Drosophila* nurse cell nucleoli. Understanding the general organization of the *Drosophila* nurse cell nucleoli and the effects of different stimuli, like heat shock, can provide greater insight into the mechanisms of how cells cope with short term environmental stressors compared to chronic stress states associated with diseases such as cancer.

451T **Determining the roles of prostaglandins in regulating nuclear architecture during collective cell migration** Ashley Goll, Tina Tootle Biology, University of Iowa

Cell migration is required for many biological processes including development, wound healing, and cancer. During migration, the cytoskeleton and nucleoskeleton undergo rearrangements. The nucleus is the largest organelle within the cell and can be the limiting factor in the cells' ability to migrate through space restrictive areas. Information about the external environment is relayed through the cytoskeleton to the nucleus and drives alterations to the nucleoskeletal composition. Altering the composition of the nucleoskeleton regulates the stiffness of the nucleus. When there is more Lamin A and Emerin the nucleus is stiffer, while when there is more Lamin B the nucleus is softer. Little is known on how the nucleoskeleton behaves during 3D collective cell migration. To address this, we use Drosophila border cell migration as a model to observe *in vivo*, 3D collective cell migration. We find that Lamin A is present within only the polar cells while Lamin B is in both the polar cells and border cells throughout migration. Emerin behaves dynamically as it is prevalent in the polar cells and border cells at the beginning of migration but becomes restricted to the polar cells by mid-migration. We next asked if the dynamic behavior of the nucleoskeleton during collective cell migration is regulated by prostaglandins (PGs). PGs are short range lipid signaling molecules that are required for on-time border cell migration. We find that loss of PGs increases Lamin A and Emerin prevalence in the border cells throughout migration, which suggest that the nuclei are stiffer and may contribute

to the migration delays. Supporting this idea, overexpression of Lamin A in the border cells results in delayed migration. These findings imply that nuclear stiffness is a limiting factor in border cell migration. Together these results suggest that the transmission of mechanical signaling from the external environment through the cytoskeleton to the nucleoskeleton is regulated by PG signaling and is necessary for 3D collective cell migration.

452T **New models to investigate Transportin-2 (TNPO2) function in Drosophila and neurodevelopmental disease** Lindsey D Goodman[1], Ziyaneh Ghaderpour Taleghani[2], Hugo Bellen[2] [1]Human Molecular Genetics, Baylor College of Medicine, [2]Baylor College of Medicine

We previously showed that de novo mutations in the nuclear-cytoplasmic shuttling protein transportin-2 (TNPO2) are associated with a rare disease involving global developmental delays and neurological features (Goodman et al. AJHG, 2019). Over 25 cases of TNPO2-associated disease have now been identified worldwide. We previously found that this gene is dosage sensitive – too much or too little expression of the fly orthologue of TNPO2, tnpo, causes developmental toxicity in multiple tissues. Furthermore, overexpressing human TNPO2 is mildly toxic and patient-associated mutations alter this toxicity – some mutations are less toxic than the human reference, indicating they are loss-of-function (LOF), whereas some mutations are more toxic, indicating they are gain-of-function (GOF). This previous work relied on overexpression of TNPO2 and provided little mechanistic insight into how mutations cause disease. Here, we are taking several approaches to further our understanding of this disorder using established and novel fly models. First, we developed a novel protein degradation assay using da-GAL4[geneswitch] (daGS) which shows that a mutant TNPO2:p.D156N reduces TNPO2 protein stability in vivo. Despite TNPO2:p.D156N protein being rapidly degraded, we found that it causes strong motor defects and a bang-sensitive phenotype when ubiquitously expressed in adult flies using daGS to avoid developmental toxicity. This is consistent with our previous work indicating that TNPO2:p.D156N is a strong GOF mutation. To investigate TNPO2-mutations in a more endogenous setting, we are now developing a humanized fly model for TNPO2-disease using novel 1xUAS-TNPO2 fly lines that carry only 1 upstream activation sequence (UAS). This system dramatically reduces the amount of protein produced from the UAS-transgene and successfully avoids toxicity caused by overexpressing human TNPO2. We are now assessing if this lower expression of TNPO2 is sufficient to rescue developmental lethality in transheterozygous tnpo CRIMIC/tnpo[Δ11] mutant flies; the CRIMIC cassette express the GAL4 transcription factor that activates 1xUAS-TNPO2. To further probe the mechanism associated with TNPO2 mutations, we are also developing a GFP-based reporter system which will be used to measure TNPO2-cargo shuttling from the cytoplasm into the nucleus in flies and cultured cells. These new models will be used to investigate novel de novo variants in TNPO2 and to expand our understanding of this rare disease.

453T **Characterization of the regulatory roles of phosphatases in endosomal Microautophagy** Laury Lescat[1], Andreas Jenny[1,2] [1]Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, [2]Department of Genetics, Albert Einstein College of Medicine

Autophagy, the lysosomal degradation of cytoplasmic proteins, organelles, and pathogens, is a major catabolic pathway conserved during evolution. Autophagy is a constitutive or adaptive process essential for the maintenance of cellular homeostasis and for the response to cellular stress such nutritional, energetic, genotoxic and oxidative stress. Three major autophagic pathways have been described in vertebrates: Macroautophagy (MA), Chaperone-Mediated Autophagy (CMA) and endosomal Microautophagy (eMI). During eMI, proteins in bulk or KFERQ-containing proteins dock at the endosomal membrane to be subsequently internalized into multivesicular bodies in an ESCRT (endosomal sorting complexes required for transport) dependent process. eMI has only recently been identified and its regulation and physiological role are not well understood. Our lab has identified eMI in *Drosophila melanogaster*, using a biosensor containing a KFERQ motif fused to a photoactivable (PA) mCherry. Briefly, the eMI sensor is expressed in a tissue specific manner using the UAS-Gal4 system to monitor eMI activity in pulse chase types of experiments under different stress conditions. MA and CMA are known to be regulated by a series of kinases and phosphates. Thus, we hypothesized that, analogous to MA, and CMA, eMI is regulated by kinases and phosphatases. Through a primary extensive RNAi screening (600 kinases and phosphatases), we have identified 67 potential candidate eMI regulators that we continue to analyze with a particular focus on 5'-nucleotidase (NT5), Inositol polyphosphate 4 phosphatase (INPP4A/B), and inositol polyphosphate-5-phosphatase (OCRL). All of these kinases are known to have a direct or indirect role in the regulation of macroautophagy and the endolysosomal system through PI3K, AMPK-Tor and GSK3signaling pathway. Using nutrient, oxidative, and genotoxic stress, we are investigating their regulatory roles in the regulation of eMI.

454T **Identification and functional analysis of substrates & regulators of starvation-induced endosomal microautophagy in *Drosophila*** Prasoon Jaya, Simone Sidoli, Andreas Jenny Albert Einstein College of Medicine

Autophagy is an evolutionarily conserved cellular stress response that degrades a wide variety of substrates in lysosomes, including oxidized and aggregated proteins, organelles, and intracellular pathogens, and is thus required for cellular

homeostasis and function. Autophagy dysfunction has been linked to a number of diseases, including HIV, cancer, metabolic disorders, liver diseases, and neurodegenerative diseases. To date, three autophagic pathways have been identified: macroautophagy (MA), chaperone-mediated autophagy (CMA), and endosomal microautophagy (eMI). The latter was discovered relatively recently, and its regulation and physiological role are still poorly understood. During eMI, substrates are engulfed into late endosomes either in bulk or selectively for proteins with a targeting KFERQ motif in a process requiring the Endosomal Sorting Complex Required for Transport (ESCRT) machinery. Our laboratory recently discovered that specific types of cellular stress, such as prolonged starvation and oxidative stress, but not ER stress, induce eMI in Drosophila, implying that eMI is required for proper cellular homeostasis. The *in vivo* eMI substrates and cellular processes regulated by eMI, however, are still unknown. To better understand the molecular basis for regulation and the physiological relevance of this pathway in Drosophila, I am using proteomics and transcriptomics to identify endogenous eMI substrates and biological pathways regulated by eMI. To accomplish this, I have used label-free quantitative proteomics to compare changes in the fat body proteome of starved larvae over different time periods (0h, 4h, and 25h), under different (genetically altered) conditions with fed larvae as a control. Additionally, I have used RNA-seq to examine how changes in gene expression correspond to variations in the protein content of the larval fat bodies over time. Our analysis has identified several proteins as potential eMI substrates. Further research will provide a new perspective regarding eMI regulation on the pathogenesis of various diseases.

455T **Talking about Bruno: revealing the code for protein trafficking into nuclear domains** Travis Main, Anton Bryantsev Kennesaw State University

Nuclear domains are membraneless organelles found in the nuclei of eukaryotic cells. The B-body is a nuclear domain that accumulates the protein Bruno (Bru) in developing Drosophila flight muscles. We used the B-body and Bru as a model to study formation of nuclear domains. Specifically, we sought to identify protein sequences that regulate Bru accumulation in B-bodies. We generated various Bru mutants, which were subsequently tested in flies by immunostaining and fluorescence microscopy. We determined that all three RNA-recognition motifs (RRMs) of the Bru protein must be intact to allow interaction with hsr-omega, a scaffolding lncRNA residing in the B-body. In addition, two intrinsically disordered regions (IDR 1&2) drive Bru into protein aggregates. Using the truncation analysis, we identified a 32-aa region within IDR1 that regulates Bru solubility. We proposed that phosphorylation controls Bru solubility, and in a subsequent RNAi screen we identified Doa kinase as a factor controlling Bru affinity toward B-bodies. In summary, protein accumulation at the B-body depends on a combination of RRM and IDR protein domains. RRMs determine accumulation specificity, while IDRs stimulate phase separation and determine Bru's affinity to B-body. Phosphorylation serves as the means to regulate Bru accumulation in B-bodies via IDR modification. Our study provides a detailed mechanistic insight into the formation of nuclear domains.

456T **Unscheduled endocycles disrupt ovarian structure and function and impair female fertility.** Hunter C Herriage, Brian R Calvi Biology, Indiana University Bloomington

Endocycling cells grow and repeatedly duplicate their genome without dividing. Cells switch from mitotic cycles to endocycles in response to developmental signals during the growth of specific tissues in a wide range of organisms. However, the purpose of a developmental switch to polyploid endocycles remains unclear in many tissues. Additionally, there is an increasing appreciation that cells can switch to endocycles in response to conditional signals, such as in wound healing, aging, or cancer, giving rise to a diversity of beneficial or pathological effects. Overall, however, the impact of these unscheduled endocycles on development is underexplored. To address this knowledge gap, I am using *Drosophila* ovarian somatic follicle cells as a model to examine the impact of unscheduled endocycles on tissue growth and function. Follicle cells normally switch to endocycles at mid-oogenesis. I have found that induction of premature endocycling can have drastic consequences for ovarian function and female fertility. Starting endocycles too early disrupted the later endocycle arrest and transition to developmental amplification of eggshell genes in later oogenesis. These females laid eggs with thin shells and resulted in significant embryonic lethality. Further examination of these ovaries revealed an array of pleiotropic defects, including reduced oocyte growth and aberrant follicular epithelial structure. Finally, premature endocycling inhibited the collective cell migration of a special set of follicle cells known as border cells in mid-oogenesis. As border cells are a powerful model for the collective cell migration observed in human metastases, my last result challenges current models that polyploidy enhances migration and metastasis of human cancer cells. Overall, these findings have broader impact by revealing how unscheduled endocycles can disrupt tissue growth and function to cause aberrant development.

457T **Regulation of Spermatogenesis by Notch Signaling** Emma OFlaherty, Jennifer Jemc, Christine Severude, Adriana Soriano Loyola University Chicago

Notch signaling is an evolutionarily conserved pathway that is crucial in fate acquisition and spatiotemporal patterning. The Notch signaling pathway plays a significant role in gonad development and spermatogenesis in the male gonad, but little is known about the specific targets of Notch signaling in the testis. The Drosophila testis contain two populations of stem cells: germline stem cells (GSCs), which produce maturing sperm and cyst stem cells (CySCs), which produce somatic support

cells known as somatic cyst cells. The CySCs and early somatic cyst cells that surround the spermatogonia express traffic Jam (tj), which encodes a MAF family transcription factor. They continue to express Tj in the somatic cyst cells surrounding the spermatogonia through the transition zone, as they begin to express Eya and shift to a late cyst cell fate. Notch signaling is active in the transition zone during this time and is activated by the Delta ligand expressed in the germline. Previous work in our lab data has shown that increased Notch signaling in somatic cyst cells appears to prevent their transition from early to late cyst cell fate, suggesting that Notch signaling is important for this transition and must be downregulated to progress through development. As little is known about the downstream effectors through which Notch signaling functions to promote cyst cell development, RNA sequencing was performed to identify potential targets of Notch. This approach led to the identification of 1619 potential Notch target genes. Further data analysis was conducted using previously published single-cell RNA sequencing data and gene ontology analysis to narrow down this list to 66 genes. We are now testing these potential targets in control, Notch overexpression, and Notch mutant flies using immunohistochemistry, in-situ hybridization and quantitative PCR to build a genetic network for the Notch signaling pathway and expand our understanding of its role in spermatogenesis.

458T **Xport-A functions as a chaperone by stabilizing the first five transmembrane domains of rhodopsin-1** Pedro Domingos ITQB-UNL, NIF 501559094 Rhodopsin-1 (Rh1), the main photo-sensitive protein of Drosophila, is a seven-transmembrane domain protein, which is inserted co-translationally in the endoplasmic reticulum (ER) membrane. Biogenesis of Rh1 occurs in the ER, where various chaperones interact with Rh1 to aid in its folding and subsequent transport from the ER to the rhabdomere, the light-sensing organelle of the photoreceptors. Xport-A has been proposed as a chaperone/transport factor for Rh1, but the exact molecular mechanism for Xport-A activity upon Rh1 is unknown. Here, we propose a model where Xport-A functions as a chaperone during the biogenesis of Rh1 in the ER by stabilizing the first five transmembrane domains (TMDs) of Rh1.

459T **Fine-tuning of Cell-ECM Assembly by Transglutaminase** Dylan Feist[1], Nicole Green[2], Erika Geisbrecht[1] [1]Biochemistry and Molecular Biophysics, Kansas State University, [2]Biology, Cornell College

The *Drosophila melanogaster* myotendinous junction (MTJ) is a unique model to understand how secretion and assembly of the extracellular matrix (ECM) contributes to cell adhesion during development and growth. MTJ formation requires myotube targeting to the appropriate tendon cell followed by the secretion and binding of ECM proteins to transmembrane integrin heterodimers on opposing muscle and tendon cells. This stable network not only links the ECM to the internal actin cytoskeleton, but also transmits tension between muscles and tendons to withstand contractile forces. Thus, knowledge of the molecular composition of the MTJ throughout development is essential to understand how forces vary at the muscle-tendon interface. We performed a targeted RNA interference (RNAi) screen to uncover secreted proteins that are required for cell-matrix adhesion in the contractile muscles of third instar larvae (L3). One candidate that emerged is Transglutaminase (Tg), a protein with known scaffold and crosslinking activity. Therefore, our hypothesis that the crosslinking function of Tg is important for maintaining extracellular adhesion and ECM integrity is exciting and may change current dogma suggesting that integrins are the primary mediator for MTJ stability. RNAi knockdown of Tg in the embryonic tendon cells resulted in smaller muscle attachment sites and occasionally led to fully detached muscles by the L3 stage. Preliminary studies indicate that Tg activity is required as an antibody generated against the epsilon-(gamma-glutamyl)lysine-isopeptide bond can be visualized at muscle attachment sites. Current and future experiments will focus on examining Tg mutants and further characterizing if the crosslinking role of Tg is essential through expression of a catalytically inactive Tg.

460T **Defining the contribution of the dendritic cytoskeleton to critical period closure** Dunham Clark[1], Sarah D Ackerman[2] [1]Cell & Developmental Biology, Washington University in St. Louis, [2]Pathology and Immunology, Washington University in Saint Louis

Neural networks undergo critical periods of heightened plasticity in development, during which neurons undergo structural and functional changes that directly affect the long-term activity of neural circuits. Disruptions in the timing of the critical periods in humans have been linked to a number of neurodevelopmental disorders, including autism and epilepsy. We have identified that *Drosophila* exhibit a motor circuit critical period that peaks in embryonic during development, during which motor neurons undergo activity-driven morphological changes in their dendrites and synapses. Motor plasticity is maximal during late embryogenesis, and is terminated by 8 hours after larval hatching (h ALH). Our previous work demonstrated that as the critical period comes to a close, and as neuronal plasticity wanes, the microtubules stabilize within the dendrites of *Drosophila* motor neurons. This research aims to characterize cytoskeletal dynamics across this critical period, and to test whether microtubule stabilization is necessary and/or sufficient for critical period closure. We are performing optogenetic activation of *Drosophila* motor neurons at 4 h ALH, midway through the critical period, combined with motor neuron-specific manipulation of genes that drive microtubule stabilization (ringmaker, no distributive disjunction, α-tubulin acetylase, and Kinesin-like protein at 10A) or destabilization (spastin, Fidgetin, Katanin 60, and leaky) to address this hypothesis. We expect

that, if microtubule stabilization is required for proper critical period closure, then motor neuron-specific knockdown of microtubule stabilizing genes will extend critical period plasticity at 8 h ALH; conversely, we expect knockdown of microtubule destabilizers to prematurely close the critical period, but have no effect on plasticity beyond 8 h ALH. Overall, this research utilizes a novel critical period model to discern the role of the cytoskeleton in neurodevelopment.

461T **Role of RRP1B in Regulating Cellular Stress Response in Triple-Negative Breast Cancer Metastasis** Wan-Ning Li, Kent Hunter Center for Cancer Research, National Cancer Institute

Triple-negative breast cancer (TNBC) is an aggressive subtype of breast cancer that remains a clinical challenge due to the lack of good therapeutic targets. Characterized by quickly growing tumors, high rates of metastasis, and unresponsiveness to therapies, patients diagnosed with TNBC are commonly associated with poor clinical outcomes and high recurrence rates. Evidence has shown that stress in the tumor microenvironment plays a critical role in malignant tumor progression by altering the genomic actions and the cellular responses in cancer cells. However, the molecular mechanism of stress-induced breast cancer metastasis remains unclarified. Here, we have observed that Ribosomal RNA Processing 1B (RRP1B), a breast cancer metastasis susceptibility gene our lab has previously identified, showed a subnuclear protein translocation from nucleolar to nuclear speckles under heat shock stress, implicating RRP1B participates in the stress-induced response in TNBC. To elucidate the mechanism of RRP1B protein trafficking, we first focused on determining the functional protein domains by bioinformatics prediction. Both tools, InterPro and MobiDB, revealed that intrinsically disordered regions (IDRs), peptides that are characterized by a high proportion of hydrophilic amino acids and low sequence complexity that make them unable to form a well-defined structure spontaneously, cover over 60% of RRP1B protein that suggests a potential role of IDRs in protein characteristics. We therefore generated a deletion construct that could express IDR-truncated RRP1B protein in TNBC cells, and the results showed deletion of IDRs leads to an exclusive expression of RRP1B outside the nucleoli, indicating that IDR is involved in the RRP1B subnuclear trafficking. To further investigate the role of RRP1B in the stress-induced processes in TNBC, we performed RRP1B-immunoprecipitation mass spectrometry analysis in MDA-MB-231 cells. Both Ingenuity Pathway Analysis and Metascape analysis revealed the 136 proteins that are shown to have increased binding with RRP1B under stress condition are strongly associated with spliceosomal cycle. Our future studies will focus on elucidating the molecular mechanism involved in the stress-induced action of RRP1B through further characterizing the nature of RRP1B re-localization and studying the role of RRP1B in splicing process that promotes cancer metastasis in TNBC.

462T **Regulation of Cdc42 Protein Levels Impacts a Cell Differentiation Program** Beatriz González, Paul Cullen Biological Sciences, State University of New York at Buffalo

The orientation of an axis of polarity is a critical feature of all organisms. Cells can reorganize their polarity during the cell cycle and in response to extracellular cues. One type of polarity regulatory protein are Rho GTPases. Rho GTPases interact with proteins that control the cytoskeleton and signaling pathways, yet how they function in specific settings remains in many cases unclear. Our work centers around the ubiquitous Rho GTPase Cdc42p, which regulates signaling through evolutionarily conserved Mitogen-Activated Protein Kinase (MAPK) pathways. In the budding yeast *Saccharomyces cerevisiae*, Cdc42p regulates MAPK pathways that govern morphogenetic changes in response to external signals. We recently discovered that Cdc42p is modified by ubiquitin. The active conformation of the protein was preferentially ubiquitinated by the ubiquitin ligase Rsp5p and by heat shock protein (HSP) chaperones for degradation in the 26S proteasome. A GTP-locked (Q61L) and turnover-defective (TD) version of Cdc42p, $Cdc42p^{Q61L+TD}$, hyperactivated the MAPK pathway that regulates filamentous growth (fMAPK). Unexpectedly, $Cdc42p^{Q61L+TD}$ did not impact the activity of another MAPK pathway that shares components with the fMAPK pathway but induces a different response (mating). An SMG-GDS-type adaptor protein for the fMAPK pathway, Bem4p, stabilized the Cdc42p protein, resulting in sustained fMAPK pathway activity. We also identified a residue on Cdc42p (K16) that was required for protein stability. Altering Cdc42p stability led to protein misfolding and the formation of cytosolic aggregates. We also discovered that the main Cdc42p effector in the MAPK pathway, the p21-Activated Kinase (PAK) Ste20p, was degraded by the 26S proteosome. The regulated turnover of Rho GTPases and PAK kinases may broadly impact signaling pathways that execute specific developmental programs.

463T **Understanding the Heterogeneity in Gene Regulatory Responses to Misfolded Protein Toxicity** Rachel Eder, Leandra Brettner, Kerry Geiler-Samerotte Arizona State University

Protein misfolding is a problem faced by all organisms, but the reasons behind misfolded protein toxicity are largely unknown. Pinpointing one exact mechanism is difficult as the effects of misfolded proteins can be widespread and variable between cells. To better understand the impact of misfolded proteins, here we explore their consequences including how they might affect cells heterogeneously. In order to look for cell subpopulations, we built and optimized a cutting-edge single-cell RNA sequencing platform (scRNAseq) for yeast. By using scRNAseq, we can study the expression variability of many genes (i.e., how the transcriptomes of single cells differ from one another). To induce misfolding and study how single cells deal with this

stress, we use engineered strains with an orthogonal protein with varying degrees of misfolding. When we computationally cluster these cells by their sequenced transcriptomes, we see more cells with the severely misfolded protein in subpopulations undergoing canonical stress responses. For example, we see these cells tend to overexpress chaperones and upregulate respiration. Both of these are hallmarks of the "Generalized" or "Environmental Stress Response" (ESR) in yeast. Interestingly, we do not see all components of the ESR upregulated in all cells, which may suggest that the massive transcriptional changes characteristic of the ESR are an artifact of having defined the ESR in bulk studies. Instead, we see some cells activate chaperones, while others activate respiration in response to stress. In sum, by using our novel single-cell approach, we have gleaned new insights about how cells respond to stress, which can help us better understand diseased cells. These results may also teach how cells contend with mutation, which commonly causes protein misfolding and is the raw material of evolution. These results are the first to explore single-cell transcriptional responses to protein misfolding, and suggest that the toxicity from misfolded proteins may not affect all cells' transcriptomes uniformly.

464T **Functional Regulation of a SUMO E3 ligase during the SUMO Stress Response** Mariana VanPelt, Cate Jones, Oliver Kerscher Biology, The College of William & Mary

The SUMO Stress Response (SSR) is conserved from yeast to humans and involves a rapid accumulation of SUMO conjugates throughout the cell. Experimental evidence suggests that this stress-induced sumoylation program maintains integrity of protein complexes and the solubility of denatured proteins prior to degradation. Siz1 and Siz2, conserved SIZ/PIAS-type SUMO E3 ligases in budding yeast, play a central role in the SSR. Double mutants of siz1Δ siz2Δ completely fail to mount a SRR and display a slow growth phenotype. However, Siz1 is the only SUMO E3 ligase with both nuclear and cytoplasmic substrates. In mitosis, Siz1 becomes sumoylated and phosphorylated by an unknown kinase and is transported across the nuclear envelope via the karyopherin Msn5. We previously showed that Siz1 is ubiquitinated and degraded in an Slx5-dependent manner when its nuclear egress is prevented in mitosis. Here we address the question of how Siz1 levels and modification are controlled in the cytosol. Since PIAS1, an orthologue of Siz1 in mammalian cells, is phosphorylated by casein kinase 2, we used a yeast casein kinase (yck) mutant to analyze steady state levels of Siz1 and sumoylated proteins in response to proteotoxic stressors such as heat and oxidizing agents. Additionally, we are presenting work on ubiquitin ligases involved in cytosolic protein quality control after heat shock, such as Rsp5, that may also be involved in Siz1 regulation. In summary, our findings may aid in delineating a regulatory network for Siz1 in the cytosolic SSR.

465T **Visualizing and Quantitating Stress-Induced Cytosolic Sumoylation** Bryant Humphries, Lily Torrans, Dilynne Hsu, Oliver Kerscher Biology, The College of William & Mary

SUMO, a small ubiquitin-like modifier protein, modulates protein function to regulate essential cellular processes, including the response to stress. In yeast and mammalian cells, exposure to stressors such as elevated temperatures or oxidizing agents initiates a wave of sumoylation that propagates throughout the nucleus and cytosol. This SUMO Stress Response (SSR) has been reported to protect protein complex integrity, prevent protein aggregation, and enhance stress-specific transcriptional responses. However, the choreography and functional targets of this stress-induced sumoylation in the cytosol are not well understood. To further understand and quantitate aspects of stress-induced cytosolic sumoylation in yeast cells, we employed a split-GFP approach. Fragments of the green-fluorescent protein are fused to SUMO-targeted proteins (GFP1-10) or anchored to the mitochondrial surface (GFP11). When these tagged proteins interact on the mitochondrial surface they reconstitute a full GFP protein and fluoresce. Our preliminary data show that there is a statistically significant increase in mitochondrial fluorescence after heat stress when Apj1 (a conserved Hsp40 chaperone) is fused to GFP1-10. In contrast, when we fused a Cdc48-interacting protein, Ubx4, to GFP1-10, we observed heat-stress induced changes of mitochondrial morphology. Additional experiments demonstrate that these stress-induced phenotypes are sumoylation dependent. Deletion of the Siz1/PIAS SUMO E3 ligase decreases fluorescence in cells with the Apj1 and Ubx 4 GFP 1-10 constructs. In summary, these data are consistent with an increase in stress-induced sumoylation on the mitochondrial surface. Refining this assay may hold great utility for the study of SUMO-dependent stress-induced protein interactions in the cytosol and the study of genetic pathways that control them.

466T **Investigating the function of Tvp18 and its role in AP-1 mediated intra-Golgi recycling** Jade Bowerman, Richa Sardana Molecular Medicine, Cornell University

The Golgi consists of cisternal compartments that mature and eventually disperse into vesicles at the *trans*-Golgi network (TGN). While many secretory proteins are modified in the Golgi and leave with these vesicles to their final destinations in the cell, the Golgi's resident proteins must be recycled via retrograde vesicular transport to maintain their proper functional location within the Golgi. Because many resident Golgi proteins are modifying enzymes, such as glycosyltransferases, that act on secretory proteins, disruption of this recycling process can have widespread implications for the health of the cell. Although the importance of cytosolic coats in intra-Golgi recycling is well known, much about how they facilitate recycling is yet to be

discovered, including the role of accessory factors that associate with coat proteins. The highly conserved heterotetrameric clathrin adaptor complex AP-1 acts as one of these coats and facilitates recycling of Golgi residents from the TGN to medial-Golgi. AP-1 can exist as two sub-complexes in *S. cerevisiae* (annotated as AP-1C and AP-1R) depending on the incorporation of an alternative isoform of one of the four subunits. Based on mutually exclusive drug sensitivity phenotypes, AP-1C and AP-1R sub-complexes recycle different subsets of Golgi residents. In an effort to understand the distinct function of the AP-1 sub-complexes we compared genetic interaction profiles to find genes that cluster with only one of the sub-complexes, and found that yeast mutants lacking Tvp18, an uncharacterized but conserved membrane protein, highly correlate with subunits of the AP-1R sub-complex of AP-1. In the work presented here, we use genetic interaction analysis, live-cell fluorescence microscopy and biochemical approaches to further characterize the relationship between Tvp18 and AP-1R function. Our preliminary results indicate that Tvp18 likely acts as a transmembrane regulator of AP-1R function. Overall, these findings are important to understand the regulation and distinct functions of AP-1 sub-complexes in intra-Golgi recycling. Furthermore, while only two alternative sub-complexes of AP-1 exist in yeast, humans are expected to express up to 12 distinct sub-complexes due to alternative isoforms of multiple AP-1 subunits. Our findings will elucidate the differential functions of alternate AP-1 sub-complexes and shed light on the conservation of function of Tvp18, and its mammalian homologue Cacfd1.

467T **Humanization of five proteasome assembly chaperones in *Saccharomyces cerevisiae* suggest orthogonal interactions governing proteasome assembly** Homin Jeong[1], Mudabir Abdullah[1,2], Aashiq Kachroo[1] [1]Center for Applied Synthetic Biology, Department of Biology, Concordia University, [2]National Human Genome Research Institute

Proteasome, comprising 19S regulatory particle (RP) and 20S core particle (CP), maintains proteostasis by degrading aging and unwanted proteins to prevent the lethal accumulation of misfolded protein aggregates. 20S CP is responsible for catalyzing substrate cleavage and consists of two outer and two inner rings of 7 distinct α and β subunits.

Complete humanization of yeast proteasome can provide a cost- and time-effective platform for studying mechanisms and diseases associated with human proteasome. While all seven yeast α and 2 of 7 β subunits are humanizable individually, we observe specific pair-wise restrictions, partly resolved by co-humanization of the neighboring interactions. In humans, dimeric complexes PAC1-PAC2 (yeast's Pba1- Pba2) and PAC3-PAC4 (yeast's Pba3-Pba4) assist α-ring assembly while POMP (yeast's Ump1) coordinate subsequent β-ring assembly. We hypothesize that CP subunits collectively generate a larger interface for accessory protein interactions. These distinct orthogonal or diverged interactions may facilitate optimal assembly or sub-cellular localization of the human proteasome. Significant upregulation of yeast assembly chaperones in a partially humanized αCP indicates suboptimal assembly as a likely reason for incompatibility. We seek to fully humanize yeast CP and explore if the co-expression of assembly chaperones is critical.

I used centromeric plasmids to express single and combinations of five human CP proteasome assembly chaperones into yeast. Their expression was insufficient for the phenotypic rescue of partially humanized CP strains. However, co-expression of 5-gene human 20S core assembly chaperones, confirmed via MS, showed synthetic negative interactions only with human α5 and β2 subunits, suggesting interaction prompting further investigation. We hypothesize that the growth inhibition likely occurs from human subunits in hybrid human-yeast CP failing to recruit yeast subunits, resulting in defective proteasome assembly.

In non-quiescent cells, the proteasome serves as a crucial regulator in controlling proteins associated with cell division and DNA repair, by dynamically shuttling between the cytosol and nucleus - process yet to be comprehensively explored. Follow-up studies will investigate if the humanization of the yeast CP affects subcellular localization of the proteasome and identify accessory factors that restore defective localization/assembly of the humanized proteasome in yeast.

468T **Assembly of Polarity Complexes in *Saccharomyces cerevisiae* Spores** Benjamin Cooperman[1], Michael McMurray[2] [1]University of Colorado Anschutz Medical Center, [2]University of Colorado Anschutz Medical Campus

The ability to break symmetry and polarize is vital in ensuring the viability and proper function of many types of cells. As such, the molecular machinery responsible for polarization is heavily conserved between Eukaryotes. This has led to use of the budding yeast *Saccharomyces cerevisiae* as a model system for studying the underlying mechanisms, often in the context of bud site selection and budding itself. In mitotically dividing (vegetative) yeast cells, bud site selection both requires and directs the placement of stable landmark proteins which mark the site of future buds. The Ras-family GTPase Rsr1 module is thought to link these landmark proteins to the cytoplasmic polarity machinery, recruiting downstream effectors to the marked bud site. Unlike vegetative cell division, sporulation does not utilize the budding process, instead relying on meiotic events to generate four *de novo* spores inside of a parent diploid cell. We have shown that that although spores are not formed by budding, the distal pole landmark Bud8 is indeed placed in the spore membrane to direct future buds.

Other than Bud8, we have shown that several other proteins are placed at the polarity spot of mature spores including the septin Cdc10 and Bud5, a GEF for the Rsr1 GTPase module. Interestingly, we found that the Rsr1 GTPase module is not

required to utilize the polarity site as a future bud site upon germination, suggesting a role for Bud8 as a default bud site. In order to understand how the polarity site is built, we used confocal microscopy to interrogate the spatiotemporal dynamics of its assembly. We found that the polarity site is assembled shortly after closure of the prospore membrane. Components of the exocyst as well as the motor protein Myo2 arrive at the polarity site shortly before Bud8 and Bud5, indicating their involvement in the assembly process. Preliminary data suggests that these proteins travel along the cortex of the prospore membrane via actin cables. As Bud8 is an integral membrane protein, we propose that it is first embedded in the membrane of secretory vesicles which are trafficked to the polarity site by Myo2. Once these vesicles reach the polarity site, they can then dock and fuse at a site above the spindle pole body. Although more work must be done to verify and improve our understanding of this process, it is our hope that understanding how spore are able polarize will prove many insights into the systems Eukaryotes have evolved to break symmetry.

469F **UV-vis spectroscopic analysis of four *C. elegans* globin proteins** Anne McAllister, Katherine M. Walstrom Div. Natural Sciences, New College of Florida

Globins are a protein superfamily found throughout many different organisms that are most commonly known as oxygen binding proteins, such as hemoglobin and myoglobin. Globin proteins in *C. elegans* were discovered over a decade ago, but only a few of these 33 globin proteins have been characterized. Three globin proteins, GLB-1, GLB-6, and GLB-26, have been characterized with UV-vis, Raman spectroscopy and x-ray crystallography (Geuens, E. et al., 2010; Yoon, J. et al., 2010). In order to contribute to the limited body of knowledge about *C. elegans* globin proteins, we examined the heme absorbance and oxygen binding capabilities of GLB-10, GLB-21, and GLB-31 under oxygenated and deoxygenated conditions using UV-vis spectroscopy and GLB-1 as a control. Each protein was overexpressed in *E. coli* and purified. Under oxygenated conditions, GLB-1 showed the expected spectrum with a Soret band at 414 nm, and Q bands at 543 nm and at 578 nm. GLB-31 also exhibited these peaks at slightly different wavelengths, with a Soret band at 418 nm and Q bands at 540 nm and 570 nm. Characterizations of GLB-10 and GLB-21 are still ongoing.

Geuens, E., *et al.* BMC Biochem **11**, 17 (2010). https://doi.org/10.1186/1471-2091-11-17.

Yoon, J. *et al.* Biochemistry 49, 5662 (2010) https://doi.org/10.1021/bi100710a.

470F **Co-clustering of nuclear pores and P granules depends on the nucleoporin Nup214 and is not essential in the *C. elegans* germline** Laura L Thomas[1], Geraldine Seydoux[2] [1]Molecular Biology and Genetics, HHMI / Johns Hopkins University School of Medicine, [2]HHMI / Johns Hopkins University School of Medicine

P granules are germline-specific condensates that enrich small RNA pathway components, including Argonautes. In the pachytene region of the *C. elegans* germline, P granules are perinuclear and overlay clusters of nuclear pores (Sheth *et al*, 2010, Development). This “nuage” organization has been proposed to facilitate surveillance of nascent germline transcripts by the small RNA machinery in P granules.

P granule attachment to nuclei depends in part of the P granule protein MIP-1 (Cipriani *et al*, 2021, eLife; Price *et al*, 2021, eLife). Here we report that the non-essential nucleoporin Nup214 also contributes to this organization. In *nup214* mutants, nuclear pores distribute more uniformly across the nuclear envelope, as typically seen in somatic nuclei, and no longer co-cluster with P granules, which accumulate in the cytoplasm away from nuclei. *nup214*;*mip-1* double mutants exhibit an even more severe phenotype with uniformly distributed nuclear pores and few P granules remaining on most pachytene nuclei, suggesting that co-clustering of P granules and nuclear pores is interdependent.

Remarkably, *nup214*;*mip-1* hermaphrodites are fertile at temperatures up to 25ºC and only exhibit sterility and increased germ cell death at 26ºC. These observations suggest that coverage of nuclear pores by P granules is not essential for mRNA surveillance but protects against apoptosis under stress conditions. We will report on our ongoing investigations of how the apoptotic machinery is impacted in *nup214*;*mip-1* mutants.

471F **Glucose-induced developmental delay is modulated by insulin signaling in *C. elegans*** Mary Ladage, Saifun Nahar, Manuel Ruiz, Jose Robledo, Luhua Song, Pamela Padilla University of North Texas

Glucose metabolism is the central pathway for energy production in all cells. While glucose is critically important for cellular functions, it has been shown that excess dietary glucose results in increased glucose concentrations and negative health outcomes in a variety of organisms. Much of the work to understand the effects of excess dietary glucose has been done in relation to aging and disease processes; however, due to global concerns over rising sugar consumption and increases in obesity and type 2 diabetes among children and adolescents, it is of interest to further investigate such effects in the context of development. In this study, we have used genetic, cell biological and transcriptomic methods in the nematode *C.*

elegans as a model to examine the impact of glucose supplementation during development. We show that a glucose-supplemented diet slows developmental progression (termed "glucose-induced developmental delay" or GIDD) and induces the mitochondrial unfolded protein response (UPR^{mt}) in wild-type animals. Mutation in the insulin receptor *daf-2* confers resistance to GIDD and UPR^{mt} in a *daf-16* dependent manner. RNA-sequencing revealed that the transcriptomic profiles of glucose-supplemented wildtype and *daf-2(e1370)* animals are distinct. From this data, we identified a set of 27 genes which are both exclusively upregulated in *daf-2(e1370)* animals fed a glucose-supplemented diet and regulated by *daf-16*, including a fatty acid desaturase (*fat-5)*, and two insulin-like peptides (*ins-16* and *ins-35*). Mutation of any of these genes suppresses the resistance of *daf-2(e1370)* to GIDD. Additionally, double mutation of *ins-16* and *ins-35* in a *daf-2(e1370)* background results in an increase in constitutive dauer formation which is suppressed by glucose-supplementation. Further investigation of the insulin-like peptides revealed that *ins-16* mutation in a wild-type background results in upregulation of *ins-35*and DAF-16 nuclear translocation regardless of diet; however, unlike *daf-2(e1370),* this translocation is not associated with resistance to GIDD. Taken together, these data suggest that glucose-supplemented *daf-2(e1370)* animals maintain developmental trajectory in part through upregulation of specific insulin-like peptide genes and fatty acid desaturation and contributes to a deeper understanding of the mechanisms underlying the resistance of *daf-2(e1370)* animals to GIDD.

472F **HUM-7, a type IX unconventional myosin, is a novel regulator of integrin adhesion complexes in *C. elegans* muscle** Hiroshi Qadota, Stefano Derossi, Jasmine C. Moody, Guy M. Benian Emory University

In vertebrate striated muscle (skeletal and cardiac), much of the force of muscle contraction is transmitted to the outside of the cell via "costameres", which are muscle-specific "integrin adhesion complexes" (IACs; aka focal adhesions). Costameres attach the myofibrils located at the perimeter of the muscle cell to the muscle cell membrane and overlying extracellular matrix and occur at each sarcomeric Z-disk. In the striated muscle of *C. elegans*, IACs reside at 3 locations—the bases of the sarcomeric M-lines and dense bodies (Z-disks) and at the muscle cell boundaries (MCBs). Each IAC consists of the heterodimeric transmembrane protein integrin and many proteins associated with it both intra- and extracellularly. The MCBs contain only a subset of proteins found at dense bodies. In a screen for mutants with defects in the MCB, we identified the gene *pix-1*, which encodes a RacGEF (guanine nucleotide exchange factor) (Moody et al., 2020) and the gene *rrc-1*, which encodes a RacGAP (GTPase activating protein) (Moody et al., in revision). During RacGAP screening, we also found that *hum-7* mutants also show the defect in the MCB. The HUM-7 protein is predicted to have the following domains: An RA (Ras association) domain, a myosin head domain, 4 consecutive IQ domains, 2 C1 (phorbol ester/diacylglycerol binding) domains, and a RhoGAP domain. Based on the sequence of its myosin motor domain and the presence of the other domains, HUM-7 is a class IX unconventional myosin. Two deletion mutants of the *hum-7* show less accumulation of PAT-6 (a-parvin) at MCBs, similar to *pix-1* and *rrc-1* mutants. Since the HUM-7 contains myosin head and RhoGAP domains, we next examined which domain is important for HUM-7's function at the MCB. We investigated missense mutations in the myosin head and RhoGAP domains. Two of three missense mutations in myosin head region show the defect at MCBs, but one missense mutation in RhoGAP domain did not show the defect at MCBs. We prepared an antibody against HUM-7, and localized HUM-7 in muscle cells. By confocal microscopy, anti-HUM-7 antibodies localize between dense bodies and at the MCB but flanking the location of IAC components in body wall muscle cells. This is a fascinating localization pattern and contrasts with the location of PIX-1 and RRC-1 which localize to the M-lines, dense bodies and the MCB. Our working hypothesis is that HUM-7 functions as a transporter of IAC components towards the MCB region.

473F **The CYK4 GAP domain controls contractile ring assembly and dissolution by regulating the cortical targeting of centralspindlin** Aleesa Schlientz[1], Sebastian Gomez-Cavazos[2], Kian-Yong Lee[2], Pablo Lara-Gonzalez[2,3], Arshad Desai[2], Karen Oegema[2] [1]School of Biological Sciences, University of California, San Diego, [2]University of California, San Diego, [3]University of California, Irvine

During cytokinesis, an equatorial contractile ring constricts to partition the cell contents. Contractile ring assembly requires active GTP-bound RhoA generated by the guanine nucleotide exchange factor ECT2. The centralspindlin complex, composed of two molecules of kinesin-6 and two molecules of CYK4, is the major ECT2 activator during cytokinesis. Centralspindlin is phosphorylated by Polo-like Kinase 1 (PLK1) at the central spindle during anaphase and diffuses to the adjacent plasma membrane where it activates ECT2. The N-terminal half of CYK4 is the primary target of PLK1 and engages with ECT2 to activate it, likely by relieving ECT2 autoinhibition, whereas the C-terminal half of CYK4 contains a C1 domain, which contributes to plasma membrane targeting, and a GTPase-activating protein (GAP) domain predicted to interact with a Rho family GTPase. The function of the CYK4 GAP domain has been unclear. Here, we show that the CYK4 GAP domain functions with the adjacent C1 domain to target centralspindlin to the cell cortex. Using an assay we developed to monitor cortical recruitment of centralspindlin during cytokinesis in the one-cell *C. elegans* embryo, we show that RhoA and the GTPase-binding interface of the CYK4 GAP domain are both essential to recruit centralspindlin to the equatorial cortex. Comparison of a CYK4 mutant that disrupts the RhoA binding interface of the GAP domain to a catalytic mutant (R459A) that selectively disrupts the ability of the GAP domain to convert bound RhoA-GTP to Rho-GDP revealed striking differences. In a mutant background partially

compromised for RhoA activation, preventing RhoA binding inhibited furrowing, whereas the catalytic mutant was largely able to complete cytokinesis. In addition, whereas the RhoA-binding mutant reduced centralspindlin recruitment to the equatorial cortex, the catalytic mutant did not. The catalytic mutant additionally seemed to prevent the normal dissolution of cortical centralspindlin and contractile ring components at the end of cytokinesis. These results lead us to propose a model in which cortical recruitment of centralspindlin by the CYK4 GAP domain is central to a feedback loop in which generation of active RhoA at the cell cortex drives further centralspindlin recruitment and RhoA activation to drive rapid contractile ring assembly. As the contractile ring disassembles, conversion of RhoA-GTP to RhoA-GDP by the CYK4 GAP domain is important to ensure timely dissolution of the contractile ring.

474F **Pavarotti and Tumbleweed function in maintaining mitochondrial integrity in post-mitotic muscle tissue** Yungui Guo[1], David Brooks[1], Erika Geisbrecht[2] [1]Biochemistry and Molecular Biophysics, Kansas State University, [2]Kansas State University

The evolutionarily conserved NUAK serine/threonine kinase plays a role in the autophagic clearance of proteins in *Drosophila* larval muscles. While many proteins that comprise the canonical autophagy pathway have been characterized, the identification of new regulators may help understand tissue and/or stress-specific responses. One of the multiple approaches we have taken toward this goal is to compare gene expression levels in control and *NUAK* mutant muscles. We found that the largest class of down-regulated genes are involved in microtubule (MT)-based structure and/or function, consistent with previous data whereby MT organization is altered in *NUAK* mutants. Muscle-specific RNAi approaches were used to knock down candidate genes that affect multiple aspects of MT regulation. Using p62/Ref(2)P/Sequestosome-1 immunostaining as a proxy to assess autophagic flux, Pavarotti (Pav)/kinesin family member 23 (KIF23) emerged as a candidate. Pav and its binding partner Tumbleweed (Tum)/RacGAP1 comprise the centralspindlin complex and are well characterized for their role in cytokinesis. However, the interconnection of Pav and Tum with autophagy has not been explored. The Pav-Tum complex was recently reported to be required for nuclear envelope budding (NEB) in larval salivary gland cells or adult muscles. In *Drosophila* larval muscles, mRNAs necessary for mitochondrial integrity and neuromuscular junction (NMJ) development are components of nuclear envelope buds. New data from our lab show that Ubiquitin and p62 are recruited to damaged mitochondria upon muscle-specific RNAi knockdown of Pav or Tum in larval muscles. Thus, we hypothesize that the loss of mitochondrial mRNAs via NEB reduces mitochondrial function which thereby recruits p62 and associated autophagosome components for eventual degradation of mitochondria in the lysosome. Interestingly, overexpression of Tum or an inactive form of Pav showed the same mitochondrial damage phenotype, suggesting that levels of the centralspindlin complex are important for function. Our results will provide new insight into how cells respond to decreased NEB at the molecular and organismal levels.

475F **Structural and Mechanistic Exploration of Wnt Ligand Maturation** Kate M Henesey, Erica M Selva Biological Sciences, University of Delaware

Wnt signal transduction is fundamental for the development of all animals and is responsible for the homeostasis of renewable cell populations in adults. During development, reduced or absent Wnt signaling results in a wide range of developmental defects and aberrant signaling in adults is recognized as a primary driver of cancers. Strikingly, Wnt signaling is so indispensable to proper organismal function that perturbation or disruption to any player within the Wnt pathways can have serious ramifications, such as osteogenesis imperfecta or colorectal cancer. While the numerous Wnt ligands and target receptors in signal-receiving cells have been extensively studied, the maturation of virtually all Wnt ligands within signal-sending cells is relegated to highly conserved yet understudied components, Porcupine (Por) and Wntless (Wls). Our initial characterization of Por and Wls function within the model organism *Drosophila melanogaster* to produce functional Wnt has informed much of our understanding of Wnt ligand maturation. *Further characterization of the mechanisms by which these players interact to produce mature, active Wnt ligand is essential to better define how Wnt signaling is regulated.*

We discovered that Wls forms homo-dimers dependent upon intermolecular disulfide bridge formation, and these Wls dimers interact with Wnt (2:1, Wls-Wnt). Remarkably, this provides a universal mechanism for Wls dimerization and a possible explanation for the uncharacterized Wnt hand-off between Por and Wls in early ER Wnt processing. My overarching project goal is two-fold: to characterize disulfide bonded Wls dimer interactions in forming Wnt maturation complexes and to characterize disulfide bonded Wls dimer importance in Wnt post-translational modification, secretion, and signaling. We have generated various tagged forms of *Drosophila* Por and Wls wild-type and conserved cysteine mutants were used in co-immunoprecipitation and functional experiments to examine the importance of Wls disulfide bonds in forming early Wnt maturation complexes and Wnt production from the signal-sending cell. **Here, we show that a conserved cysteine amino acid pair within Wls Dimerization Domain 1 (DD1) is required for Wls dimer interaction with Wnt**, and when only one cysteine in the pair is mutated, the total Wnt bound Wls population shifts in favor of dimer formation. Furthermore, conserved cysteines in Wls DD1 are required for proper Wnt N-glycosylation, secretion, and canonical Wnt signaling activity. *This work establishes*

an understanding of how Wls dimers function within a cell to produce functional Wnt ligand, impacting our comprehension of Wnt cellular dynamics, processing, and secretion mechanisms.

476F **Transport of centrioles as cargo ensure proper neural stem cell asymmetric division** Matthew Hannaford[1], Rong Liu[2], Carey Fagerstrom[1], Brian Galletta[1], James Sellers[1], Nasser Rusan[1] [1]National Heart Lung and Blood institute, [2]West Virginia University

Centrosomes are a key microtubule organizing center in the cell that comprise a pair of centrioles surrounded by a matrix of proteins termed the pericentriolar material (PCM). Centrosomes are responsible for the organization of the mitotic spindle, as well as the formation of cilia and flagella. To fulfill these functions both the positioning and microtubule nucleating activity of centrosomes must be tightly controlled. Typically, centrosome positioning is thought to be governed by the activity of microtubule motors, pushing or pulling on the microtubules anchored at the centrosome. In some cell types, centrioles lack PCM and microtubules, and are referred to as inactive centrioles. Inactive centrioles must be motile and their intracellular positioning is critical for asymmetric cell division, yet it remained unknown how centriole motility is achieved and regulated. Our work has revealed that centrioles are microtubule cargo, moving along the microtubule network in a manner involving Kinesin-1. We discovered that Kinesin-1 localized to the outside of centrioles where it interacts with the centrosomal scaffolding protein Pericentrin-Like-Protein (Plp). Through yeast-2-hybrid and an *in vitro* interaction assay we found that Plp interacts with the cargo binding region of the Kinesin-1 heavy chain. Importantly, the specific disruption of this interaction blocked centriole motility *in vivo.* Kinesin-1 is regulated by an autoinhibitory interaction between the motor domain and the cargo binding tail, we have shown using a constitutively active Kinesin Heavy Chain allele that the autoinhibited conformation is unable to interact with Plp for centriole transport. Kinesin-1 autoinhibition can be relieved via the combined activity of microtubule associated proteins such as MAP7 (Ens) or multiple cargo adaptor molecules. We will discuss our recent efforts to combine biophysical methods *in vitro* with *in vivo* genetic analysis to identify the mechanisms relieving Kinesin-1 autoinhibition for centriole transport and asymmetric cell division. In this work we propose the first comprehensive mechanism of how centrioles can move independently of their role as an MTOC, in the context of developing tissue.

477F **Dysregulation of the ER blocks recruitment of centrosome associated proteins resulting in mitotic failure** Katherine Rollins[1], J. Todd Blankenship[2] [1]University of Denver, [2]Biological Sciences, UNIVERSITY OF DENVER

The Endoplasmic Reticulum (ER) is the largest organelle by surface area and makes contact with other organelles throughout the cell. In recent years, the ER's roles within the cell have expanded beyond the canonical roles of calcium storage and protein synthesis. Additionally, the ER has been shown to undergo remarkable morphological transitions throughout cell division. However, whether these changes in ER behavior and morphology modulates mitotic events is less clear. Here, we use the mitotic divisions of the *Drosophila* syncytial embryo to study ER behaviors during mitosis. In a screen for Rab proteins present in the embryo, the ER associated GTPase, Rab1 was identified. Depletion of *Rab1* led to highly penetrant disruption of division cycles along with enhanced buildup of ER at the spindle poles. Interestingly, this excess clustering of the ER is correlated with the formation of a shortened 'mini-spindle' in embryos that are depleted for *Rab1*. Importantly, the recruitment of several key centrosomal proteins at mitotic onset to the spindle poles is weakened after *Rab1* disruption leading to reduced γ-tubulin function, suggestive of a defect in centrosomal maturation. We implicate Dynein in maintaining some ER contact with the spindle poles in embryos and find that dual disruption of *Rab1* and Dynein can rescue maturation defects. We further explore a subset of ER shaping protein's in organizing the ER during mitosis. These results demonstrate that ER levels must be carefully tuned in an organized manor during mitotic processes to ensure proper assembly of the division machinery.

478F **Alternate roles for the actin formin Cappuccino during *Drosophila* oogenesis.** Hannah M Bailey[1], Margot E Quinlan[1,2] [1]Chemistry and Biochemistry, University of California Los Angeles, [2]Molecular Biology Institute, University of California Los Angeles

The *Drosophila* oocyte has long served as a model for understanding oogenesis, the process of egg development. An essential structure in *Drosophila* oocytes is a cytoplasmic actin meshwork that persists during mid-oogenesis. This complex actin network is built by the collaboration of actin nucleators, Spire (Spir) and Cappuccino (Capu). Loss of the actin mesh, and concurrent decrease in Spir and Capu expression, permits the initiation of fast cytoplasmic streaming, thereby mixing nurse cell and oocyte cytoplasmic contents and reinforcing establishment of polarity. Analogous actin meshes, built by Spir and Capu, have been characterized in the mouse oocyte and melanocyte. The function of these networks appears to differ in these two cell types, based on the localization of Capu (the formin). In melanocytes, Capu (FMN1) is cytosolic and contributes to a dispersion mechanism for cargo transport. Yet in mouse oocytes, Capu (FMN2) is found bound to membranes where it is involved in a convergence mechanism to position the mitotic spindle. CapuA, the isoform expressed in the *Drosophila* ovary, appears diffuse, suggesting that Spir, Capu and the mesh they build may function more like the melanocyte than the mouse oocyte. This raises several questions, such as: how does the fly mesh compare to the mesh in the mouse oocyte, how does

it suppress fast streaming, and does it play additional roles? To address these questions, I tested the impact of driving Capu localization to membranes, using the bipartite GAL4/UAS system. I compared the ability of CapuA to rescue a *capu*-null background with that of CapuJ, a testis isoform that contains a myristoylation site – dramatically increasing the membrane localization pattern of Capu. Interestingly, the actin mesh is built and then correctly removed by both isoforms. However, fertility is reduced from 90% for CapuA to 50% for CapuJ. This result suggests that Capu, in addition to building the actin mesh, is important for one or more other processes. Further data suggest that Capu plays a more direct role in anterior/posterior axis establishment than previously thought. Localization of two critical polarity factors, Staufen and MyosinV, are both altered in the CapuJ-expressing egg chambers. This work contributes new insights into *Drosophila* oogenesis. In addition, it demonstrates that subtle changes in the interaction between two actin nucleators leads to formation of actin-based structures that play distinct cellular roles.

479F **The Rho GAP *crossveinless-c* (*cv-c*) plays an important role in caudal visceral mesoderm (CVM) migration during *Drosophila* embryogenesis** Shiva Ahmadi, Jayden Ogbodo, Afshan Ismat Biology, University of St. Thomas

Proper organ formation is dependent upon the migration of cells from one location to another during embryonic development. The intracellular mechanism of actin polymerization which allows cells to move is similar in different cell types and organisms. When a migratory cell receives a signal to move, actin fibers push on the cell membrane which extends out the leading edge (front) of the membrane while the trailing edge (back) retracts. This process of actin polymerization repeats until the cell reaches its destination. One class of proteins that regulates actin polymerization is the Rho GTPases. Rho GTPases are regulated by GEFs (Guanine Exchange Factors) and GAPs (GTPases-Activating Proteins), two classes of proteins that respectively activate and inactivate Rho GTPases. The gene *crossveinless-c (cv-c)* encodes a RhoGAP protein that regulates the GTPase Rho. Caudal visceral mesoderm (CVM) cells are one type of migratory cell that forms the longitudinal visceral muscles which surround the midgut of Drosophila. Currently, we have shown that loss cv-c results in mis-migration of CVM cells and stalled CVM migration. We also show that expressing a constitutively active (CA) version of Rho1 displays an extreme stalled CVM migration. Conversely, expressing a dominant negative (DN) version of Rho1 shows a slightly stalled CVM migration. Continuation of this research will serve to characterize the effects of losing *cv-c* and over-expression of *cv-c* on actin polymerization and CVM migration.

480F **The conserved protein phosphatase inhibitor, Inhibitor-2, regulates the collective cell migration of border cells** Yujun Chen, Jocelyn McDonald Division of Biology, Kansas State University

Collective cell migration is essential in many developmental and pathological processes. In *Drosophila*, border cells travel as a cluster during oogenesis, making them an excellent genetic model for studying mechanisms of collective movement. In our previous study, we demonstrated that Phosphatase 1 (Pp1) catalytic subunits are critical for collective versus single cell behaviors of border cells, but the Pp1 regulatory subunits that mediate these behaviors were poorly characterized. In a recent RNAi screen to identify Pp1 regulatory subunits, we found that the conserved Pp1 regulatory subunit I-2 (Inhibitor-2) is required for border cell collective migration. I-2 is a small intrinsically disordered protein that was originally described as a potent inhibitor of Pp1. Later studies, however, found that I-2 can function as a chaperone as well as an activator of Pp1. Although I-2 has been reported to be involved in diverse cellular processes, its function in collective cell migration is unexplored. Here, we report that loss of I-2 prevents border cell delamination from the follicular epithelium, whereas a weak hypomorphic allele of I-2 delays migration. Live imaging shows that I-2 promotes the correct number and size of cellular protrusions, which help border cells leave the epithelium and migrate. Further, genetic interactions between Pp1 catalytic subunits and I-2 suggest that I-2 behaves as an activator of Pp1 in border cells rather than as an inhibitor. Nek2 (NimA-related kinase), which can form a complex with I-2 and the Pp1 catalytic subunit, may function together with I-2 in border cells as knockdown of Nek2 impairs migration. Overall, our work implicates I-2 as a key regulator of collective border cell delamination and migration through regulation of protrusion dynamics.

481F **An intestinal G Protein-Coupled Receptor regulates metabolism and immunity in Drosophila melanogaster** Daniela Barraza[1], Xiang Ding[2], Bat-Erdene Jugder[3], Paula Watnick[4] [1]Department of Microbiology, Harvard Medical School/Boston Children's Hospital, [2]Infectious Diseases, Boston Children's Hospital, [3]Boston Children's Hospital, [4]Infectious Diseases, Harvard Medical School/Boston Children's Hospital

The intestinal enteroendocrine cell (EEC) senses stimuli through various receptors, including G Protein-Coupled Receptors (GPCRs). Upon activation, EEC GPCRs regulate expression and secretion of enteroendocrine peptides (EEPs) that control important physiological processes including satiety, systemic metabolism, and immunity. We previously found that expression of a previously uncharacterized EEC-specific GPCR, which we temporarily call GPRx, is regulated by the levels of acetate in the intestine. Acetate is a microbiota-derived short chain fatty acid that is known to act through EEC GPCRs in mammals to regulate host metabolism and immunity via production of EEPs. To test the hypothesis that GPRx plays a role in intestinal metabolism and immunity, we knocked down *GPRx* in a subset of EECs that express the EEP Tachykinin (Tk) (Tk>*GPRx*^{RNAi})

and conducted an RNA sequencing experiment. We observed transcriptional downregulation of *Tk, NPF,* and *Dh31*, which are the EEPs expressed in Tk+ EECs. In addition, gene ontology analysis revealed differential expression of lipid metabolism genes. Tk has been shown to regulate intestinal lipid homeostasis and knockdown of *Tk* results in intestinal lipid droplet accumulation. We used fluorescence microscopy to quantify intestinal lipids and the number of cells containing detectable Tk peptide in Tk>*GPRx*^{RNAi} flies. Consistent with our RNA seq results, we observed accumulation of intestinal lipids and a decrease in the number of Tk-expressing EECs. Because EEPs regulate metabolism and energy expenditure beyond just the intestine, we measured resistance to starvation over time and systemic lipids in Tk>*GPRx*^{RNAi} flies after a 3-day starvation period. We observed higher susceptibility to starvation and higher levels of systemic triglycerides (TG) in Tk>*GPRx*^{RNAi} flies, which is indicative of lipid utilization defects in these flies. Finally, since EEC-signaling is known to regulate immunity in the gut, we assessed the impact of GPRx on the response to intestinal infection by orally infecting Tk>*GPRx*^{RNAi} flies with the diarrheal pathogen *Vibrio cholerae*. Interestingly, we found that these flies were more susceptible to infection despite having reduced *V. cholerae* bacterial loads. We are currently exploring the mechanism underlying these seemingly contradictory observations. Overall, our data suggests that intestinal GPRx regulates expression of EEPs, energy utilization during starvation, and the response to intestinal infection.

482F **ArfGAP1 regulates the endosomal sorting of guidance receptors to promote directed collective cell migration in vivo** Alison Boutet[1], Carlos Zeledon[2], Gregory Emery[2] [1]Molecular Biology, Institut de recherche en immunologie et en cancérologie (IRIC), [2]Institut de recherche en immunologie et en cancérologie (IRIC)

Introduction: Collective cell migration plays important roles in morphogenesis, embryonic development and is a main feature of metastasis formation in several cancers. Collective cell migration is characterized by cell-cell adhesion and cell-cell communication. We have previously demonstrated that vesicular trafficking plays a critical role in cell guidance and cell-cell communication during collective cell migration. A screen identified ArfGAP1, a regulator of vesicular trafficking, as important for border cell (BC) migration in Drosophila ovary.

Methods and Results: Between stages 9 and 10 of Drosophila egg chamber development, the so-called BCs form a cluster that is attracted by the oocyte through the secretion of ligands to receptor tyrosine kinases (RTKs). We found that ArfGAP1 loss-of-function induces migration defects, as clusters loose directionality. Further investigations revealed that ArfGAP1 is required to maintain active RTKs at the plasma membrane by inhibiting its sorting in the endolysosomal degradative pathway. Looking further in the degradative pathway, we discovered an increase in Rab7 signal and lysosomes in BCs depleted of ArfGAP1. Our results show that ArfGAP1 is necessary for the proper sorting of active RTKs in endosomes. Moreover, rescue experiments suggest that the role of ArfGAP1 is dependant of its GAP activity and act upstream of Hrs and Lrrk, two regulators of the degradative pathway.

Conclusion and Relevance: We identified ArfGAP1 as a new regulator of BC migration that acts through vesicular trafficking to maintain RTKs at the plasma membrane and promote chemotaxis. This study could reveal a new important mechanism in collective cell migration, and by extent in cancer dissemination.

483F **Investigations into the role of ER in Wolbachia distribution in host somatic tissue.** I›frica Jalai Norman[1], Blake Riggs[1], Ulises Diaz[2] [1]Biology, San Francisco State University, [2]Biology, University of California San Francisco

Insects are major disease vectors, different methods exist for combatting these vectors, but one understudied method is the targeting of the endosymbiont *Wolbachia*. *Wolbachia* is an intracellular alpha-proteobacterium known for infecting most arthropods. It infects most of the host's somatic cells and relies exclusively on the female germline to pass itself on. In addition to this, it's also known for developing symbiotic relationships with certain infected hosts and can grant viral resistance to infected cells. A major question involving *Wolbachia* is how it localizes itself to different parts of the host body during embryonic development, how it distributes itself from cell to cell during the hosts adult phase. Here, we propose to address this question and hypothesize that *Wolbachia* are using a similar mechanism that mitochondria use for distribution around the cell. To examine this, we plan on performing fixed stained and live analysis of *Wolbachia* and the Endoplasmic Reticulum (ER) using confocal microscopy in the early Drosophila embryo. We believe that *Wolbachia* are using ER-mitochondria contact sites for transport and inheritance into daughter cells during division, thereby displacing mitochondria. This is based on preliminary data that *Wolbachia* infected cells displays lower mitochondria levels during division. We will examine the localization of *Wolbachia* at ER-Mito contact sites and disrupt the Rho GTPase Miro, which has been shown to control ER-Mitochondria contact sites in Drosophila. Understanding how *Wolbachia* is able to distribute among somatic cells will deepen our knowledge of cellular organization and provide an intervention strategy towards insect-borne diseases.

484F **Neuronal triglyceride metabolism regulates sex differences in fat breakdown** Colin Miller[1], Jasper Fisher[1], Lianna Wat[1], Sanjana Prakash[1], Niyoosha Yoosefi[1], Serena Hollman[1], Yi Han Xia[1], Romane Manceau[2], Danie Majeur[2], Tao Huan[1], Thierry

Alquier[2], Elizabeth Rideout[1] [1]University of British Columbia, [2]Universite de Montreal

Drosophila females store more fat than males and have slower fat breakdown after nutrient withdrawal. We previously showed that neuronal loss of triglyceride lipase *brummer* (*bmm*) blocked the sex difference in fat breakdown. Because we now reproduce these sex-specific effects in flies with neuronal loss of additional genes related to intracellular triglyceride metabolism and storage, our data suggests that the sex-specific regulation of neuronal triglyceride contributes to male-female differences in body fat. Yet, the underlying mechanism(s) remain unclear, as much remains to be discovered about the intracellular regulation and function of triglyceride in neurons. To address this knowledge gap, we expressed a lipid droplet-targeted GFP within neurons. This allowed us to monitor neuronal lipid droplets, a specialized organelle dedicated to triglyceride storage. We found lipid droplets in neurons under normal physiological conditions and showed age- and diet-dependent changes to neuronal lipid droplets in both sexes. We identified multiple genes, including *bmm,* that regulate the number of neuronal lipid droplets in a sex-biased manner and show profound sex-specific changes to brain lipidome caused by loss of neuronal *bmm*. Given that loss of *bmm* within the adipokinetic hormone-producing cells (APC) reproduced the sex-specific effect on fat breakdown associated with reduced function in these neurons, our findings suggest a model in which triglyceride supports APC function in males. In light of our discovery of a similar male-specific requirement for neuronal ATGL, the mammalian homolog of *bmm,* in regulating whole-body energy homeostasis in mice, our data identifies a previously unrecognized and sex-specific role for triglyceride in supporting the function of metabolic neurons.

485F **ALS8-related endoplasmic reticulum protein Vap33/VAPB is extracellularly secreted via the topological inversion and MMP1/2-mediated cleavage** Mizuki Tando[1], Kosuke Kamemura[1], Rio Kozono[1], Misako Okumura[1], Daisuke Koga[2], Satoshi Kusumi[3], Kanako Tamai[4], Aoi Okumura[1], Sayaka Sekine[5], Daichi Kamiyama[6], Takahiro Chihara[1] [1]Program of Biomedical Science, Graduate School of Integrated Sciences for Life, Hiroshima University, [2]Department of Microscopic Anatomy and Cell Biology, Asahikawa Medical College, [3]Department of Morphological Sciences, Graduate School of Medical and Dental Sciences,Kagoshima University, [4]Department of Biological Science, School of Science, Hiroshima University, [5]Graduate School of Life Sciences, Tohoku University, [6]Department of Cellular Biology, University of Georgia

VAMP-associated protein (VAP) is a type IV integral transmembrane protein at the endoplasmic reticulum (ER). VAP is required for tethering ER membranes and various intracellular organelles at membrane contact sites to maintain their structure and function. Humans possess two VAPs (VAPA and VAPB). Several mutations (P56S, T46I, etc.) in human *VAPB* have been reported to be associated with amyotrophic lateral sclerosis (ALS). VAPB is composed of an N-terminal MSP (major sperm protein) domain, a coiled-coil domain, and a C-terminal transmembrane domain. In addition to its intracellular functions, the N-terminal MSP domain of VAPB is cleaved, secreted to the extracellular space, and acts as a signaling ligand for cell-surface receptors including Eph and Roundabout. In humans, the VAPB MSP domain is secreted in the cerebrospinal fluid, and its amount was significantly decreased in sporadic ALS patients, suggesting that impairment of VAPB extracellular functions may contribute to the pathogenesis of ALS. Although the extracellular functions of VAPB are beginning to be understood, it is unknown how the VAPB MSP domain facing the cytosol is secreted to the extracellular space. In this study, we use Vap33 (a *Drosophila* VAPB) and human VAPB to investigate the secretion mechanism of Vap33/VAPB. We show that *Drosophila* Vap33 uses the COPI/II-dependent secretion pathway to reach the plasma membrane, where the MSP domain is exposed extracellularly by topological inversion. Similarly, human VAPB is also extracellularly localized by topology inversion in HeLa cells, suggesting that the extracellular localization of the MSP domain of Vap33/VAPB is an evolutionarily conserved phenomenon. We also found that the externalized MSP domain is cleaved by Matrix metalloproteinase 1/2 (Mmp1/2), membrane-bound or secreted proteinases that cleave extracellular proteins. Overexpression of Mmp1 restores decreased levels of extracellular MSP domain derived from ALS8-associated Vap33 mutants. We propose an unprecedented secretion mechanism for an ER-resident membrane protein, which may contribute to ALS8 pathogenesis.

486F **The role of the SR protein 9G8 in the *Drosophila* intestine to regulate lipid metabolism** Roman Voskoboynikov, Justin DiAngelo Penn State Berks

For the last several decades, the rate of metabolic diseases in humans, such as obesity or type 2 diabetes, has been increasing drastically. These diseases arise from defects in the body's ability to take in and store nutrients such as carbohydrates and triglycerides. Previous studies in the fruit fly, *Drosophila melanogaster*, have identified mRNA splicing factors as having an impact on fly lipid storage. Specifically, adipose tissue knockdown of SR proteins, which regulate splice-site selection, results in alterations in triglyceride storage in whole flies. However, whether SR proteins function in other tissues to regulate nutrient metabolism is not known. We focused on studying the role of SR proteins in intestines by decreasing their levels in the fly gut and measuring the concentrations of lipids and glycogen. We explored eight such proteins, including *9G8*, *B52*, *SF2*, *SC35*, *Rbp1*, *Rbp1-Like*, *RSF1*, and *Srp54*. Decreasing *9G8*, *RSF1*, *SC35*, and *Srp54* in the intestine increased triglyceride levels, while decreasing *Rbp1* in the intestine limits triglyceride storage in female flies. Decreasing *RSF1* and *Rbp1-Like* in the intestine also resulted in glycogen to accumulate, while inducing RNAi

towards *Rbp1* and *Srp54* decreased glycogen levels in female flies. We next further investigated *9G8*, an SR protein which displayed a prominent lipid accumulation phenotype when knocked down in the fat body and intestine. To identify the genes that 9G8 regulates to control lipid storage and metabolism in the gut, we performed RNA-Seq on *9G8-RNAi* intestines. Interestingly, decreasing *9G8* in the intestine resulted in increased expression of five fatty acid synthesis/elongation enzyme genes, as well as four triglyceride lipase genes, which may contribute to the triglyceride accumulation phenotype we observed in *9G8-RNAi* intestines. Together, we found that most SR proteins have a unique metabolic phenotype in the fly intestine and specifically *9G8* regulates whole body and intestinal lipid homeostasis by altering the expression of lipid metabolic enzyme genes in the fly intestine.

487F **Differential expression analysis in *9G8-RNAi* fat tissue reveals upregulation of acyl-CoA synthetase genes in *Drosophila*** Erick Astacio, Justin DiAngelo Penn State Berks

Evolutionarily, animals have adapted systems that store excess nutrients for times of starvation. However, due to the abundance of food in Western society, these storage mechanisms can lead to obesity and other metabolic diseases. Genome-wide RNAi screens in *Drosophila* cells have identified several groups of genes involved in triglyceride metabolism and storage. Previous studies from our lab have characterized the metabolic role of a group of splicing factors called SR proteins that function to identify intron/exon borders. Specifically, one SR protein that has been shown to regulate triglyceride storage in fly fat tissue is 9G8; decreasing 9G8 function resulted in an increase in triglyceride storage phenotype. To better understand the mechanism whereby 9G8 affects the storage of excess nutrients as triglycerides, RNA sequencing was performed on flies with decreased levels of *9G8* in the *Drosophila* fat body. A group of genes that was upregulated in *9G8-RNAi* flies and potentially responsible for the increase in triglyceride phenotype were acyl-CoA synthetases. These proteins facilitate an early step of fat metabolism by adding CoA groups to fatty acids for activation. Once activated, these fats are transported to the mitochondria for beta-oxidation or used for triglyceride esterification in the cytosol. Two uncharacterized acyl-CoA synthetase genes in *Drosophila*, *Acsx4* and *Acsx5*, were identified from the RNA-Seq analysis. To assess their function, RNAi knockdown of *Acsx4* or *Acsx5* was performed in the adult *Drosophila* fat body. Decreasing the expression of both *Acsx* genes resulted in a triglyceride accumulation phenotype suggesting that these genes are important for beta-oxidation of fatty acids. These findings indicate that the *Acsx4* and *Acsx5* genes are necessary for regulating lipid breakdown in the fat body of *Drosophila*, and their increased expression may be compensatory for the increased TAGs observed in *9G8-RNAi* flies.

488F **The Intrinsically disordered region of Drosophila Canoe plays a critical role in linking adherens junctions to the cytoskeleton during embryonic morphogenesis** Corbin Jensen, Emily D McParland, Noah J Gurley, Yufei Xiao, Kevin C Slep, Mark Peifer Biology, University of North Carolina - Chapel Hill

It is becoming increasingly apparent that Intrinsically Disordered Regions (IDRs) play key roles in virtually every cellular function, but we're only beginning to dissect their precise molecular roles. Our lab focuses on mechanisms that link cell-cell adherens junctions (AJs) to the actin cytoskeleton. During embryonic development the interactions between AJs and the cytoskeleton are both dynamic, as the embryo and its component cells are constantly changing shape, as well as robust since the cytoskeleton generates a high level of pulling force on cell-cell contacts as the cells change shape and move. Disrupting interactions between AJs and the cytoskeleton disrupts diverse morphogenetic events, from gastrulation to germband extension to dorsal closure. Connections between AJs and the cytoskeleton involve a complex network of proteins. A central member of this network is the Drosophila protein Canoe. Canoe and the mammalian homolog Afadin contain multiple domains, some of which have known binding partners and are well studied, e.g. Rap1-binding RA domains and the E-cadherin-binding PDZ binding domain. However, Canoe and Afadin also contain a large C-terminal IDR, comprising over 1/3 of the total protein. The IDRs of both Canoe and Afadin are quite different in length, charge and amino acids composition, and have little sequence conservation. Several of the regions in the IDR that are most conserved over evolution are predicted to be alpha-helical by AlphaFold, two of which are the only regions conserved between Canoe and Afadin. Combining bioinformatic, genetic and cell biological analyses, we seek to define the function of the IDR on Canoe function and localization during embryonic development. We generated mutants that completely remove the IDR from Canoe *in vivo*. Loss of the IDR in Canoe dramatically reduces function and largely, but not completely, eliminates localization of Canoe to cell junctions. Instead, deleting the IDR results in strong nuclear localization of Canoe. Replacement of the Canoe IDR with that of Afadin restores substantial but not full function. We're currently analyzing mutants that delete different regions of the IDR, to determine the balance of function of unstructured regions and the two conserved helices. This in-depth analysis of the IDR will provide a clearer picture of how different sequence features of IDRs help Canoe maintain the interaction between junctions and the cytoskeleton, and thus drive embryonic development.

489F **Identifying neurons in which Glut1 acts to regulate nutrient storage in *Drosophila*** Prem Patel, Katelyn Acrie, Justin DiAngelo Penn State Berks

Metabolic homeostasis is regulated by many genes, and defects in some of these genes result in metabolic diseases, such as obesity and diabetes. Several genetic screens have been performed in *Drosophila* to identify genes important for lipid and carbohydrate storage. A gene identified in one of these screens is *Glut1*, a gene that codes for a glucose uniporter in *Drosophila*. Previous studies in our lab have identified a metabolic function of *Glut1* in the fly brain; however, the specific neurons in which *Glut1* acts to regulate nutrient storage are not known. To determine the neuronal populations in which Glut1 acts to regulate lipid and carbohydrate storage, we decreased *Glut1* levels in specific neurons, and measured triglycerides (TAGs), glycogen, and glucose levels. Inducing RNAi to *Glut1* in all neurons resulted in a decrease in TAG and glycogen for both males and females. We next focused on a specific group of neurons expressing the corazonin gene, *Crz*, a neuropeptide that has been shown to be involved in glucose and lipid metabolism by playing a role in regulating insulin-producing cells. We used a *Crz-Gal4* driver to knockdown *Glut1* specifically in the *Crz*-expressing neurons and measured TAGs and glycogen. Inducing RNAi to *Glut1* in *Crz* neurons resulted in a decrease in glycogen in males, but not in females, while there was no change in glucose and TAG in either sex. These data suggest that Glut1 acts in the *Crz* neurons to regulate carbohydrate homeostasis within male *Drosophila*.

490F **Effects of alterations in vesicular acetylcholine transporter expression on acetylcholine homeostasis in the central nervous system** Rohina A. Nemat, Benjamin A. Church, Hakeem O. Lawal Biological Sciences, Delaware State University

Acetylcholine neurotransmission is necessary for the regulation of essential life functions such as locomotion and cognition. As a result, increases or decreases in neuronal cholinergic signaling lead to an impairment in learning and memory, and normal locomotive functions. Although much about how acetylcholine is regulated is known, the mechanism through which changes in cholinergic signaling effects changes in ACh-linked behavior is not fully understood. The vesicular acetylcholine transporter (VAChT) mediates the packaging and transport of acetylcholine (ACh) for exocytotic release. However, the manner through which this process occurs and is regulated is not fully understood. Here we use both an overexpression of VAChT (using a construct that we have reported on previously) and mutants in *Vacht* that cause varying decreases in the gene's expression, as tool to increase or decrease (respectively) the amount of ACh released into the synaptic cleft. And we are measuring the effect of that altered state on synaptic activity using a biochemical approach. We have optimized an assay that allows us to reliably measure cholinergic pathway components ACh and choline from as little as ten *Drosophila* heads. Using this assay, we report the surprising data that while VAChT overexpression does not increase total head ACh levels, there is an increase in choline levels, suggesting that there are homeostatic consequences for changes in VAChT expression. We also present preliminary findings from similar experiments with *Vacht* mutants that have reduced transporter expression. Importantly, we report the effects of increase or decreases in *Vacht* expression of the distribution of VAChT to synaptic vesicles relative to other subcellular compartments using super resolution microscopy. Taken together, these data provide important insight into the consequences that follow a disruption in VAChT expression and advance our understanding of how the vesicular acetylcholine transporter mediate the exocytotic release of ACh in *Drosophila*.

491F **Cell-specific genetic manipulation of Drosophila sallimus severely impacts muscle and motor-neuron morphology and physiology.** Andrew H Michael, Tadros A Hana, Veronika G Mousa, Kiel G Ormerod Biology, Middle Tennessee State University

Skeletal muscle allows animals to produce movement, facilitating a robust set of behaviors and interaction with our environment. The ability of skeletal muscles to contract is derived from the unique genes and proteins that are expressed within muscles, most notably thick and thin filaments, and elastic proteins. Within *in vivo* systems investigations of these proteins are particularly difficult as they often lead to gross phenotypic changes, compensatory mechanisms, or lethality. To circumvent this limitation, Drosophila biologists exploit the Gal4/UAS system to selectively express transgenic manipulations in a subset of cells. Here we investigate the role of the sallimus (sls) protein, which encodes a homologue of titin, in muscle development and function at the larval neuromuscular junction. RNA interference (RNAi) of sls using a ubiquitously expressed muscle driver caused embryonic lethality. We next screened for muscle drivers that express in subsets of larval body wall muscles and identified a driver which expresses Gal4 only in muscle fiber 12 (MF12). Knocking down sls using MF12-Gal4 did not impact larval viability. Immunostaining for elements of the sarcomere revealed significant changes in the structure of MF12. Surprisingly, muscle-specific knockdown of sls in MF12 also resulted in drastic changes in synaptic morphology. We also reveal dramatic changes in the size and number of nuclei in the affected muscles. Using our muscle force transducer system, no obvious changes in whole larval force production were observed. Changes in larval crawling are currently being explored. Mutations in human titin are known to cause cardiomyopathies. Dilated cardiomyopathy is associated with mutations in genes encoding sarcomere proteins, with mutations in titin being the most frequent. This disease is found in ~ 1/ 20 000 individuals but causes 10,000 deaths and 46,000 hospitalizations yearly in the United States. Dilated cardiomyopathy is the most common reason for heart transplantation and the third most common reason for heart failure. Despite the prominence and impacts of these diseases, *in vivo* model organism studies of these elastic protein defects are minimal due to the associated lethality. This

work in *Drosophila* provides a potential *in vivo* model for investigations of titin, other elastic proteins, and of muscle proteins generally.

492F **Addressing the role of endosomal Microautophagy in health and diseases** Satya Surabhi[1], Andreas Jenny[2] [1]Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, [2]1.Department of Developmental and Molecular Biology; 2.Department of Genetics, Albert Einstein College of Medicine

Autophagy is a catabolic process that degrades damaged organelles and aggregate-prone proteins and thus is essential for development and cellular homeostasis. It is induced in response to different stressors including starvation, oxidative stress, and accumulation of misfolded proteins. As such, it counteracts various human diseases, and its reduction leads to aging-like phenotypes. Of the three major forms of autophagy, Macroautophagy can degrade organelles or aggregated proteins, and Chaperone-mediated autophagy is specific for proteins containing KFERQ-related targeting motifs. Endosomal Microautophagy (eMI), is a form of autophagy during which substrates are taken up into multivesicular bodies for degradation in a KFERQ-specific manner or in bulk.

Among the three forms of autophagy, the physiological role of eMI is poorly understood. Using a KFERQ-tagged fluorescent biosensor, we are characterizing the physiological role of eMI with a focus on what types of cellular stress activate eMI. Our data suggest that oxidative stress and DNA damage, but not ER stress can elicit an eMI response in an ESCRT machinery-dependent manner, implying a stress-selectivity of the process. Further, we are trying to understand the mechanism of stress-induced eMI by identifying novel regulators of the eMI pathway. We have identified Wiskott-Aldrich Syndrome Protein (WASp) as an eMI regulator that alters the kinetics of eMI induction, as its overexpression results in faster eMI induction in a Cdc42-dependent manner.

Since targeting autophagic pathways has been proposed as a treatment strategy, particularly in non-dividing neurons, we currently are testing the effect of boosting eMI with WASp on the degradation of faulty proteins in fly models of human neurodegenerative disease. We anticipate that the physiological role of eMI in stress regulation and neurodegeneration is conserved in humans.

493F **The effect of loss of ER membrane complex subunit 4 (EMC 4) on life history traits in *Drosophila melanogaster* is cell type-dependent** Otoha Tatami, Maria Jose Orozco Fuentes, Inés Riojas, Rebecca Delventhal Lake Forest College

The endoplasmic reticulum (ER) is involved in the modification, packaging, and insertion of membrane proteins in the cell. The ER membrane protein complex (EMC) is composed of 8-10 subunits that work together to facilitate protein biogenesis. Through a previous RNAi screen, our lab observed that fruit flies (*Drosophila melanogaster*) with a knockdown of the EMC subunit 4 in glial cells resulted in delayed development and a very short lifespan of 5-6 days instead of the normal 2-3 months. We wondered whether EMC4 plays an important role in other types of cells, so we conducted a small screen knocking down EMC4 in different cells of the fly's brain and body utilizing the UAS-Gal4 system. We knocked down expression of EMC4 in all cells, all neurons, subtypes of neurons (insulin-producing and circadian regulatory neurons), a subtype of glia (astrocytes) as well as hemocytes and fat body cells. Knockdown of EMC4 in some cell types (all neurons and insulin-producing neurons), but not all, resulted in a similar developmental delay as seen with the glial knockdown. We also found that the strength of knockdown appears to have an impact, as a weak pan-neuronal driver resulted in a developmental delay, yet the knockdown with a stronger pan-neuronal driver was pupal lethal. Knockdown in none of the other cell types led to as severe of a decrease in lifespan as in glia, but a knockdown in circadian regulatory neurons led to a lifespan of 23-28 days. Interestingly, EMC4 knockdown in some cells resulted in sex-specific increases in their lifespans. Taken together, these findings suggest that EMC4 plays different roles in different cell types and that the loss of EMC4 in some cell types can affect organismal phenotypes such as lifespan and developmental timing. Future research will focus on exploring how EMC4 knockdown affects specific cell functions by measuring phenotypes tied to the expected role of that cell type in *Drosophila*. This will include testing starvation sensitivity of flies with EMC4 knockdown in insulin-producing or fat body cells and measuring circadian activity of flies with knockdowns in circadian regulatory neurons. Overall, our research highlights the potential importance of the role of EMC in producing membrane proteins, which are crucial for many aspects of the nervous system.

494F **Trehalose accumulation rescues altered Ca^{2+} homeostasis phenotypes of the *S. cerevisiae pgm2Δ* mutant** Micaiah M. Wetzold, Niki M. Hamraei, Kelly A. Hernandez, Lara I. Shehadeh, Shruti V. Raghavan, Zoya Waheed, Katherine E. McBroom, Shreya Uppala, Sarah J. Smith, Akshaya Selvamani, Rebecca J. McDonald, Pranavya M. Manickavelu, Krishna Patel, Katrina Ngo, Ashley Charales, Vana Bahram, David P. Aiello Biology, Austin College

Phosphoglucomutase (*PGM*) interconverts glucose-1-phosphate (G1P) and glucose-6-phosphate (G6P) in *Saccharomyces cerevisiae*. Yeast lacking *PGM2*, the major isoform of *PGM*, exhibit slow growth, calcium homeostasis defects, increased G1P accumulation, and a hyperaccumulation of glycogen when metabolizing galactose as a carbon source. Previous work in the

lab demonstrated that increased trehalose synthesis resulting indirectly from *GPH1* overexpression has a rescue effect on the *pgm2Δ* mutant. It is hypothesized that the partial rescue of *pgm2Δ* mutant phenotypes is due to the protective effect of increased trehalose levels in response to the stress induced by the *pgm2Δ* mutation. To examine the effect of trehalose accumulation on the calcium homeostasis defects in the *pgm2Δ* mutant, we both increased and decreased trehalose presence in *pgm2Δ* mutants metabolizing galactose. Trehalose hydrolysis is predominantly driven by two enzymes, acid vacuolar trehalase, and neutral cytosolic trehalase, encoded by *ATH1* and *NTH1,* respectively. *ATH1* and *NTH1* were each knocked out and overexpressed in the context of the *pgm2Δ* mutation. Loss of *ATH1* function rescues the growth sensitivities associated with the *pgm2*Δ mutant. Alternatively, the overexpression of *ATH1*, which promotes vacuolar trehalose hydrolysis, exacerbates the *pgm2*Δ growth defects. Furthermore, the overexpression of the neutral cytosolic trehalase, *NHT1*, exacerbates the growth defects associated with the *pgm2*Δ mutant to a lesser extent when compared to *ATH1* overexpression. This may indicate that vacuolar trehalose plays a larger role in the rescue of the *pgm2Δ* mutant. Our results support the hypothesis that trehalose accumulation has a protective effect in the *pgm2*Δ mutant.

495F **Altered reserve carbohydrate metabolism rescues altered growth phenotypes of the *S. cerevisiae pgm2Δ* mutant** Niki M. Hamraei, Micaiah M. Wetzold, Kelly A. Hernandez, Luke T. Wild, Lara I. Shehadeh, Shruti V. Raghavan, Zoya Waheed, Katherine E. McBroom, Shreya Uppala, Sarah J. Smith, Akshaya Selvamani, Rebecca J. McDonald, Pranavya M. Manickavelu, Krishna Patel, Katrina Ngo, Ashley Charales, Vana Bahram, David P. Aiello Biology, Austin College

Phosphoglucomutase (*PGM*) is responsible for interconverting glucose-1-phosphate (G1P) and glucose-6-phosphate (G6P) in *Saccharomyces cerevisiae*. Yeast lacking *PGM2*, the major isoform of *PGM*, exhibit slow growth, calcium homeostasis defects, and an accumulation of glycogen when metabolizing galactose as a carbon source. While decreasing glycogen accumulation has little effect, increasing glycogen breakdown by overexpression of *GPH1*, encoding glycogen phosphorylase, partially rescues *pgm2Δ* mutant defects. This rescue due to *GPH1* overexpression is also accompanied by an increase in trehalose levels in the cell. The nonreducing disaccharide trehalose is known to have protective properties in yeast cells undergoing a variety of stress responses. We hypothesized that the partial rescue of *pgm2Δ* mutant phenotypes is due to the protective effect of increased trehalose levels in response to the stress induced by the *pgm2Δ* mutation. Indeed, we show that overexpression of trehalose-6-phosphate synthase 1 (*TPS1*) increases trehalose levels and rescues *pgm2Δ* growth defects. Alternatively, the *tps1Δ* mutant exacerbates *pgm2Δ* mutant phenotypes, supporting the hypothesis that increased trehalose can suppress *pgm2Δ* growth defects. To further test this hypothesis, we investigated the roles of *ATH1*, encoding acid vacuolar trehalase, and *NTH1*, encoding neutral cytosolic trehalase, in maintaining cellular levels of trehalose in the *pgm2Δ* mutant. Our data further supports the hypothesis that trehalose accumulation has a protective effect in the *pgm2*Δ mutant.

496F **In vivo Proximity Labeling Identifies New Functions for the Lifespan and Autophagy-regulating Kinase Pef1, an Ortholog of Human Cdk5** Haitao Zhang[1], Dong-Mei Zhang[2], Belinda Willard[2], Kurt W Runge[1] [1]Inflammation and Immunity, Cleveland Clinic Lerner Research Institute, [2]LRI Research Core Services, Cleveland Clinic Lerner Research Institute

Cdk5 is a noncanonical cell division kinase important to the terminal differentiation of cells in the nervous system, musculature and kidney. Human cdk5 can substitute for its ortholog in various fungi, showing that cdk5, its cyclins and their activities are conserved across evolution. We previously identified the *Schizosaccharomyces pombe* ortholog of cdk5, Pef1, as regulator of chronological aging and autophagy. To better understand cdk5 function, we used proximity labeling in *S. pombe* to identify proteins that may transiently interact with or bind to Pef1. The APEX2 system, which is activated to biotinylate proteins within an ~10 nm radius by the addition of 1 mM H_2O_2 for 1 minute, was chosen for its short labeling times and robust user-initiated biotinylation. Labeling was optimized by partially digesting the cell wall to increase uptake of the biotin-phenol substrate for the reaction. We also found that immunodepletion of the endogenous biotinylated proteins (pyruvate carboxylase and acetyl CoA carboxylase) from cell extracts did not markedly improve detection of APEX2 labeled proteins.

The APEX2 ORF was fused to the end of the chromosomal Pef1 gene, and proximity labeling was followed by purification of the biotinylated proteins and identification by mass spectroscopy. Of the 255 high-confidence Pef1 neighbors identified in growing cells, one was the 14-3-3 protein Rad24, a regulator of the DNA damage response. The Pef1-Rad24 interaction was validated by reciprocal proximity labeling and co-immunoprecipitation. Deleting the *rad24*$^+$ gene caused the expected reduction in growth on medium with DNA damaging agents, while cells lacking both Pef1 and Rad24 grew better under these conditions, indicating partial rescue of the DNA damage sensitivity. Thus, proximity labeling revealed a novel function for Pef1 in DNA repair. To monitor how Pef1 protein neighbors change under different conditions, we have applied this approach to cells starved for nitrogen to induce autophagy. We identified 177 high-confidence Pef1 neighbors in autophagic cells, 80 of which were not detected in growing cells. GO slim analysis of the Pef1 neighbors' biological functions identified proteins in two processes required in autophagy: regulating actin dynamics and vesicle-mediated transport. These data suggest that Pef1 may regulate autophagy through these two processes.

Supported by grants NIH AG R01 051601 and NSF 1908875.

497F **Characterizing the role of *YDL206W* in *Saccharomyces cerevisiae*** Leah Ding, David P Aiello Biology, Austin College

In *Saccharomyces cerevisiae*, the enzyme phosphoglucomutase (PGM) conducts interconversion between the metabolites glucose-1-phosphate (G1P) and glucose-6-phosphate (G6P). The gene *PGM2* encodes for the major isoform of the enzyme. Previous research has shown that galactose-grown cells lacking *PGM2* exhibit a slow-growth phenotype and an altered ratio of G1P to G6P in comparison to galactose-grown wildtype cells. The *pgm2Δ* strain also exhibits defects in calcium ion homeostasis, including increased calcium uptake, elevated intracellular calcium accumulation, sensitivity to high extracellular calcium levels, and sensitivity to the calcineurin inhibitor cyclosporin A. Previous research using RNA-Seq and DESEQ-2 analysis identified that the loss of *PGM2* altered gene expression globally. One of the genes that displayed elevated expression levels in *pgm2Δ* was *YDL206W*, an uncharacterized ORF with no direct characterization study until recently. Previous work suggests that *YDL206W* encodes a Na+/Ca2+ exchanger (NCX) protein localized to the vacuolar membrane. It was also categorized within the Calcium Cation Antiporter (CaCA) Superfamily, along with its human ortholog *SLC8B1*. This study aims to characterize the role of *YDL206W*, the localization of its encoded protein, and its relation to *pgm2Δ* growth phenotypes and calcium homeostasis defects. By investigating whether *YDL206W* contributes to the calcium homeostasis defects of *pgm2Δ*, this study could elucidate whether *YDL206W* would function as a model gene for *SLC8B1* to better understand how *SLC8B1* regulates calcium ion homeostasis in humans.

498F **Molecular Logic of TORC1 regulation through Gtr1/2 and Pib2** Andrew Capaldi University of Arizona

The Target of Rapamycin kinase Complex 1 (TORC1) is the master regulator of cell growth and metabolism in eukaryotes. In the presence of pro-growth hormones and abundant nutrients, TORC1 is active and drives growth by stimulating protein, ribosome, lipid, and nucleotide synthesis. In contrast, when hormone or nutrient levels drop, TORC1 is inhibited, causing the cell to switch from anabolic to catabolic metabolism and eventually enter a quiescent state.

Numerous proteins and pathways have been shown to regulate TORC1, including: (i) the small GTPases Rag A/B and C/D and the associated GTPase Activation Protein (GAP), GATOR1/2; (ii) Rheb and the Tuberous Sclerosis Complex; (iii) AMPK; (iv) the Nemo-like kinase; (v) PKA; and (vi) Arf1. However, it remains unclear how the proteins/pathways listed above (and others) cooperate to control TORC1.

Here, to address this question, we examine signal integration at TORC1 in the simple model organism, *Saccharomyces cerevisiae*. Previous work in *S. cerevisiae* has shown that amino acid and nitrogen signals are transmitted to TORC1 via: (1) a heterodimeric pair of small GTPases that are homologous to RagA/B and RagC/D, called Gtr1 and Gtr2. (2) The phosphatidylinositol 3-phosphate binding protein, Pib2. But how and why do Gtr1/2 and Pib2 work together to regulate TORC1?

In this study, we examine the impact that Gtr1/2 and Pib2 have on TORC1 signaling across the proteome, using a combination of phosphoproteomics and standard reporter assays. The resulting data show that Gtr1/2 and Pib2 are both required for full TORC1 activation. Importantly, however, deletion of Gtr1/2 or Pib2 only blocks signaling to a subset of the TORC1 substrates—primarily those involved in amino acid metabolism and nutrient transport. These observations lead us to propose a new model where partial starvation triggers metabolic reprograming via TORC1 (by inactivating Gtr1/2 or Pib2) but does not block cell growth. And in follow up experiments, we confirm that this is, indeed, the case. Specifically, we show that when yeast are first transferred from medium containing a high quality nitrogen source, to medium containing a low quality nitrogen source, TORC1 is completely inhibited to block growth and activate metabolic reprogramming. Then, as the cells adapt to the low-quality nitrogen source, Pib2 is turned on again to re-initiate growth, while Gtr1/2 remains mostly off to ensure that the cells continue to activate the metabolic pathways and transporters necessary for adaptation/survival.

Thus, the TORC1 circuit in yeast uses two different amino acid/nitrogen signaling proteins to drive the cell into a rapid growth state, an adaptive growth state, or a quiescent state, depending on the environmental conditions. We argue that other signaling pathways probably work in a similar way, but multi-level responses tend to be overlooked since most studies follow signaling to a single reporter protein.

499F **Studying the Mechanism for Ribosome-Inactivating Protein-Induced Apoptosis** Daniel Judge West Virginia University

Apoptosis, a conserved process of programmed cell death, can be activated through diverse cellular mechanisms, many of which remain poorly understood. This study focuses on a specific mechanism triggered by ribosome-inactivating proteins (RIP), a category of potent toxins such as ricin and sarcin. Ricin halts translation by irreversibly damaging large ribosomal subunit rRNA through an adenine N-glycosidic cleavage referred to as depurination. While the role of the catalytic subunit of

ricin, known as ricin toxin A chain (RTA), is well-established, the precise process that initiates apoptosis in RTA-compromised cells remains unclear. Importantly, while ricin induces apoptosis, translation inhibitors employing mechanisms other than depurination, such as the peptidyl transferase inhibitor anisomycin, often only induce cell cycle arrest. Ribosome depurination may be a critical step in initiating apoptosis. We hypothesize that ribosomes translating on the same mRNA would collide with the stalled depurinated ribosome resulting in improper recycling when translation terminates. The resulting physical damage to ribosomes would activate ribosome quality control mechanisms, ultimately leading to apoptosis. Disomes resulting from random or induced ribosome collisions activate the integrated stress response. In this study, we will utilize an *in vivo* ricin reporter plasmid to modulate RTA gene expression and examine the apoptotic response in *Saccharomyces cerevisiae*. Previous studies have used galactose-inducible promotors, requiring yeast to be grown on an alternative carbon source that represses ribosome biogenesis. We will use a tetracycline-regulatable promoter novel to RIP studies in yeast, allowing for growth on traditional dextrose media. We will closely monitor ribosomal biogenesis, localization, and degradation before and during apoptosis and compare the effects of wildtype RTA to catalytically dead mutants such as E177K, S215F, and P95L, which do not induce apoptosis. Genetic screens will be conducted to identify the essential elements required for ricin-induced apoptosis, and in-lab evolution experiments will be carried out to identify mutations that confer resistance to ricin-induced apoptosis. Long-term, this research aims to provide a comprehensive understanding of the cellular pathways affected after exposure to RTA and establish a controlled method for reliably inducing apoptosis in specific target cells. The insights gained from this study are likely to have broader implications in the fields of cancer biology, embryology, and immunology, offering new avenues for exploring cellular homeostasis and understanding how cells respond to stress.

500F **Maternal Regulation of Microtubule Organizing Centers in the Egg and Oocyte** Allison Marvin[1], Ruth Cisternas[2], Ronald Heller[2], Ricardo Fuentes[2], Mary Mullins[1] [1]University of Pennsylvania, [2]Universidad de Concepcion

The centrosome is a vital organelle that serves as the main microtubule organizing center (MTOC) of the cell. One of its most crucial functions is to duplicate and form a bipolar spindle structure for chromosome division in mitosis. The faithful division of genetic material is likewise important in meiosis, but the female gamete comprises a special case of microtubule (MT) organization. In early oogenesis, the oocyte disassembles its centrosome. This elimination of the maternal centrosome is conserved across most metazoans and protects the zygote from early aneuploidy. Despite its conservation, maternal centrosome elimination remains poorly understood. In the absence of centrosomes, several noncanonical MT organization strategies have been identified in model species and humans, including acentrosomal MTOCs (aMTOCs). The mechanisms by which oocytes control noncanonical MTOCs spatially and temporally remain obscure. Thus, MTOC regulation during oogenesis is not well-understood, despite its function to prevent aneuploidy in development. We performed a large scale forward genetic screen to identify maternal factors required for early development. This screen generated a maternal-effect mutant whose offspring exhibit numerous ectopic aster-like MT formations and fail to complete the first cell division. This work aims to determine if the ectopic structures are centrosomes or aMTOCs, which will establish the function of the gene mutated as a mediator of centrosome elimination or as a negative regulator of aMTOCs during oogenesis. Our vertebrate model will advance understanding of MT organization in oogenesis and in the egg. Given the importance of proper MT organization for human fertility, this work will address knowledge gaps in the advancement of fertility treatments. Research reported in this abstract was supported by the National Institute of General Medical Sciences of the National Institutes of Health under award number R35GM131908 and in part by T32 HD083185.

501F **Reactive oxygen species (ROS) relax wounds to allow healing and regrowth.** Chang Ding Purdue University

The reactive oxygen species (ROS), pivotal secondary messengers, promote wound healing and tissue regeneration. However, whether ROS trigger wound closure by regulating wound mechanical behaviors remains unknown. Using pharmacological inhibitors and genetic modifications, we observed that ROS relax wound contraction. ROS production-inhibited groups exhibit prolonged wound contraction periods after wounding and impaired tailfin regrowth two days post-amputation. Notably, DPI-treated groups show delayed wound closure 30 mins after wounding, while the control group's epithelia mechanically restore their barrier function. To further delineate the underlying mechanisms through which ROS regulate wound dynamics, we employed inhibitors targeting Rho-associated coiled-coil-containing protein kinase (ROCK) and the myosin light chain kinase (MLCK). The ROCKOUT-treated groups exhibit reduced contraction extent and duration compared to controls, while the ML-7-treated group does not contract at all post-amputation. In addition, ML-7 supplement immediately after amputation eliminates the contraction period after wounding, even under the background of DPI treatment, indicating downstream regulation of MLCK by ROS. In summary, we revealed that ROS relax wound contraction to allow wound closure through actomyosin regulation, which may offer novel therapeutic strategies for promoting wound closure, especially in chronic wounds.

502S **RAB-10 Antagonizes the AP-1 Clathrin Adaptor to Promote EGFR Signaling in C. elegans** Clare FitzPatrick[1], Christian E Rocheleau[2] [1]McGill, [2]Anatomy and Cell Biology, McGill

Polarized trafficking and signaling is critical to cellular function and development. *C. elegans* Epidermal Growth Factor Receptor (EGFR) localizes to the apical and basal membranes of the vulva precursor cells. However, it is the basal pool of EGFR that is essential for proper vulva induction. We have previously characterized an AGEF-1 (an Arf guanine nucleotide exchange factor), ARF-1 GTPase and AP-1 clathrin adaptor pathway that antagonizes EGFR basal localization and signaling. Loss of *agef-1* results in increased basal EGFR and ectopic vulva induction. We found that the RAB-10 GTPase is required for the mislocalization of EGFR in *agef-1* mutants. Furthermore, RAB-10 is required for the negative effects on EGFR signaling caused by AGEF-1 and ARF-1, but not AP-1, suggesting that RAB-10 functions via AP-1. We found that AP-1 localization in the induced vulva precursor cells is strongly reduced, and this requires EGFR, the downstream Ras GTPase, and RAB-10. Furthermore, RAB-10 localization to cytoplasmic foci is increased in the induced vulva precursor cells and RAB-10 overexpression displaces AP-1 from intracellular compartments into the cytoplasm. We hypothesize that EGFR/Ras signaling promotes EGFR localization to the basal membrane in the vulva precursor cells via activation of RAB-10 which in turn inhibits AP-1. The goal of this study is to determine how EGFR signaling regulates AP-1 localization and RAB-10 activity as well as determine how RAB-10 regulates AP-1.

503S **Securin Regulates the Spatiotemporal Dynamics of Separase** Christopher G.S. Turpin[1], Marian LaForest[2], Dillon Sloan[3], Lindsey Uehlein-Klebanow[4], Diana Mitchell[5], Aaron Severson[6], Joshua N Bembenek[7] [1]Wayne State University, [2]Columbia University, [3]University of North Carolina, [4]Esko Bionics, [5]University of Idaho, [6]Cleveland State University, [7]Mott Center for Human Growth and Development, Wayne State University

Separase is a key regulator of the metaphase to anaphase transition with multiple functions. Separase cleaves cohesin to allow chromosome segregation and localizes to vesicles to promote exocytosis in anaphase. The anaphase promoting complex/cyclosome (APC/C) activates separase by ubiquitinating its inhibitory chaperone, securin, triggering its degradation. How this pathway controls the exocytic function of separase has not been investigated. During prometaphase I in *C. elegans* oocytes, separase and securin colocalize to kinetochore structures at the spindle and in the cortical cytoplasm. Securin is signal decreases substantially over several minutes prior to anaphase onset. After significant securin reduction, separase quickly relocalizes from kinetochore structures to sites of action on chromosomes and vesicles at anaphase onset. Separase does not colocalize with cohesin at the midbivalent region of chromosomes until seconds before cohesin loss and poleward movement of chromosomes. Inactivation of APC/C traps separase on kinetochore structures and prevents separase localization to the midbivalent or vesicles. In contrast, partial securin depletion by RNAi causes precocious separase vesicle localization and abnormal chromosome localization. Given that APC/C and securin depletion have pleiotropic effects, we overexpressed non-degradable Securin fused to GFP (Securin^{DM}) to determine how it affects separase in the presence of normal APC/C activity. Securin^{DM} is stably expressed during anaphase and causes severe embryonic lethality, chromosome segregation defects, polar body extrusion failures and inhibition of cortical granule exocytosis. SecurinDM localizes with separase to kinetochore structures prior to anaphase onset. However, Securin^{DM}interferes with separase localization to vesicles but not the spindle during anaphase. This data suggests that Securin^{DM}inhibits separase binding to vesicle substrates but does not inhibit interactions with kinetochore proteins at the spindle. We conclude that APC/-induced securin degradation controls separase localization. This spatiotemporal regulation will impact the effective local concentration of separase for more precise targeting of substrates in anaphase.

504S **Temperature effects on proteostasis in *C. elegans*** Nhan V.T. Huynh[1], Cole J. Shifferly[1], Jordan B. Carter[1], Grant M. Johnson[1], Erika B. Sorensen[2], Walter R.P. Novak[3] [1]Wabash College, [2]Biology, Wabash College, [3]Chemistry, Wabash College

The 26S proteasome is important for maintaining proteostasis in eukaryotic organisms and possesses multiple proteolytic active sites for cleavage after basic (trypsin-like, TL), acidic (chymotrypsin-like, CT-L) and hydrophobic (caspase-like,CL) residues. The *C. elegans glp-1*(*e2141ts*) mutant grown at restrictive temperature (25 ˚C) has several phenotypes including a germline stem cell proliferation defect, longevity, and a pronounced increase in CT-L proteasomal activity relative to wild type animals and *glp-1*(*e2141ts*) mutants grown at permissive temperature (15 ˚C). Interestingly, different animals show a temperature-dependent reduction in proteasomal activity at higher ambient temperatures. In *C. elegans*, short-term heat stress causes an increase in proteasomal activity in some tissues but no change in others. We set out to assess the proteasomal activity in Glp-1 and wild type animals grown at low (15 ˚C) and high (25 ˚C) temperatures to determine the impact of both temperature and genotype on proteostasis. In alignment with previous studies, we observed that Glp-1 worms have a pronounced increase in CT-L activity when grown at restrictive temperatures, assessed using the fluorogenic substrate Z-GGL-AMC. Proteasome inhibitors such as bortezomib and MG132 are often used to determine background proteasome activity when using fluorescent substrates; however, these inhibitors are not specific for the proteasome and may also inhibit cellular proteases. We observed that while bortezomib inhibits *glp-1*(*e2141ts*) and wild type proteasome activity at 25 ˚C, there was a substantial increase in proteolysis of CT-L substrate in the presence of bortezomib in lysate from worms grown at 15 ˚C, regardless of genotype. To test if additional proteases might be responsible for CT-L cleavage observed in lysate from animals 15 ˚C, we added a protease inhibitor cocktail (PIC). PIC completely abolished the background activity in N2 and *glp-1*(*e2141ts*) animals grown at 15 ˚C. Our results show there are temperature-induced differences in the proteolytic components

responsible for maintaining proteostasis in *C. elegans*. This finding may impact other studies which rely on the assumption that proteostasis is consistent from 15-25 ˚C in wild-type worms.

505S **Molecular and genetic interactions between the DBL-1/BMP signaling pathway and BLMP-1/BLIMP1 regulate organismal traits** M. Farhan Lakdawala[1,2], Matt Crook[3], Tina L. Gumienny[1] [1]Biology, Texas Woman's University, [2]AbbVie (United States), [3]Biology, Wofford College

Bone morphogenetic protein (BMP) signaling helps orchestrate multiple organismal traits throughout the lifetime of animals by regulating target gene expression. Regulation of this signaling pathway is critical for normal development and homeostasis, but an understanding of how this pathway's transcription regulators, called Smads, control target gene expression to generate different traits is not well understood. In the roundworm *Caenorhabditis elegans*, BMP member DBL-1 and its signaling pathway are involved in a spectrum of postembryonic developmental traits. Using the *C. elegans* system, we identified the conserved chromatin remodeler and transcriptional regulator B-lymphocyte-induced maturation protein-1 (BLIMP1) homolog BLMP-1 as a partner in Smad-mediated gene expression regulation. Previous studies in show that BLMP-1 affects a similar array of traits as the DBL-1 signaling pathway. However, the relationship between BMP and BLIMP1 in a post-embryonic developmental context in any animal has not been clarified. While body size was smaller than either single mutant, *blmp-1(tm548)* was epistatic to DBL-1 pathway mutants for lipid content, male tail development, hermaphrodite gonad development, brood size, movement, and survival traits. We showed the DBL-1 signaling pathway and BLMP-1 transcriptionally regulate each other. We also identified a physical interaction between BLMP-1 and the DBL-1 pathway Smads using yeast-two hybrid analyses. Using bioinformatics and qPCR analysis, we showed that Smads and BLMP-1 regulate many common downstream target genes. This work identifies novel interactions between the DBL-1 signaling pathway and BLMP-1, two conserved major transcriptional regulators, that ultimately influence a spectrum of organismal traits.

506S **Regulation of *C. elegans* germline stem and progenitor cell mitosis by developmental and environmental signaling networks.** Eric Cheng, Ran Lu, Abigail Gerhold Biology, McGill University

Equal partitioning of the replicated genome is essential to produce genetically identical daughter cells during mitosis. How mitotic fidelity is affected by physiological changes in developmental or environmental signaling networks remains unclear. *C. elegans* germline stem and progenitor cells (GSPCs) provide an excellent model system in which to investigate the influence of signaling networks on mitotic cells within their native environment. Using *in situ* live-cell imaging, we have shown that caloric restriction and developmental changes affect GSPC proliferation and are associated with a prolonged duration of GSPC mitosis, as measured from nuclear envelope breakdown to anaphase onset. Here we investigated whether developmental signaling pathways also affect GSPC mitotic timing. We find that reducing activity of the insulin receptor *daf-2*/IGFR (*daf-2(e1370*)) leads to an increase in the duration of GSPC mitosis that depends on the mitotic checkpoint. *daf-2(e1370)* also enhances the sterility of checkpoint null mutants and may increase the frequency of chromosome segregation defects, suggesting that reducing *daf-2/*IGFR activity compromises mitotic fidelity in GSPCs. *daf-2(e1370*) mitotic delays depend on the canonical insulin signaling pathway, converging on the regulation of DAF-16/FOXO. However, despite a measurable increase in DAF-16/FOXO nuclear localization in *daf-2(e1370*) GSPCs, we find that this does not predict mitotic duration, and that both DAF-2/IGFR and DAF-16/FOXO are required in the soma, and not in the germline, to affect GSPC mitosis. In addition, although *daf-2(e1370*) phenocopies the effect of caloric restriction on GSPC mitosis, we find that mitotic delays upon caloric restriction require *daf-18*/PTEN and *aak-1/2*/AMPK, but not *daf-16*/FOXO. Overall, our work indicates that distinct signaling networks make genetically separable contributions to the regulation of mitosis in GSPCs and highlight the challenges cells face to preserve mitotic timing and fidelity in complex physiological environments.

507S **A novel molecular mechanism underlying the attachment of myosin A in *C. elegans* striated muscle with the M-line component UNC-89/obscurin** Sarah A Almuhanna[1], Humayra Oishi[2], KarMen Lee[2], Pamela E Hoppe[2] [1]4Clinical Laboratory Sciences, Imam Abdulrahman bin Faisal University, [2]Biological Sciences, Western Michigan University

The goal of this study was to determine the role of different M-line proteins in mediating the attachment of the myosin filaments to the M-line. The contractile unit of striated muscle is the sarcomere, in which myosin-containing thick filaments slide the actin-containing thin filaments to shorten sarcomere length. The M-line is a focal-adhesion-like structure that is anchored at its base to the muscle cell plasma membrane and, through integrin-mediated attachments, to the surrounding basal lamina that is adjacent to the epidermis and cuticle of the body wall. In *C. elegans* the central portion of the thick filament, which attaches to the M-line, is formed by myosin A whereas the filament arms are formed by myosin B. The M-line components that link myosin A to the large structural M-line component UNC- 89/obscurin were investigated using in vivo assays testing the ability of UNC-89/obscurin to associate with myosin A within the contractile apparatus or in ectopic accumulations of filamentous myosin A in different mutant backgrounds. The results showed that the zinc-finger (ZnF) protein UNC-98, but not UNC-82/NUAK kinase or UNC-96, is required for association of UNC-89/obscurin with ectopic myosin

structures. However, UNC-89/obscurin localization to the M-line in the contractile apparatus can occur independently of UNC-98/ZnF. UNC-98/ZnF was detected in the ectopic myosin A structures, but the focal adhesion protein UNC-97/PINCH, which binds to UNC-98/ZnF, was not. Experiments using chimeric myosins revealed that a 170-residue region of the myosin A C-terminus that is known to bind UNC-98/ZnF is sufficient to localize UNC-98/ZnF and UNC-89/obscurin to the M-line in worms lacking endogenous myosin A. An interaction between myosin A and UNC-89/obscurin during development is supported by the highly disrupted localization of UNC-89/obscurin in embryos lacking myosin A. The defects are due to loss of myosin A rather than loss of contraction since UNC-89/obscurin organizes in a mutant lacking the thin-filament protein troponin. Our results identify a novel molecular mechanism underlying attachment of the thick filaments to the M-line and reveal the importance of myosin A in organizing the M-line structure during early development.

508S **Dual transcriptional programs coordinate lipogenic and UPR^{Golgi} programs in *C. elegans* and human cells** Amy K Walker[1], Matthew Fanelli[2], Daniel Higgins[2], Christofer Welsh[2] [1]Program in Molecular Medicine, UMASS Medical School, [2]PMM, UMASS Medical School

Preserving membrane homeostasis is essential for cell structure, organelle function, and signaling. This homeostasis is disrupted when low phosphatidylcholine (PC) causes cells to overproduce stored lipids. We previously discovered that a master regulator of lipogenic transcription, SREBP-1 (*C. elegans* SBP-1), is proteolytically activated in low PC, stimulating fat storage in *C. elegans*, murine liver, and human cell lines. SREBPs are stored in the ER membrane and released by cleavage by Golgi-resident proteases. Subsequently, we found that the phospholipid imbalances activating SBP-1/SREBP-1 are likely to act by disrupting function of the ARF1 GTPase, a key regulator of Golgi/ER traffic. Thus, imbalances in phospholipids can feedback to activate SBP-1/SREBP-1 and lipid production by altering .

In C. elegans, we noted that imbalances in phospholipid levels through interference with PC production drive high-level expression of an ARF1 paralog, *warf-1/arf-1.1*. WARF-1 differs from ARF-1/ARF1 primarily in the N-terminal membrane-insertion helix. We hypothesized that warf-1 might be part of a transcriptional program compensating for the loss of ARF-1/ARF1 function when phospholipid levels are imbalanced. Indeed, we found that *warf-1* is required for *arf-1* RNAi animals to grow past initial larval stages, showing that this paralog biological compensates for the reduction in ARF1 function. Using a screen for transcriptional activators of *warf-1*, we found that *let-607*/CREBH was required for the low-PC activation of warf-1. Interestingly, CREBH proteins reside in the ER and utilize the same protease-dependent activation systems as SREBPs. We hypothesize that blockage of ARF1 activity initiates a bipartite program, stimulating SBP-1/SREBP-1 dependent lipogenesis and activating a protective transcriptional program including a compensatory ARF1 paralog. Finally, we show that *C. elegans* fed E. coli, which lack PC, are sensitized to this stress pathway, however, providing PC-rich *Pseudomonas* strains is protective. Thus, our discovery links membrane-lipid stress responses and ARF1 dysfunction to transcriptional of a compensatory program, providing a novel example of how cells use gene regulatory pathways to sense and respond to changes in lipid homeostasis.

509S **Dosage sensitive screen for maternal factors that effect Cytoplasmic Incompatibility in *Drosophila melanogaster*** Jillian Porter[1], Jillian B. Porter[2], William Sullivan[2] [1]MCDB, University of California Santa Cruz, [2]MCDB, UCSC

Wolbachia is a maternally inherited endosymbiont that manipulates host reproduction to favor infected females. Cytoplasmic Incompatibility (CI) is the most common form of reproductive manipulation. Crosses between infected males and uninfected females result in dramatic reductions in egg hatch (CI) while crosses in which both parents are infected produce normal egg hatch rates (RESCUE). This provides a selective advantage to infected females. The Wolbachia factors that cause CI and Rescue, known as the cif genes, have been identified but their host targets remain unknown. To identify these host targets we have taken advantage of the wealth of genetic reagents in *D. melanogaster* to screen for dosage sensitive enhancers and suppressors of CI. The results of this analysis will be presented.

510S **Decreased muscle performance correlated with increased carbon dioxide exposure in *D. melanogaster* lacking *CG5577*** Abigail Tramell[1], Jennifer Kennell[2] [1]Vassar College, [2]Biology, Vassar College

Many genes in *Drosophila melanogaster* remain uncharacterized, especially genes that have the potential to regulate metabolism, such as the *CG5577* gene. Sequence similarity suggests this gene encodes a likely member of the haloacid dehydrogenase (HAD) domain superfamily of non-protein phosphatases, in particular, a protein similar to human pyridoxal phosphate phosphatase (PDXP). One function of PDXP is to dephosphorylate pyridoxal 5'-phosphate (PLP), the co-enzymatically active form of vitamin B6. PLP is a cofactor for over 140 biochemical pathways, some reactions involving amino acid, neurotransmitter, and glycogen metabolism. Consequences of an increased intracellular concentration of PLP through *PDXP* knockout in mice have been shown to cause muscular and locomotor defects, as well as improved cognition and memory. Our goal for this project is to determine if the *CG5577* gene is the possible ortholog to *PDXP* by knocking out the *CG5577* gene in *Drosophila* and determining if our mutants show similar phenotypes as reported in previous studies. So

far, we have seen that our mutants have decreased flight and climbing performance and an erect wing phenotype compared to our controls. These defects are exacerbated by longer exposure to carbon dioxide prior to testing. In addition, female mutants also showed long-term climbing and flight defects with increasing exposure to carbon dioxide, as well as a fertility defect. These results tell us this gene is involved in muscular ability, fertility, and other aspects of physiology impacted by carbon dioxide exposure. Though the motor defects we see are consistent with previous studies of this possible ortholog in mice, we have also uncovered an interesting interaction between this gene and carbon dioxide exposure that we plan to explore further.

511S **Insights into the role of the acute myeloid leukemia protein, the "LIM-only protein, LMO" in myeloid cells development and function** Sakshi Jain[1], Upendra Nongthomba[1,2] [1]Department of Developmental Biology and Genetics, Indian Institute of Science, [2]Indian Institute of Science

Transcription factors play an important role in maintaining homeostasis during development by controlling the expression of essential genes. However, their aberrant expression due to chromosomal translocations or gene mutation can lead to cancer. LIM-only protein, or LMO, is an important transcriptional regulator of hematopoietic stem cells and progenitor cell development. It regulates erythropoiesis and the survival of T-cell progenitors. Hence, its aberrant expression leads to T-cell acute lymphoblastic leukemia. Additionally, its expression is found to be highest in acute myeloid leukemia and is associated with poor prognosis in these patients. Therefore, this study aims to understand the role of LIM-only protein in myeloid cell lineage specification and function. Our results in *Drosophila melanogaster* have shown that LMO protein, referred to as dLMO or Beadex, is required for plasmatocyte specification, a type of myeloid lineage cell. *Beadex* mutant plasmatocytes have reduced phagocytic ability. The phagocytes of mutant flies feature reduced filopodia length and number, suggesting *Beadex* could function in regulating actin dynamics. *Beadex* has been named a "pathogenesis-specific gene" as its mRNA levels are reduced when infected with a virulent strain of *Pseudomonas aeruginosa.* This study has also shown that *Beadex* mutants are susceptible to infection by Gram-negative bacteria *Salmonella typhimurium*. Moreover, injured flies also die faster, indicating a defective wound-healing process in mutants. Knockdown of *Beadex* orthologs LMO2 and LMO4 in human monocyte-derived THP-1 cells impairs their migration and differentiation potential, respectively. Other LIM domain proteins are known to function as "mechanosensors," which relay information about the mechanical properties of a cell's local environment through force-dependent interactions with the cytoskeleton. LIM proteins directly modulate the dynamics of cytoskeletal networks and act as transcriptional co-activators that alter gene expression. We hypothesize that *Beadex* and other LMO proteins could operate through similar mechanistic principles to modulate phagocytosis in immune cells. Therefore, the present study aims to understand how LIM-only protein engages in regulating the lineage specification in myeloid cells and their role in regulating the kinetics of immune cell movement and function.

512S **The mRNA cap-binding protein eIF4E-Homologous Protein (4EHP) promotes the Integrated Stress Response by stimulating synthesis of NELF-E protein in *Drosophila*** Kristoffer Walsh[1], Christoph Dieterich[2], Hyung Don Ryoo[1] [1]Department of Cell Biology, New York University School of Medicine, [2]Department of Medicine III: Cardiology, Angiology and Pneumology, University Hospital Heidelberg

The Integrated Stress Response (ISR) is a signaling pathway initiated by stress-activated eIF2a kinases that enhance cellular adaptation to various stresses, including amino acid deprivation. Key to ISR-mediated adaptation to amino acid deprivation is the stress-induced synthesis of ATF4, a transcription factor that activates the expression of genes that regulate mRNA translation and enhance amino acid biosynthesis. ATF4-target genes include the translational inhibitor Thor (homolog of mammalian 4E-BP). When active, Thor binds and inhibits the mRNA cap-binding protein eIF4E, a translation initiation factor required for general protein synthesis. How stress-responsive protein synthesis proceeds while eIF4E is inhibited remains an active area of research.

Here, we report that the noncanonical translation initiation factor, eIF4E-Homologous Protein (4EHP), is required for ISR signaling and adaptation to starvation in the *Drosophila* fat body. 4EHP, like eIF4E, is an mRNA cap-binding protein. However, 4EHP is not subject to regulation by Thor. We observe that 4EHP loss results in decreased ATF4 protein and Thor mRNA. Furthermore, loss of 4EHP reduces general amino acid metabolism and enhances vulnerability to nutrient starvation.

Through an RNA-binding screen known as TRIBE, we found NELF-E mRNA as one of the top 4EHP-binding mRNAs. NELF-E encodes one of four subunits that compose NELF, a regulator of RNA polymerase pausing that occurs in many stress-responsive genes. Gene expression profiling indicates that NELF-E knockdown reduces most genes positively regulated by 4EHP, including Thor. Consistently, NELF-E knockdown flies have decreased levels of ATF4 protein and display a nutrient starvation phenotype similar to that seen in loss of 4EHP. Consistent with the idea that 4EHP mediates NELF-E translation, loss of 4EHP reduced NELF-E protein levels with no change in mRNA stability. Together, these findings indicate that 4EHP is a previously unrecognized regulator of ISR signaling that promotes stress adaptation by binding to NELF-E mRNA to mediate its translation. We speculate our observations are consistent with a model by which 4EHP can promote ISR signaling to occur in stressed cells

with Thor-mediated eIF4E inhibition.

513S **A targeted genetic screen for proteins involved in trafficking of neuropeptides in the nervous systems of *Drosophila*** Hardik Bansal, Asha Ali, Tadros a Hana, Veronika G Mousa, Andrew H Michael, Kiel G Ormerod Biology, Middle Tennessee State University

Trafficking of cargoes along the microtubule tracks within the axons of neurons is a critical process necessary for development, maintenance, physiology, and behavioral function. Unlike a typical cell, neurons have axons that can travel long distances, exceeding a meter in humans. Incredible variability exists within the type of cargo and proteins/molecules associated with the cargo vessel. It is well-established that the motor protein kinesin is responsible for anterograde trafficking of axonal cargo, while the dynein/dynactin complex regulates retrograde trafficking. However, there is still much to uncover regarding the various isoforms of these motor proteins as well as the adapter and cargo-associated proteins involved in the precise trafficking dynamics. Here we use a targeted genetic approach using the UAS/Gal4 system combined with RNA interference (RNAi) to knockdown candidate genes and proteins involved in trafficking the organelles synaptic vesicles, mitochondria, and dense core vesicles in motor neurons. Using fluorescently tagged cargo proteins, we conduct live-imaging experiments to quantify changes in trafficking in our RNAi candidate lines. Of the 30 lines we have currently screened, 9 strong trafficking phenotypes were observed when examining cargo localization in the somas, axons, and at the neuromuscular junction. We are currently looking for changes in NMJ structure using immunostaining for pre-and post-synaptic proteins as well as performing electrophysiological recordings to examine changes in synaptic efficacy. We are additionally looking for changes in larval crawling behavior associated with these strong deficits. Taken together, we are uncovering novel roles for motor proteins, adapter and cargo-associated proteins involved in axonal trafficking of organelles, and assessing how deficits are associated with the downstream function of motor neurons.

514S **Examining the role of evolutionary changes in *Esterase 6* protein function in *Drosophila sechellia* toxin resistance** Idenya Bala-Mehta Biology, Wesleyan University

Drosophila sechellia is an island endemic host-specialist fruit fly native to the Seychelles Islands. Central to specialization on the fruit of *Morinda citrifolia* was the evolution of resistance to the defense compounds made to deter herbivory. The primary toxins involved are volatile medium chain fatty acids and fatty acid esters. Prior work from our group showed that *Esterase 6* (*Est6*) plays a role in resistance to the toxic effects of *M. citrifolia* volatiles. Both changes in gene expression and protein function are hypothesized to have contributed to evolutionary differences in *D. sechellia Est6* function. Here we begin to investigate how species-specific differences in *Est6* sequence, including a non-conservative substitution that projects into the enzyme's active site, are involved in catalysis. Using a published high-resolution crystal structure of *Est6* we used computational binding simulations generated by multiple different software platforms to test hypotheses about structural and predicted functional differences associated with known protein sequence differences. This work was then followed by *in vitro* analysis of the different protein variants tested with different *M. citrifolia* derived substrates. This method has thus far suggested that previously overlooked volatiles are important components of *M. citrifolia* toxicity and evolved *D. sechellia* resistance to them is mediated by derived *Est6* protein function.

515S **Sorting of Neuropeptides into Dense Core Vesicles.** Veronika g Mousa, Hardik Bansal, Kiel G Ormerod Biology, Middle Tennessee State University

Neuromodulation through the release of neuropeptides stored within dense core vesicles (DCVs) plays an essential role in regulating behavior. Given the diversity of neuropeptides encoded in animal genomes and their distinct effects on behavior, it is critical to define how different neuropeptides are sorted, packaged, and released. Here, we use fluorescent-tagging of multiple independent neuropeptides in *Drosophila* motor neurons to follow their sorting and transport. We find unique neuropeptides co-expressed within the same neuron largely sort into separate DCVs that do not intermix during their lifecycle. In addition, the same neuropeptide encoded from different mRNAs also sort to unique DCV populations, while multiple neuropeptides encoded in the same mRNA transcript are usually sorted, packaged, and transported together. Altering the expression of key enzymes involved in neuropeptide processing did not disrupt their sorting or transport, but caused an accumulation of DCVs at synapses, providing a link between neuropeptide processing and their subsequent release. These data indicate cargo of single DCVs can be associated with neuropeptides generated from one mRNA population that do not intermix during biogenesis or transport, allowing DCV release to activate specific downstream signaling pathways associated with their individual neuropeptide content.

516S **Interweaving Autophagy and Exosome Functions: Unraveling CryAB** Ziwei Zhao, David Brooks, Yungui Guo, Erika Geisbrecht Kansas State University

Phosphorylation reactions performed by protein kinases are one of the most studied post-translational modifications

within cells. Much is understood about conserved residues within protein kinase domains that perform catalysis of the phosphotransfer reaction, yet the identity of the target substrates and downstream biological effects vary widely among cells, tissues, and organisms. Here we characterize key residues essential for NUAK kinase activity in *Drosophila melanogaster* myogenesis and homeostasis. Creation of a *NUAK* kinase-dead mutation using CRISPR/Cas9 results in lethality at the embryo to larval transition, while loss of NUAK catalytic function later in development produces aggregation of the chaperone protein CryAB in muscle tissue. Yeast two-hybrid assays demonstrate a physical interaction between NUAK and CryAB. We further show that a phosphomimetic version of NUAK promotes the phosphorylation of CryAB and this post-translational modification occurs at two previously unidentified phosphosites that are conserved in the primary sequence of human CryAB. Mutation of these serine residues in *D. melanogaster* NUAK abolishes CryAB phosphorylation, thus proving their necessity at the biochemical level. Numerous human CryAB mutations cause cataracts, myofibrillar myopathy and/or cardiomyopathies. Modeling four of these human mutations in *D. melanogaster* muscle tissue causes varying degrees of muscle degeneration and the abnormal accumulation of CryAB, ubiquitin, and p62 aggregates. Interestingly, the small GTPase Rab 27 also colocalizes with a proportion of the CryAB-positive structures. This suggests that CryAB mutations not only affect the degradation of intracellular misfolded proteins but also alter the degradation and exocytosis of multivesicular bodies (MVBs). Further analysis reveals phenotypic clustering of aggregate morphologies that correlate with the location of the human mutations within the CryAB protein structure. These studies together highlight the importance of kinase activity regulation and provide a platform to understand the molecular role of CryAB in normal and diseased states.

517S **Developmental periodic oscillations of JAK/STAT signaling serve as a switch for maturation-inducing steroid pulse by regulating lipid droplet pool.** Jie Sun, Calder Ellsworth, Adam Aldahir, YICHUN HUANG, Wu-Min Deng Tulane University School of Medicine

The onset of sexual development is closely linked to changes in hormonal secretory activities of the pituitary gland in vertebrates and the steroidogenic prothoracic gland (PG) in insects. Steroid pulse frequency, amplitude, and duration are crucial for triggering insect sexual maturation through initiating genetic response programs. Here we reveal that the oscillations of JAK/STAT signaling, regulating the periodic dynamics of lipid droplet pool, contribute to the initiate sexual maturation. Lipid droplets, serving as storage organelles, maintain lipid and steroids homeostasis, dynamically facilitating coordination and communication between different organelles. The rhythmic oscillations of JAK/STAT signaling control a bidirectional loop of lipid droplet biosynthesis and degradation in PG cells. In late third-instar larvae, accompanied by the release of abundant steroids from PG, intracellular JAK/STAT signaling is significantly suppressed, thereby inhibiting lipolysis and promoting lipogenesis. If external inductions such as hyperinflammation or wounds activate JAK/STAT signaling during this period, it reverses lipid metabolism, leading to rapid degradation of lipid droplets and abnormal cholesterol accumulation. Ultimately, this hinders steroid hormone biosynthesis, preventing larvae from entering the pupal stage. We further found that the BTB zinc-finger transcription factor *fruitless (fru)* is a key participant in regulating lipid metabolism and negatively regulates the lipid droplet accumulation in PG cells by responding to JAK/STAT signaling levels in the body. Specifically, we show that Fru dynamic expression within the PG cells: a high concentration of Fru in the nuclei is concomitant with low-titer ecdysone levels in the body, and the protein is absent from PG nuclei at developmental stages when high-titer ecdysone pulses occur. Depletion of Fru in the PG accelerates larval development by causing precocious ecdysone signaling and a failure to repress ecdysone pulses. In contrast, excessive Fru expression in the PG arrests development that can be rescued by administrating an active Ecdysone. In summary, our findings elucidate how the JAK/STAT signaling pathway controls the decision-making process of maturation by maintaining a delicate balance in lipid metabolism and steroid homeostasis.

518S **An EMS screen for neuropeptide biology in the nervous system of *Drosophila*** Amber Washington, Veronika g Mousa, Asha Ali, Marina Khalil, Kiel G Ormerod Biology, Middle Tennessee State University

Neuromodulatory substances regulate critical processes spanning from regulated secretion to physiology and behaviour. It is therefore not surprising that most genomes encode hundreds of neuromodulatory substances and their receptors. The *Drosophila* genome encodes over 30 genes for neuropeptides alone. Neuromodulatory substances like neuropeptides are packaged within cells in large electron dense structures known as dense core vesicles (DCVs). DCVs are responsible for the transport, storage, and release of proteins and neuropeptides at multiple cellular locations and are known to be involved in a multitude of biological processes including synaptogenesis, synaptic transmission, synaptic plasticity, and others. However, much of cellular machinery involved in sorting, processing, trafficking, and ultimately secretion of DCV contents remains largely unknown. Here we have taken advantage of the genetic and molecular toolkit of *Drosophila* to conduct a genetic screen for changes in cellular localization of fluorescently labelled neuropeptides. We have identified several critical proteins necessary for proper processing of prepropeptides into bioactive neuropeptides ultimately impacting their ability to be trafficked to and undergo regulated secretion at the neuromuscular junction. Using this EMS screen and other approaches in our lab, we are beginning to characterize cellular mechanisms of sorting of different uniquely tagged DCV cargo. Lastly, by employing quantal resolution imaging of vesicle fusion at individual active zones, we are also characterizing the synaptic

machinery mediating trafficking and secretion of DCVs. The novel mutants isolated here enable a more comprehensive understanding of the critical mechanisms of neuropeptide sorting, trafficking, and secretion *in vivo*.

519S **TGFβ/Activin signaling positively regulates mitochondrial genome maintenance and glycogen homeostasis** Heidi Bretscher, Michael O›Connor University of Minnesota- Twin Cities

Mitochondria are one of the central regulators of metabolic homeostasis providing a significant source of ATP and metabolic intermediates required to sustain organismal growth and survival. Unlike most organelles, mitochondria contain their own genome and transcriptional machinery. The protein complexes required for mitochondrial oxidative phosphorylation and ATP production are composed of both nuclearly and mitochondrialy encoded subunits. Thus the balance of nuclearly and mitochondrialy encoded subunits must be maintained for optimal function. We have uncovered a new role for the TGFβ/Activin ligand Actβ in regulation of mitochondrial DNA maintenance. Loss of Actβ results in decreased mitochondrial DNA and decreased expression of nuclearly encoded mitochondrial transcriptional machinery including the mitochondrial RNA polymerase, *polrMT*, as well as two mitochondrial DNA helicases, *twinkle* and *suv3*. Accordingly, we see down regulation of mitochondrialy encoded, but not nuclearly encoded, subunits required for oxidative phosphorylation. As a readout for mitochondrial function, we measured mitochondrial membrane potential and ATP levels in the muscle of control and *actβ* mutant larvae. We found that *actβ* mutants have increased mitochondrial membrane potential, but decreased ATP levels suggesting that Actβ is required for efficient oxidative phosphorylation. In order to understand the metabolic consequences of decreased mitochondrial DNA in *actβ* mutants we measured glycogen and lipid levels and found that Actβ is a strong positive regulator of glycogen storage, with mutants having only about one third the glycogen of control animals. Importantly, knockdown of either *mtRNApol/PolrMT* or *mtDNA helicase/twinkle* in muscle led to decreased organismal glycogen levels establishing a direct link between mitochondrial genome maintenance and glycogen homeostasis. Thus, our model is that Actβ regulates glycogen homeostasis via expression of nuclearly encoded mitochondrial transcriptional machinery required for mitochondrial genome maintenance.

520S **Investigating the interaction between Uif, Mmp1 and PNPase with insulin signaling in tissue-specific growth of the larval trachea** Zihao Yu, Robert Ward Case Western Reserve University

Most animal species show allometric growth, which means that different organs and tissues grow at different rates relative to each other. Understanding the mechanisms of how different tissues grow is important, since it can provide insight about unique signals and pathways required for development of different organs. The Drosophila larval trachea is an excellent model since they show tissue-specific growth and the trachea can be easily visualized due to optical properties of the air-liquid interface in the trachea. In addition, we and other labs have identified genes required for growth specifically in the larval trachea, including *uninflatable (uif)* and *matrix metalloproteinase 1 (mmp1)*, which are positive regulators of tracheal growth and *Polynucleotide phosphorylase (PNPase)*, which is a negative regulator of tracheal growth. We have also identified a mutation in an uncharacterized gene that is also a negative regulator of *growth (l(3)12265).*
The larval trachea is an endoreplicating tissue (ERT) and previous work from the Edgar lab showed that cellular growth in ERTs are regulated through the insulin signaling pathway. Tracheal-specific expression of dominant active, dominant negative and RNAi constructs to insulin signaling components results in predictable alterations in tracheal growth. We therefore hypothesize that these tracheal specific growth regulators act to modulate insulin signaling specifically in the larval trachea.
Here, our goal is to investigate how tracheal growth genes interact with the insulin signaling pathway to regulate growth. We will measure readouts of insulin signaling in *uif, Mmp1, PNPase and l(3)12265* mutant larvae including phospho S6 kinase and the expression and localization of tGPH. We will also perform genetic experiments to manipulate insulin signaling in these mutants and test for enhancement or suppression of the tracheal growth phenotypes.

521S **FoxO is necessary for heat-induced fat loss.** Jin Seo, Tucker Hopkins Biology, Rogers State University

Animals must develop mechanisms to cope with environmental challenges for their survival. Daily and seasonal fluctuating temperatures are inevitable and common obstacles, imposing pressure to adapt to heat in all living organisms. Organisms tend to lose their stored body fat at temperatures higher than their optimum, which is observed in mammals as well as insects. However, the mechanisms controlling this heat-induced fat loss have not been fully understood. We hypothesized that organisms must have developed a specific mechanism, likely ancient and common throughout all animal kingdoms, as temperature fluctuations are a persistent occurrence. When fruit flies are exposed to heat, they significantly lose their body fat. Analysis of gene expression in the flies incubated at an elevated ambient temperature revealed significant changes in genes regulating the insulin singling pathway as well as lipid metabolism. The expression of various insulin like peptides (Ilps) was differentially regulated. Further, insulin signaling was suppressed in *Drosophila* S2R+ cells at an elevated temperature without Ilp regulation, indicating that heat autonomously inhibits the insulin signaling pathway regardless of Ilps. *In vivo* expression of constitutive active form of insulin receptor completely blocked heat-induced fat loss. Subsequently, we

demonstrated the insulin receptor- FoxO branch in the insulin signaling pathway is necessary for heat-induced fat loss.

522S **X-ray Radiation Induced Cellular Plasticity in the Drosophila Wing Imaginal Disc** Michael Shiferaw Molecular, Cellular & Developmental Biology, University of Colorado, Boulder

Ionizing radiation, while a potent weapon against cancer, appears to induce a unique adaptability in cells, enabling them to survive and relocate within tissues. This phenomenon is distinctly observed in the Drosophila wing imaginal disc where post-radiation, hinge cells migrate unidirectionally to damaged pouch areas, undergoing transformation to replace lost or damaged cells. Such cell fate changes and migrations prompt exploration into the foundational intercellular communications driving this adaptability and plasticity. To tackle this, the study aims to decipher the intercellular signaling orchestrating this migration, with a spotlight on the pivotal ligand-receptor interactions. Through an in-depth analysis of a comprehensive RNASeq dataset (Ledru et al., 2022), complemented by validation techniques such as in-situ hybridization, we intend to identify the key players and underlying mechanisms. Emphasizing ligand-receptor interactions is motivated by their central role in signaling cascades, with the potential to trigger downstream migration-driving events. We will utilize pouch and hinge specific drivers to overexpress or knockdown candidate genes, allowing us to further explore the roles of these genes in regulating cellular plasticity and migration. By delineating these radiation-induced cellular behaviors, our goal is to deepen the understanding of cellular plasticity in response to radiation, subtly alluding to its wider implications in refining therapeutic approaches.

523S **Local nuclear to cytoplasmic ratio regulates chaperone-dependent H3 variant incorporation during zygotic genome activation** Anhsua Bhatt[1], Madeleine Brown[1], Aurora Wackford[2], Yuki Shindo[2], Amanda A Amodeo[2] [1]Biology, Dartmouth College, [2]Dartmouth College

The process of differentiation is characterized by lineage-specific gene expression and chromatin micro-environments. Cells in the early embryo of many species have relatively unstructured chromatin that lacks active and inactive domains typical of more differentiated cells. In many species, including Drosophila, these regulatory domains are established during zygotic genome activation (ZGA). In Drosophila, ZGA occurs after 13 fast, reductive, syncytial nuclear divisions during which the nuclear to cytoplasmic (N/C) ratio grows exponentially without cytoplasmic growth. These divisions incorporate maternally loaded cytoplasmic pools of histones, into the chromatin. Previous work has shown that the relative amount of replication-coupled histone H3 decreases while its variant H3.3 increases on chromatin in the cell cycles leading up to ZGA. H3.3 is known to associate with active promoters and enhancers as well as heterochromatin domains, suggesting a link between H3.3 incorporation and chromatin changes during ZGA. Here, we examine how H3.3 incorporation is regulated during ZGA. We identify a decrease in the overall nuclear import of H3, but not H3.3, over the final pre-ZGA cycles. We also observe an N/C ratio-dependent increase in H3.3 incorporation at high N/C ratios within mutant embryos with uneven N/C ratios. We evaluate the contributions of chaperone binding and gene expression by creating H3/H3.3 chimeric proteins at the H3.3A locus. We measured H3-like incorporation of those chimeras with the H3 chaperone-binding site. We test the specificity of the H3.3 chaperone pathways for H3.3 incorporation using Hira (H3.3 chaperone) mutant embryos. Overall, we propose a model in which local N/C ratio and chaperone binding regulate differential incorporation of H3.3 during ZGA.

524S **Atypical FGF ligand Pyramus, a Type I transmembrane protein, undergoes intracellular cleavage that affects mesodermal cell fate** Chen Zhang, Jingjing Sun, Vincent Stepanik, Angelike Stathopoulos Biology and Biological Engineering, California Institute of Technology

Fibroblast Growth Factor (FGF) signaling is an evolutionarily conserved receptor-ligand signaling pathway that contributes to multiple vital developmental functions including cell proliferation, differentiation, and migration. During heart development, the fibroblast growth factor (FGF) Pyramus (Pyr) and its receptor (FGFR) Heartless (Htl) play a vital role in the differentiation of pericardial precursors through the activation of *even-skipped (eve)* gene expression via the mitogen-activated protein kinase (MAPK) pathway. In both *htl* and *pyr* mutants, a complete loss of *eve* expression and, subsequently, failure of pericardial cell differentiation and heart formation are observed.While most FGF signaling ligands are secreted in entirety, our previous study identified Pyr as the first characterized transmembrane FGF protein (Stepanik, Sun et al., *Curr Biol* 2020). Its transmembrane domain (TMD) separates an extracellular FGF-homologous portion from an extended intracellular domain (ICD) of unknown function. We showed that cleavage of Pyr results in various truncated forms of Pyr that lack the TMD and/or the extended ICD. These isoforms are associated with different levels of diphosphorylated form of ERK (dpERK), which indicates that different Pyr truncations have varying capacity to activate MAPK signaling. In this new study, we investigated Pyr cleavage dynamics in vivo utilizing a new sensor, a Pyr fusion protein in which GAL4 is inserted in the intracellular domain (Pyr-GAL4-ICD) that monitors ICD detachment from the TMD. By monitoring Pyr-GAL4-ICD driven expression of GFP relative to eve expression, we show that cleavage of Pyr takes place as early as stage 9 of embryogenesis and is coincident with eve expression in Eve pericardial cells (EPCs). Furthermore, *pyr* truncation mutants were further examined finding that deletion of the Pyr ICD is associated with change in *eve* and *runt* expression dynamics. Our results point to a role for Pyr cleavage in supporting temporal

regulation of MAPK signaling. Mammalian FGF proteins FGF21 and FGF23 also interact differently with their FGFRs depending on their cleavage states. By understanding the molecular mechanisms controlling Pyr cleavage and the effects on downstream intracellular signaling, we may elucidate novel regulatory mechanisms relating to the FGF signaling pathway including the possibility that ligands also signal in reverse.

525S **The Role of Myosin in Pupal Wing Expansion** Anni Yi[1], Kenneth D Irvine[2] [1]Molecular Biology and Biochemistry, Rutgers University New Brunswick, [2]Molecular Biology and Biochemistry, Waksman Institute of Microbiology

During the pupal stage of Drosophila melanogaster, it is known that the pupal wing flattens and expands to form the adult wing and that pupal wing cells change shape and flatten during this expansion. However, this crucial step in pupal development is still not very well understood in its early stages. We are investigating the behavior of the protein non-muscle Myosin II, encoded by the gene Spaghetti Squash in Drosophila, during pupal wing expansion since it is well known to have structural functions within the cell such as helping to facilitate cell migration and cell division. We investigated Myosin II's localization in fixed pupal wings of various ages by performing in vivo experiments using fluorescent protein-tagged Myosin II transgenes. While previous studies have shown that Myosin II relocalizing to the lateral sides of the cell from 6-8 hours post pupariation plays a role in pupal wing expansion, our results suggest that it may be a different mechanism that controls the cell shape changes involved in pupal wing expansion. Additionally, we have found the presence of previously unreported bright, strongly apical localizing Myosin II structures towards the end of this 2-hour window in pupal wing development. Currently, we are trying to understand the role that these structures play in pupal wing development using ex vivo experiments, which could provide new insight into the biomechanical controls of the early stages of pupal wing development.

526S **The role of ubiquitin and multivesicular body formation in the stem cell niche of the *Drosophila melanogaster* testis** Sheetal Kooduvalli, Mara Grace, Erika Matunis Johns Hopkins University

Post-translational protein modifications such as ubiquitylation control protein interactions, stability, function, and localization, all of which are essential for maintaining optimal conditions in the cell. The *Drosophila melanogaster* testis stem cell niche serves as an ideal model to understand the role of ubiquitylation in stem cell maintenance. The niche supports two different population of cells- germline stem cells (GSCs) which later differentiate into sperm and cyst stem cells (CySCs) which support the germline. Here we find that RNAi-mediated knockdown of the endosomal sorting complexes required for transport (ESCRTs) in CySCs results in a dramatically enlarged niche due to an increased number of cells, a striking phenotype, as niche cells are normally quiescent. ESCRTs recognize ubiquitylated receptors in endosomes and control downstream formation of multivesicular bodies (MVBs) necessary to silence receptor signaling, leading us to a model where ESCRTs mediate signaling from CySCs to their niche. Consistent with disruption of endocytic trafficking and MVB formation we detected ubiquitin and early endosome accumulation in CySCs following ESCRT knockdown. We hypothesize that ubiquitylated and internalized receptors accumulate in endocytic vesicles and continue to signal to the niche, driving hub cell proliferation. Disruption in ESCRT functioning is seen in many diseases such as cancer and we hope to understand the etiology through pathways that lead to abnormal cellular communication.

527S **Large secretory vesicles employ a unique mechanism of exocytosis** Eyal Schejter[1], Kumari Kamalesh[1,2], Tom Biton[1,2], Nadav Scher[2], Shari Carmon[1], Yael Elbaz-Alon[2], Ori Avinoam[2], Benny Shilo[1] [1]Molecular Genetics, Weizmann Inst Sci, [2]Biomolecular Sciences, Weizmann Inst Sci

Secretion of adhesive ("glue") glycoproteins from the apical surface of *Drosophila* larval salivary gland cells to the gland lumen, serves as a prominent model for exocytosis via exceptionally large vesicles. This process poses significant challenges to various aspects of the secretory apparatus, including the mechanisms of vesicle fusion, cargo release and cell membrane homeostasis. Our studies address the unique cellular and molecular mechanisms underlying key junctures along this specialized route of secretion. We find that the fusion pore, through which vesicle content is released, displays a dynamic behavior, involving expansion, stabilization and eventual contraction. Progression through these steps is regulated by Bin-Amphiphysin-Rvs homology (BAR) domain proteins, most notably the fly homolog of the I-BAR domain protein MIM. Following fusion, a Rho GTPase-based pathway, employing balanced and regulated input from specific RhoGEF and RhoGAP elements, is activated, leading to coating of the vesicles by a contractile actomyosin network, which is constructed in a temporally biphasic manner. Contraction of this network serves multiple roles: content release to the lumen, regulation of fusion pore dynamics, and notably, "crumpling" of the vesicle membrane, which keeps it insulated from the apical cell membrane, thereby maintaining membrane homeostasis.

528S **Role and Regulation of Polarity Proteins during Mitosis** Sarah JL Robinson, Gayaanan Jeyanathan, Milena Pellikka, Ulrich Tepass University of Toronto

In cancer, the shift from a hyperplastic to a neoplastic tumor capable of metastasis is partly due to loss of cell polarity. Our

recent work in Drosophila embryonic epithelia has established that morphogenetic movements including mitosis challenge epithelial polarity, thus threatening tissue integrity. Reducing morphogenesis by, for instance, blocking cell division or cell ingression, releases pressure from the polarity machinery and ameliorates polarity protein loss-of-function mutant phenotypes. This interaction is dose-dependent; the more morphogenetic activity, the more polarity is required to maintain tissue integrity. Cell division poses a unique challenge to epithelial polarity, as apical-basal polarity is transiently lost during division, a process called 'mitotic polarity oscillation'. We and others have found that apical polarity proteins and adherens junction components are removed from the apical membrane at the onset of mitosis and return after the cell divides. Additionally, the apical polarity protein Crumbs (Crb) is crucial for re-establishing and maintaining polarity in dividing tissue. However, the role of Crb relocalization during division is not yet understood.

To further expand on the importance of polarity in morphogenetically active tissue, we investigated other polarity proteins, and whether their loss-of-function phenotypes can be rescued by removing morphogenetic movement. We focus on basolateral polarity proteins Scribbled, Discs Large, Lethal Giant Larvae, and Yurt. We either blocked cell division or cell ingression, or both movements simultaneously in a basolateral polarity protein loss-of-function background. We will present our findings and compare them to interactions between morphogenesis and apical polarity proteins. We are also interested in understanding mitotic polarity oscillation, and whether the relocalization of apical Crb is a necessary step for proper mitosis or a by-product of cell division. We hypothesize that Crb removal facilitates formation of a uniform actin cytocortex which aids in mitotic rounding prior to division. Using a Crb protein lacking a target site for Clathrin-mediated endocytosis (CrbRR), we aimed to prevent the loss of Crb from the apical membrane and observe any changes in mitosis. Preliminary findings suggest that CrbRR is removed from the membrane of mitotic cells in contrast to interphase cells, suggesting that apical plasma membrane removal does not engage a Clathrin-dependent mechanism.

529S **Developing Single-Cell Mass Spectrometry Methods to Identify Candidate Actin Mesh Regulatory Proteins** Merin M Rixen, Joseph Loo, Margot E Quinlan Chemistry and Biochemistry, UCLA

During egg development, oogenesis, actin filaments form a meshwork inside of the oocyte which aids in establishing oocyte polarity. Polarity establishment is a critical event that determines the major body axes of the egg and ensures the development of healthy offspring. This is a highly conserved process and analogous actin mesh networks have been observed in various species, including fruit fly (*Drosophila melanogaster*), worm, mouse, and human oocytes. The *Drosophila* actin mesh fills the oocyte during mid-oogenesis but disappears at the onset of late oogenesis. This timely removal is integral for the proper establishment of germline polarity. If the mesh is removed too early or too late, oocyte polarity is not established or has delayed establishment, and the fertility of the fly is decreased. However, little is understood about the mechanism behind the mesh removal. This research aims to identify candidate proteins that regulate actin mesh removal and investigate their functions in relation to mesh disappearance. I will use single-cell mass spectrometry to measure protein levels and abundance changes in single *Drosophila* oocytes between mid and late egg development stages. This technique will allow me to identify the proteins that reflect relevant abundance changes between the stages of mesh maintenance and disappearance. I will complement my mass spectrometry analysis by using fly knockdown lines to determine what role these proteins have on actin mesh disassembly. Identifying the proteins that regulate actin mesh removal, and determining their roles, will advance our comprehension of the mechanisms and machinery that direct actin mesh regulation. Our findings will promote a deeper understanding of the developmental defects that arise from improper egg maturation across multiple species. Furthermore, the relevant results from this research may be extended to other systems of organized actin assembly that govern important cellular processes.

530S **Disrupted endosomal trafficking of polarity proteins causes congenital trachea-esophageal separation anomalies** Nicole Edwards[1], Adhish Kashyap[2], Alissa Warren[2], Zachary Agricola[2], Alan Kenny[2], Yufeng Shen[3], Wendy Chung[3,4], Aaron Zorn[2] [1]Division of Developmental Biology, Cincinnati Children's Hospital Medical Center, [2]Cincinnati Children's Hospital Medical Center, [3]Columbia University Medical Center, [4]Harvard Medical School

Trachea-esophageal defects are life-threatening congenital anomalies that arise when the trachea and esophagus do not correctly separate from the common anterior foregut tube. The genetic causes of trachea-esophageal anomalies are not well known, and how the trachea and esophagus normally separate during embryonic development is not well understood. In a collaborative network called the CLEAR Consortium, we are using animal models and patient genome sequencing to discover new trachea-esophageal anomaly-related variants and determine their disease mechanisms. Using the complementary advantages of mouse and *Xenopus* embryos, we recently defined a novel endosome-mediated epithelial remodeling process that is critical for separation of the foregut into tracheal and esophageal tubes. We aimed to determine the cellular mechanisms regulated by endosomal trafficking by mutating the key endosomal pathway proteins Dynamin, Rab5a, and Rab11a in *Xenopus*. We found that disrupting endosome trafficking leads to trachea-esophageal fistulas, occluded trachea-esophageal lumens, and epithelial cell disorganization in the transient septum connecting the trachea and esophagus. We also

find significantly altered localization of the polarity proteins laminin and Vangl2 in endosomal mutant embryos, suggesting that these proteins may be trafficked by recycling endosomes to maintain epithelial apical-basal cell polarity during trachea-esophageal separation. We also observed disrupted polarity in *Xenopus* mutants of novel patient variants in genes predicted to function in endocytosis, suggesting that disrupted endosome-mediated polarity maintenance may be a common disease mechanism underlying human trachea-esophageal anomalies. This work is funded by NICHD P01 HD093363.

531S **Modeling single-cell phenotypes in wild-type and regulatory mutant yeast to explore growth control and stress defense** Rachel A Kocik[1,1,2], Andrew C Bergen[1,2], James Hose[1,2], Megan McClean[2,3,4], Audrey P Gasch[1,2,3] [1]Genetics, University of Wisconsin-Madison, [2]Center for Genomic Science Innovation, University of Wisconsin-Madison, [3]University of Wisconsin Carbone Cancer Center, University of Wisconsin School of Medicine and Public Health, [4]Biomedical Engineering, University of Wisconsin-Madison

Cells must respond dynamically to a multitude of environmental changes to maintain cellular homeostasis and protect against environmental stresses. To properly manage changing environments, cells utilize signaling pathways; however, the ways in which these pathways are controlled, including protein activation, localization dynamics, and gene expression are not fully understood. In the case of environmental stresses, many studies done in bulk culture fail to capture cellular heterogeneity, which can reveal unique phenotypic relationships found only in subsets of cells. To investigate what gives rise to variation in stress response, we paired live-cell imaging with a microfluidics system to study multiple phenotypes of single *Saccharomyces cerevisiae* cells before and after salt stress. We simultaneously followed cell and colony growth, cell size and volume, cell-cycle phase, and nuclear localization of two Protein Kinase A (PKA) co-regulated stress responsive transcription factors, transcriptional activator Msn2 that regulates stress-induced genes and repressor Dot6 that represses expression of ribosome-biogenesis genes. We found unexpected differences in Msn2 and Dot6 localization changes across cells, revealing unanticipated discordance in their regulation. This discordance persists even in cells lacking a PKA regulator, phosphodiesterase Pde2; however, the overall distribution of both Msn2 and Dot6 nuclear localization was significantly lower in cells lacking Pde2. Interestingly, post-stress growth recovery was positively correlated with activation of the Dot6 repressor. In contrast, cells lacking Dot6 (and paralog Tod6) displayed slower growth acclimation even though they grow normally in the absence of stress. Cells lacking Pde2 also displayed slower post-stress growth, further underscoring the role of Dot6 activation in the stress response. Unlike cells lacking Dot6, cells without Msn2 (and paralog Msn4), exhibited faster post-stress growth, despite growing normally without stress. While Msn2 and Msn4 are not required for basal stress tolerance, they are needed for cells to survive a secondary stress, suggesting Msn2 activation may be predictive of cells acclimation to a secondary stress. Our results demonstrate that, while cells' responses are highly dynamic, specific cellular attributes can partially predict how cells will respond to stress.

532S **Characterization of the developmentally important disaggregation activities of Abcf proteins** Sydney Skuodas, Amy Clemons, Bryan Phillips, Jan Fassler University of Iowa

The *ABCF* gene family encodes ABC type ATPases. In yeast, members of this family are involved in translation and ribosome biogenesis, however, this gene family is related to the fungal specific New1 protein, which exhibits Hsp104-independent disaggregation activity. Analyses of potential disaggregation activity in yeast revealed that depletion of Abcf proteins in yeast reduces the rate of resolubilization of denatured proteins and reduces the aggregate burden of cells carrying an Htt-Q97 reporter.

Animal Abcf proteins complement the yeast defects and knock-down in *Xenopus* embryos result in developmental defects. In *C. elegans* we find that ABCF-1 limits amyloid aggregation and is required for maternal fecundity and embryonic survival. Some aggregates that accumulate in ABCF-1 deficient animals contain the RNA binding protein CAR-1, which is normally localized to RNA processing bodies. These data suggest that aggregation-prone RNA processing membraneless organelles are regulated by ABCF-1.

Yeast Arb1 (Abcf2) co-localizes with heat-denatured aggregates suggesting a possible direct interaction with aggregate clients. However, Arb1 does not co-localize with heterologous amyloid reporters. Because endogenous amyloids (prions) significantly influence heterologous reporter aggregates, we sought to investigate the role of Arb1 in endogenous amyloid processing. Our results show that the Arb1 protein co-localizes with the Sup35 encoded [PSI$^+$] prion and that *ARB1* overexpression alters the number and spectrum of [PSI$^+$] aggregates while the absence of *ARB1* influences the aggregate load in strains carrying the weak [PSI$^+$] prion variant. These results are consistent with a direct role for Arb1 in disaggregation as predicted by its phylogenetic relationship with the yeast disaggregase, New1.

We have also begun to investigate possible Arb1 co-factors. A functional interaction with Hsp104 is suggested by our observation that the two proteins co-localize following heat shock and that *ARB1* overexpression can suppress the thermosensitive phenotype of *hsp104* mutants. We further find that *ARB1* overexpression lysates have a large impact on the

extent to which denatured luciferase can be reactivated in the presence of low levels of recombinant Hsp104. We propose that Hsp104 and Arb1 may work sequentially or collaboratively in refolding disordered aggregates. Additional chaperone mutant lysates are being screened for changes in Arb1 and Hsp104 mediated refolding.

533S **Modulatory inputs into the MAPK pathway that controls filamentous growth in yeast** Atindra N Pujari, Paul J Cullen Biological Sciences, State University of New York at Buffalo

Signal transduction pathways control the execution of cellular responses to intrinsic and extrinsic stimuli. Erroneous activation of signaling pathways and their cognate transcription factors due to gain-of-function and loss-of-function mutations in genes encoding positive regulators and negative regulators, respectively, have been linked to diseases such as cancer in humans. A type of signaling pathways that are highly conserved are mitogen-activated protein kinase (MAPK) pathways. Model organisms like yeast contain MAPK pathways and serve as a platform to learn how these pathways are regulated. To better understand the regulation of MAPK pathways, a genetic screen was performed by measuring the activity of a MAPK pathway reporter combined with next-generation sequencing. Mutants were identified that showed elevated activity of a crosstalk growth reporter (*FUS1-HIS3*) whose activity provides a readout of the MAPK pathway that controls filamentous growth. Spontaneous mutants were selected on media lacking histidine and containing 3-amino-triazole, a competitive inhibitor of the His3p enzyme. In total, 159 mutants were identified and analyzed by secondary screens for invasive growth by the plate-washing assay, filament formation by microscopy, and measurement of pathway activity by the β-galactosidase assay. The genomes of thirty-two separate mutants showing strong reporter activity were individually sequenced, and the genomes of a larger collection of mutants were sequenced in a combined pool. This approach identified mutations in genes previously known to regulate the fMAPK pathway. These included presumed gain-of-function or activating mutations in the genes encoding the MAPKKK (Ste11p), the MAP kinase (Kss1p), and the transcription factor (Ste12p). Loss-of-function or inactivating mutations were identified in negative regulators, including one of the GTPase activating protein (GAP) for Cdc42p, Rga1p, and one of the GAPs for Ras2p, Ira2p. Alleles in previously identified negative regulators were also uncovered in *ALY1, AIM44, RCK2,* and genes that function in protein glycosylation (*KAR2* and *MNN4*). Many of the mutants contained multiple mutations, suggesting that negative regulators have additive effects on MAPK pathway activity. Understanding how negative regulatory inputs combine to modulate signaling can provide insight into the overall dynamics of MAPK pathway regulation.

534S **Analysis of the functional role of the microtubule-associated [*PUB1/SUP35*] prion-like assembly and regulation of its formation** Irina L Derkatch, Susan W Liebman, Irina Alexandrova, Dania Maldonado, Kassandra Gomez Pharmacology, University of Nevada, Reno

Prions are self-propagating protein conformations that can be acquired by various cellular proteins and then passed on to newly synthesized protein molecules with the same primary sequence. The underlying structure of most prions is amyloid, beta-sheet-rich fibers with protein molecules neatly stacked on one another. Prions and prion-like amyloid aggregates are associated with many devastating diseases, including Creutzfeldt-Jakob, Alzheimer's, Parkinson's, Huntington's, type 2 diabetes and amyotrophic lateral sclerosis. Noteworthy, most disease-associated proteins are intrinsically amyloidogenic. Mutations just increase the likelihood of forming amyloid and reduce the age of disease onset.

Saccharomyces cerevisiae is an excellent model organism for studies of prions: yeast harbor several prion forming proteins that can exist in a prion state without affecting growth rate or strain viability. Analysis of prion-forming domains reveals that many of them are rich in glutamines and asparagines (Q/N-rich) and can promote prion formation or prion-like aggregation without mutations. Retention of such domains by up to 5% of proteins is puzzling. The simplest explanation is that these proteins form functional aggregates. One possibility is that prion-like aggregation drives the assembly of membraneless organelles and large protein complexes. Indeed, the proportion of proteins with Q/N-rich domains is dramatically increased among components of P-bodies and stress granules and RNA-binding proteins. We aim to reveal functional prion-like complexes and understand the regulation of their assembly.

One candidate functional prion-like assembly is a microtubule-associated complex formed by Sup35 and Pub1 proteins encompassing Q/N-rich domains. In this complex Sup35 and Pub1 co-aggregate. Based on the preliminary analysis of other components of the complex and its importance for microtubule stability, it is hypothesized that the complex's functional role is to direct the synthesis of tubulin to the site of microtubule assembly. While testing this hypothesis we found that a spontaneous change in a yeast strain can simultaneously modulate the aggregation of one of the complex components, Sup35, and increase the stability of centromeric plasmids that depend on microtubule cytoskeleton for their transmission. We conclude that the change affects the assembly / functionality of the complex.

NIH GR10595 (PA-18-592 Suppl.); ARO W911NF-23-1-0122, UNR COBRE P30GM145646 (pilot grant)

535S **Fluorogen Activating Proteins are a powerful new imaging tool for quantitative protein trafficking studies in *S.***

cerevisiae Katherine G Oppenhiemer[1], Natalie A. Hager[1], Ceara K. McAtee[1], Chaowei Shang[1], Jeffrey L. Brodsky[1], Derek C. Prosser[2], Adam V. Kwiatkowski[3], Allyson F. ODonnell[1] [1]Biological Sciences, University of Pittsburgh, [2]Department of Biology, Virginia Commonwealth University, [3]Department of Cell Biology, University of Pittsburgh

Advances in genetically encoded fluorescent probes led to development of fluorogen-activating proteins (FAPs). This technology has two components: a non-fluorescent single chain antibody (SCA), which is fused to the protein of interest, and a fluorogen, which in this case is a malachite-green (MG) dye derivative that is non-fluorescent. Binding of the fluorogen to the SCA results in a 20,000-fold fluorescence increase, producing a signal in the far-red range (633 nm) for live cell imaging. FAPs have advantages over traditional fluorescent proteins. Specifically, the MG-dye can be derivatized to be cell impermeant, selectively detecting SCA-tagged proteins at the cell surface and facilitating quantitative endocytic dynamics studies. Although developed in yeast, FAPs are underutilized in this system. Here we: 1) optimized the SCA sequence for yeast expression, 2) created a series of FAP-tagging plasmids, 3) generated a suite of FAP-tagged sub-cellular markers, and 4) used FAPs to assess the endocytic trafficking of yeast G-protein coupled receptor Ste3. We mapped Ste3 endocytosis post ligand stimulation, identified *cis*-acting regulatory sequences in Ste3 and demonstrated that the alpha-arrestins, a conserved class of protein trafficking adaptor, are critical for Ste3 endocytic trafficking. We have developed a useful tool for the yeast cell biology community and demonstrate its powerful capabilities for quantitative protein trafficking studies.

536S **Deformation of the cell nucleus after high-speed stretching.** Maia Garcia[1], Sam Boland[2] [1]Bemidji State University, [2]University of Minnesota

Traumatic brain injury (TBI) affects thousands of people. As of 2021, 190 people die each day of TBI. TBI and blast induced trauma can both lead to lifelong health problems. Blast-induced traumatic brain injury (bTBI) specifically can change cellular phenotypes and contractability. Knowing how bTBI and TBI affects vascular cells is incredibly important because TBI often does not cause visible wounds, making observation of the injury difficult. Using a custom technique called cellular microbial stretching, we are able to measure the effects of traumatic mechanical injury in singular vascular smooth muscle cells. We stretch vascular smooth muscle cells at different rates and then we measure the deformation of the nucleus via fluorescent imaging. The preliminary results show that the nucleus deforms during stretching, and the deformation depends on the rate of stretching. Prior works suggest that nuclear deformation affects gene expression in cells, so these results provide us insight into how TBI can affect the function of individual vascular smooth muscle cells.

537V **Balance of recycling and degradative endosomal microdomains is controlled by the oligomerization of Hsc70 co-chaperone RME-8** Anne Norris[1], Ryan Feehan[2], Joanna Slusky[2], Barth D Grant[1] [1]Rutgers, [2]Kansas University

Endosomes balance the opposing activities of degradation and recycling. This process is facilitated by recruitment into physically distinct degradative or recycling microdomains on endosomes. Endosomal sorting complexes required for transport (ESCRT) mark the degradative microdomain, while the recycling domain is marked by the retromer complex and associated proteins RME-8 and SNX-1. How these physically and functionally distinct membranes remain separated is a major question in the field of endosomal trafficking.

Two proteins RME-8 and SNX-1 keep these domains separate in part via removal of degradative component HRS/HGRS-1 from the recycling microdomain. This activity is due to recruitment and activation of chaperone Hsc70 on the endosome by the RME-8 DNAJ domain. To better understand the mechanism of RME-8 function we used mutagenesis and structural modeling of RME-8. We identified the IWN3 domain RME-8, to be important for the autoinhibitory DNAJ domain binding, with IWN3 playing a critical role in HRS uncoating activity. Combining AlphaFold structural predictions with in vivo mutation analysis of RME-8, we propose a model whereby SNX-1 controls the oligomerization status of RME-8 and hence the productive exposure of the DNAJ domain. Furthermore we provide a model of a tetrameric RME-8 structure that exists on membranes and while dimeric and monomeric forms exist in the cytosol.

538V **Multidimensional study of exosome biogenesis in human A375 melanoma cells in response to Doxorubicin** Laura Fernandez[1,2], Adriana Umaña[1], Luis Alberto Gomez Grosso[2], Susana Novoa[2] [1]Universidad Nacional de Colombia, [2]Instituto Nacional de Salud

Extracellular Vesicles (EVs) are membranous structures responsible for transporting bioactive molecules, including proteins, lipids, metabolites, and nucleic acids, to local and distant environments. The chemotherapeutic agent Doxorubicin (Doxo) is known to induce damage to distant organs from the tumor site, being the heart particularly affected. Cancer cells increase the release of EVs, like exosomes, when treated with Doxorubicin, potentially mediating cardiotoxic effects. Challenges remain in comprehending factors influencing EV biogenesis; hence, our study aims to understand how exposure to Doxorubicin impacts

the generation and release of EVs in A375 human melanoma cells.

We exposed A375 cells to 10nM Doxo to assess the intracellular exosome generation within a period ranging from 4 to 24 hours post-exposure and examined the release of small vesicles (sEV) into the culture medium after 96 hours of exposure, followed by a 24 or 48-hour medium conditioning. By Immunocytochemistry/Immunofluorescence (ICC/IF) we explored the intracellular distribution of exosomal markers (CD9, CD63, CD81, TSG101, Rab7) over time. Acidic vesicles were stained using acridine orange, while the Golgi apparatus and multivesicular bodies (MVBs) were visualized within live cells using Bodipy-TR. Nanoparticle Tracking Analysis (NTA) was utilized to determine the size and concentration of EVs.

Exposure to Doxorubicin led to a substantial increase in CD81+, CD9+, CD63+, and TSG101+ vesicles within A375 cells, particularly at 8 and 24 hours. The EV populations exhibited sizes consistent with exosomes (24 hours: 132.4 ± 5.7 nm, 48 hours: 145.0 ± 7.8 nm), with more particles in the Doxo group compared to the Control group (Fold Change: 24 hours: 4.0 ± 0.2, 48 hours: 19.4 ± 0.1). In addition, cells exposed to Doxorubicin and cultured for 48 hours showed a significantly shortened cell cycle of A375 cells and an increased production of MVBs, which could lead to a higher exosome secretion.

In conclusion, our findings suggest that exposure of A375 cells to 10nM Doxorubicin intensifies the process of exosome biogenesis and secretion. The heightened transport of biomolecules by tumoral EVs could potentially contribute to both local and distant effects induced by Doxorubicin. This may expand our understanding of cancer biology and hold significant clinical implications for cancer treatment and the reduction of its side effects.

539V **Select mitochondrial toxicants induce an enhanced RNA interference response in *C. elegans*** Clare Sparling[1], Dillon King[1,2], Joel Meyer[1] [1]Duke University, [2]National Institute of Environmental Health Sciences

Mitochondrial dysfunction activates immune responses and plays a role in many immune diseases. Given that many environmental toxicants also target mitochondria, we assessed whether mitochondrial toxicants activate immune responses in *Caenorhabditis elegans.* Studying this question serves two purposes. One, it may identify environmental toxicants that modulate immune activity. Two, probing various aspects of mitochondrial dysfunction with mechanistically distinct toxicants may provide insight into the specific characteristics of dysfunction that induce immune activation in *C. elegans.* RNA interference (RNAi) is used by *C. elegans* to defend against pathogens. Thus, enhanced RNAi was used to screen for immune activation*. Lir-1* double-stranded RNA (dsRNA) causes lethality in *C. elegans* with enhanced RNAi but fails to do so in worms with basal levels of RNAi. *C. elegans* were developmentally exposed to various mitochondrial toxicants and stressors and fed *lir-1* dsRNA to screen for an enhanced RNAi (eri) response. Antimycin A (Complex III inhibitor), rotenone (Complex I inhibitor), paraquat (redox cycler), and sodium azide (Complex IV inhibitor) exposures induced an eri phenotype in *C. elegans*. Carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (uncoupler), N,N'-dicyclohexylcarbodiimide (ATP synthase inhibitor), thenoyltrifluoroacetone (Complex II inhibitor), and UVC (mtDNA damage) exposures failed to induce an eri phenotype*.* Our findings suggest that certain aspects of mitochondrial dysfunction induce an enhanced RNAi response in *C. elegans* while others do not.

540V **Analysis of calcium-regulated phosphorylation changes in fly and mouse egg activation** Jonathon M Thomalla[1,2], John C Schimenti[2], Mariana F Wolfner[1] [1]Molecular Biology and Genetics, Cornell University, [2]Biomedical Sciences, Cornell University College of Veterinary Medicine

The oocyte to embryo transition ("egg activation") switches a terminally differentiated oocyte to a totipotent zygote. A rise in cytoplasmic calcium (Ca^{2+}) in the oocyte is the conserved trigger for new translational programs, completion of meiosis, and other activation events; these events all occur without new transcription. Here, we use a dual-model approach (Drosophila and mouse) to identify how this conserved transition is regulated. In Drosophila, Ca^{2+}-activated enzymes modify the phosphorylation states of stored maternal proteins to regulate meiotic and translational processes. We compared the Drosophila egg activation phosphoproteomes to those in Xenopus laevis, the only vertebrate with an egg activation phosphoproteome. We identified conserved phospho-proteins, and we have begun to use the Drosophila model to test the importance of their phospho-regulation by engineering versions of the endogenous loci that will encode non-phosphorylatable or phosphomimetic phosphoproteins. In addition, we are exploring the upstream regulators of the phospho-changes. While one cation channel (TRPM) is necessary for the most dramatic rise of calcium during Drosophila egg activation, the phospho-modulation appears to require additional channels, which we are currently identifying. To test whether mammals follow the Drosophila phospho-regulatory paradigm described above, we have collected over 40,000 wild type (WT, C57BL/6J) mouse oocytes and activated eggs to analyze by quantitative phosphoproteomic LC-MS/MS. Our preliminary proteomics detected proteins belonging to egg activation processes, such as spindle components, cell cycle regulators, and translation factors; we also detected phosphorylated peptides belonging to phospho-modulated proteins, like Importin-alpha-2, that we found among phospho-proteins in Drosophila and Xenopus activating eggs. To test whether Ca^{2+}-activated enzymes regulate

phospho-state in activating mammalian oocytes, as in flies, we generated a mutant mouse line for the Ca^{2+}-dependent protein kinase CaMKIIg. This CaMKIIg-/- mutant is female sterile, and its eggs fail to complete meiosis, consistent with a previous report. To test whether CaMKIIg regulates the phosphoproteome as mouse oocytes activate, we will compare the CaMKIIg-/- phosphoproteome to WT. Taken together, we are leveraging the strengths of the mouse and fly model systems to interrogate foundational and detailed mechanistic aspects of egg activation.

541T **WormAtlas: New Chapters, New Data, New Worms** David H Hall[1], Nathan E Schroeder[2], Laura A Herndon[1], Catherine A Wolkow[1], Zeynep F Altun[1] [1]Neuroscience, Albert Einstein College of Medicine, [2]Crop Sciences, University of Illinois

The well-characterized anatomy of *C. elegans* has propelled its use as a model organism. Initially characterized through extensive light and electron microscopy (EM) observations, these data continue to provide insight into *C. elegans* biology. The Center for *C. elegans* Anatomy is a hub for the presentation and interpretation of anatomical data through the WormAtlas and WormImage websites. WormAtlas comprises multiple resources designed to assist users in understanding the structure of *C. elegans* and, ultimately, in interpreting their own anatomical data. During 2023, WormAtlas and WormImage logged over 260,000 pageviews from 43,000 users. Users came from 172 countries, with the U.S. having the largest user base, followed by Germany, Japan, India, China and Canada. The WormAtlas handbook chapters include tissue-specific descriptions of *C. elegans* anatomy. Originally, focused on the adult hermaphrodite and male, we have expanded our handbooks on dauer anatomy and structural changes that occur during aging. During the past year, new chapters were posted on muscle and the reproductive system in aging *C. elegans*. We are also extending our coverage of anatomy beyond *C. elegans* by recruiting members of the nematode community to contribute chapters on *Pristionchus pacificus* and the human parasitic nematode *Strongyloides stercoralis.* In addition to our collection of physical EM archives of *C. elegans,* mostly now available in digital form on WormImage, we have begun retrieving archival EM data sets of other nematode species. These additional data sets include approximately 50,000 negatives and prints that are being digitized and annotated for future inclusion on WormImage. We have recently partnered with the NIH-funded BossDB image repository to host datasets used for the "Mind of the Worm" (White et al., 1986). To ensure the long-term viability of WormAtlas, the Hall and Schroeder labs are working together to develop new tools and features. Together, we co-hosted a workshop recently in Glasgow on advances in EM techniques for the worm. Over the next year much of the physical archives will be transferred to the University of Illinois where they will remain accessible to the research community.

542T **A robotic platform for fully automated developmental and ageing studies in *C. elegans*: application to the genetic mapping of lifespan and mitochondrial stress response** Elena Katsyuba[1], Arwen Gao[2,3], Lazar Stojkovic[1], Gaby El Alam[3], Fabien Tâche[1], Maroun Bou Sleiman[3], Matteo Cornaglia[1], Johan Auwerx[3], Laurent Mouchiroud[1] [1]Nagi Bioscience SA, [2]Laboratory Genetic Metabolic Diseases, Amsterdam UMC, [3]Laboratory of Integrative Systems Physiology, École Polytechnique Fédérale de Lausanne

C. elegans is a powerful model organism for biomedical studies. However, the traditional protocols, which continue to be broadly used, rely on manual handling, making them labor-intensive and time-consuming. Automation of these processes would greatly benefit long-term studies of *C. elegans*. Significant progress has been achieved over the past decade in the techniques to study worm's biology: the introduction of microfluidic approaches for different assay types and the use of machine learning-based algorithms for data processing offer an increase in experimental throughput and a better control of experimental conditions.

We propose here a novel solution for automated developmental and ageing studies in *C. elegans* aggregating these new mentioned methodologies. Our microfluidic-based robotic platform is capable to fully automate all the key aspects of *C. elegans* experimentation, including worm culture, treatment, imaging, as well as data recording and analysis. The unique characteristics of the platform allow high content phenotypic studies on multiple worm populations in parallel that go beyond a simple tracing of growth or survival curves. We present here a panel of standardized bioassays allowing automated: (1) monitoring of *C. elegans* lifespan, (2) assessment of worm fitness, (3) testing of different stress responses activation and (4) identification of developmental and reproductive phenotypes that can serve as potential predictors of ageing.

To validate the performance of the assays, we mapped the genetic determinants of lifespan in a worm genetic reference population – the recombinant intercross advanced inbred lines (RIAILs). From 85 worm lines, we assessed the life-history traits on-chip, including the development time, growth dynamics, and reproduction. RIAIL lifespans, previously generated with the traditional on-plate method, exhibited large variations, and were positively correlated with developmental time on-chip. Among the top candidates obtained from QTL mapping, novel longevity modulators were identified and validated.

543T **Fourth Chromosome Resource Project: a comprehensive resource for genetic analysis in Drosophila that includes humanized stocks** Michael Stinchfield[1], Brandon Weasner[2], Bonnie Weasner[2], David Zhitomersky[3], Justin Kumar[2], Michael O'Connor[3], Stuart Newfeld[1] [1]Arizona State Univ, [2]Biology, Indiana University, [3]Genetics, Cell, Development, University

Minnesota

The 4th chromosome is the final frontier for genetic analysis in Drosophila. Small, heterochromatic and devoid of recombination the 4th has long been ignored. Nevertheless, its long arm contains 79 protein coding genes. The Fourth Chromosome Resource Project (FCRP) has a goal of facilitating the investigation of genes on this neglected chromosome. The project has 446 stocks publicly available at the Bloomington and Kyoto stock centers with phenotypic data curated by the FlyBase and FlyPush resources. Four of the five stock sets are nearly complete: 1) UAS.fly cDNAs, 2) UAS.human homolog cDNAs, 3) gene trap mutants and protein traps, plus 4) stocks promoting meiotic and mitotic recombination on the 4th. Ongoing is mutagenesis of each 4th gene on a new FRT bearing chromosome for marked single cell clones. Beyond flies, FCRP facilitates the creation and analysis of humanized fly stocks. These provide opportunities to apply Drosophila genetics to the analysis of human gene interaction and function. In addition, the FCRP provides investigators with confidence through stock validation and an incentive via phenotyping to tackle genes on the 4th that have never been studied. Taken together, FCRP stocks will facilitate all manner of genetic and molecular studies. The resource is readily available to researchers to enhance our understanding of metazoan biology, including conserved molecular mechanisms underlying health and disease.

544T **Deciphering the contribution of 3D interactions between cis-regulatory elements and promoters to regulate gene expression using graph neural networks** Yang Chen[1], Elissa Lei[2] [1]LGB, NIH, [2]LBG, NIH

Gene expression is regulated by various factors including histone modifications (HMs), binding of transcription factors (TFs), and interplay of diverse cis-regulatory elements (CREs) in a cooperative manner. Two previous methods (GC-MERGE and Chromoformer) have been developed to predict gene expression by constructing a promoter-centered network based on 3D physical contacts between the promoter and CREs. However, these published models lack transferability to various sizes of gene graphs and explanation of the influence of these factors on gene expression.

We present a novel deep learning architecture creGNN based on a graph transformer network. Our approach can ascertain the key factors that regulate gene expression and can identify important CREs for each gene. We pre-trained the model using data augmentation and contrastive learning. We used ~800 ChIP-seq datasets of HMs and TFs, Hi-C/micro-C, ATAC-seq and RNA-seq data from human, mouse and fly genomes. Promoter-centered graphs were built for each gene based on the regions across the genome that contact the promoter in 3D space.

We trained a model based on HMs and calculated the Pearson correlation, AUC, and AUPRC between raw gene expression and predicted gene expression in four cell lines. creGNN showed better prediction performance relative to other existing methods. Second, we trained another model based on TFs, which showed close performance relative to that using HMs. By ranking node importance, we found that TFs and HMs co-regulate gene expression by binding to different CREs. Third, we tested the effect of 3D contacts on gene expression. 3D contact frequency showed low correlation with attention scores for all genes on a global level. Our results suggest that gene expression is dictated by promoter region activation or repression by CREs and that 3D contacts are important/necessary in specific cases but provide a lower relative contribution to overall gene expression than promoters and CREs themselves.

Compared to previously developed methods, creGNN exhibited higher accuracy and good transferability. We aspire to use our method to identify novel specific 3D contacts among promoters and CREs that contribute to the regulation of specific genes. This predictive power should not only contribute to our knowledge of specific gene regulatory mechanisms on the 3D level but also allow us to design targeted strategies to modify gene expression within individual cells.

545T **Nitroreductase Assay: A new method of cell ablation in Drosophila** Gary Teeters[1], Christina Cucolo[1], Sagar Kasar[1], Sarah Siegrist[2] [1]University of Virginia, [2]Biology, University of Virginia

Genetic control of cell ablation has allowed *Drosophila* researchers to uncover many mechanisms of development and regeneration. While powerful, this method is limited in temporal control. Gal80s can be utilized, however they use oscillations between 18°C and 29°C which changes the development rate of *Drosophila*. Disruptions of development rate can lead to difficulties interpreting results from development and regeneration assays. We have developed a new method for cell ablation in *Drosophila* based on previous work done in *Danio Rerio*. This method utilizes a UAS driven Nitroreductase gene isolated from E. coli which transform nitroaromatic drugs into strong DNA cross linkers leading to cell death. This construct allows us genetic and temporal control of cell death without the need for temperature shifts. We have found this ablation system to be effective at killing multiple developing tissues of *Drosophila*, with nearly no viability defects. In addition, we have found that animals only need to be exposed to drug for 12 hours to initiate cell death. These results lead us to conclude that the nitroreductase assay is a superior method for cell ablation in development and regeneration studies.

546T **A recombination system to assemble an integrated genetic circuit at a single locus in animals** Junjie Luo[1,2], Cheng

Huang[1,3], Seung Je Woo[1], Jane Li[1], Mark J. Schnitzer[1,2,3,4,5] [1]James Clark Center, Stanford University, [2]Howard Hughes Medical Institute, [3]Department of Biology, Stanford University, [4]CNC Program, Stanford University, [5]Department of Applied Physics, Stanford University

Transgenic reporters and effectors are important tools for genetic, developmental and neuroscience experiments. To achieve highly specific expression patterns, or to use a combination of multiple reporters and effectors, it is often desirable to create transgenic animals that have multiple transgenic elements. When recombining multiple transgenic elements into an animal genome by traditional approaches, researchers generally need to screen for a strain containing all the transgenic elements, the frequency of which declines exponentially with the number of transgenes. For this reason, traditional methods of recombination are poorly suited to the generation of animals with many transgenic elements.

To overcome this limitation, we developed a set of genetic tools that we call the 'Super Recombinator' system (SuRe), which facilitates the recombination of a chosen pair of transgenes at the same locus. The SuRe system adds an adaptor sequence upstream or downstream of each transgene. These adaptors then facilitate the recombination of the two transgenes in a transgenic tandem. Because this transgenic tandem does not segregate in the subsequent recombination steps, the SuRe system exponentially accelerates the recombination process and dramatically reduces the level of effort needed to screen for a strain with all the transgenic elements.

We tested two variants of the SuRe system in *Drosophila melanogaster*, SuRe-C (SuRe based on CRISPR/Cas9) and SuRe-CR (SuRe based on CRISPR/Cas9 and recombinase). Both variants showed recombination efficiencies dramatically higher than that of natural recombination, which is zero for recombination at the same locus. SuRe-CR has a recombination efficiency of ~48% and can recombine tandems up to 2 Mbps. SuRe-C has a lower recombination efficiency (~30% for females and ~7% for males) but involves fewer enzymes and should generalize more easily to other species.

We demonstrated the use SuRe by using it to successfully concatenate multiple splitGAL4 elements to drive the joint expression of several different fluorescent voltage indicators, enabling *in vivo* imaging of spikes in several different types of neurons simultaneously. Overall, the SuRe approach represents a new strategy for creating animals that have multiple transgenic elements and that are in increasing demand for state-of-the-art experiments in genetics, neuroscience and synthetic biology.

547T **GIVIAR: GRN Inference and Visualization from Independent scATAC-seq and scRNA-seq Data** Justin Currie, Tuan Pham, James Kentro, Gunjan Singh, Kate O›Connor-Giles, Erica Larschan Brown University

Gene Regulatory Networks (GRNs) control dynamic gene expression and thus play a fundamental role in the generation and maintenance of diverse cellular states. GRN inference methods can achieve higher resolution by integrating both gene expression and chromatin accessibility data at the single cell level. This has significantly increased demand for multi-omic datasets in which gene expression (scRNA-seq) and chromatin accessibility (scATAC-seq) data are obtained from the same cell. However, generating multi-omics data is both expensive and challenging. Therefore, the ability to integrate the large number of existing independent datasets to form pseudo-multiomic datasets is of great importance. Additionally, single-cell data suffers from high dropout levels, leading to insufficient results after downstream analysis. Here, we present GIVIAR - a GRN Inference and Visualization pipeline from Independent scATAC-seq and scRNA-seq data. Our pipeline compiles existing methods for scRNA-seq dropout imputation, integration of scRNA-seq and scATAC-seq data, and multi-omic GRN inference to produce candidate GRNs. We applied our pipeline to a single-cell atlas of embryonic D. melanogaster data with the goal of identifying transcription factors responsible for orchestrating the coordinated expression of genes involved in synapse formation. Our results reveal several known regulators of synaptic genes, as well as many new candidate regulators for in vivo validation.

548T **Generating gene-specific-split-GAL4 lines from coding intronic MiMIC lines via *in vivo* crosses for *Drosophila*** Siqi April Li[1], Hongzhou Gustave Li[2], Yu-Chieh David Chen[3], Claude Desplan[1] [1]Biology, New York University, [2]New York University Shanghai, [3]New York University

Recent technical advances in *Drosophila* genetics have enabled the generation of gene-specific T2A-split-GAL4 lines, which can be used for genetic manipulation of gene expression in various experimental settings. Our lab has recently shown that gene-specific T2A-split-GAL4 lines recapitulate well with the scRNAseq data compared to the enhancer-based split-GAL4 lines. However, converting the existing MiMIC lines into gene-specific T2A-split-GAL4 lines required embryo injection of corresponding donor DNA, which is often expensive when outsourcing *Drosophila* microinjection services to a company.

This project aims to generate MiMIC split-GAL4 drivers via *in vivo* crosses, which can provide a more accessible alternative to

traditional microinjection methods and contribute to the *Drosophila* research community. The *in vivo* crosses for generating the gene-specific T2A-split-GAL4 lines involve four rounds of crosses followed by two validation steps. First, we cross female flies carrying the T2A-split-GAL4 donor sequence with male flies carrying the MiMIC insertion and select offspring that have both donor and MiMIC genetic components. Next, we cross male offspring with female flies carrying hs-Cre and vas-PhiC31 and then select male offspring that carry all three genetic components (hs-Cre, vas-PhiC31, donor, and MiMIC) from the parents. By crossing them with female double balancer genes, we can induce the expression of Cre recombinase and thus excise the split-GAL4 donor into the circular DNA, which will then be integrated into the MiMIC insertion site by the Recombinase-mediated cassette exchange (RMCE) process. We select the males that are successfully swapped by the loss of yellow marker and then set up a single male fly cross with 3-4 double balancer females to establish potential crosses. A PCR genotyping verification of integration orientation is required since the PhiC31 system does not recognize orientation and the split-GAL4 fragments can be inserted in either direction. Finally, the potential stocks with correct orientation will then be crossed with flies carrying UAS-EGFP and constitutively expressing either GAL4DBD or VP16 to test for expression of GFP to ensure the validity of the potential stock. Our work will significantly reduce the cost and increase the accessibility of generating gene-specific T2A-split-GAL4 lines, which will enable fly researchers to generate cell-type-specific genetic tools at lower cost.

549T **Video Analysis System for Behavior and Activity Assessment of Fruit Flies in High Throughput Studies** Ibraheem Farooq[1], Brian Oliver[1], Ghadi Salem[2], Marcial Garmendia-Cedillos[2], Abhishek Somenhalli[2], Nikhil Khandekar[2], Luis Argueta[2], Noah Cubert[2], Maria Jaime[3], Tom Pohida[2], Jessica Holsopple[4], Shannon Smoot[4], Thomas Kaufman[4], Jason Tennessen[4] [1]National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), National Institutes of Health (NIH), [2]Instrumentation Development and Engineering Application Solutions (IDEAS), NIBIB, National Institutes of Health (NIH), [3]Exact Sciences Laboratories, [4]Department of Biology, Indiana University-Bloomington

Behavioral analysis in organisms is very valuable because it provides insight beyond just genotypic examination, however, it is generally low throughput. Therefore, we have devised a compact, high throughput, automated behavioral screening system. The video-based system reports on the activity of each fly within each well of custom designed 24-well plate. The viewing arena is comprised of a near-infrared backlight stage with programmable white light LEDs located on the perimeter of the viewing arena. Atop the stage, the custom housing plate rests on the feeding plate allowing for an interface between the holes on the bottom on each housing well and the liquid fly food located in the feeding plate wells below. Fly survival rate upon testing in this arena environment with 25 uL of food is 96% after 12 hours and 83% after 24 hours. The survival rate improves after 24 hours if food is replaced after 12 hours and if wells are loaded with larger initial food quantities. The video monitoring system is designed to perform 24-hour plus behavioral assays where flies are exposed to liquid fly food that has been spiked with one of 216 chemicals to observe behavioral differences from wild type caused as a result of those spiked compounds. The system records video from 4 different cameras which are then stored and processed via a resnet-50 that automatically labels 2D fly skeleton key points and automatically assigns behavioral predictions based on training through a large annotation set. Current work on this project focuses on improving our data set for training, developing algorithms to automatically quantify activity and behavior for each individual fly, tracking fly key points in 3D space, and implementing real-time analysis.

550T **Rat Resource and Research Center** Elizabeth C Bryda[1], Hongsheng Men[2], Daniel Davis[2], Craig L Franklin[2], James M Amos-Landgraf[2], Yuksel Agca[2], Aaron C Ericsson[2] [1]Veterinary Pathobiology, University of Missouri, [2]University of Missouri

The NIH-funded Rat Resource and Research Center (RRRC) serves as a centralized repository for maintaining/distributing rat models and providing rat-related services to the biomedical community. Currently, the RRRC has close to 600 rat lines; all are archived by cryopreservation to ensure against future loss. The RRRC distributes live animals, cryopreserved sperm/embryos, and rat embryonic stem (ES) cell lines. Quality control measures for all materials include extensive genetic validation and health monitoring. The RRRC has expertise in rat reproductive biology, colony management, health monitoring, genetic assay development/optimization, isolation of germline competent ES cell lines from transgenic rats and can partner as consultants/collaborators. Fee-for-service capabilities include a wide variety of genetic analyses, strain rederivation and cryopreservation, isolation of rat tissues, microbiota analysis and characterization of genetically engineered rats. The RRRC, in conjunction with the MU Animal Modeling Core, makes genetically engineered rat models from start to finish using a variety of state-of-the-art technologies including genome editing (*e.g.*, CRISPR/Cas9) as well as traditional methods such as random transgenesis and modified embryonic stem cell microinjection into blastocysts. Our website (www.rrrc.us) allows user-friendly navigation. Current research efforts include generation and characterization of a variety of new rat models and improvements to rat *in vitro* fertilization. The University of Missouri is home to the NIH-funded MU Mutant Mouse Resource and Research Center (MMRRC) and the National Swine Resource and Research Center (NSRRC) as well as the MU Animal Modeling Core and MU Metagenomics Center. Together, these highly collaborative groups provide a variety of animal model-related services across species to facilitate biomedical research. Funding: NIH 5P40 OD01106.

551T **Updating Uninformative Mouse Gene Symbols** Monica McAndrews, Cynthia Smith Mouse Genome Informatics, The

Jackson Laboratory

Standardization of nomenclature for mouse genes, alleles and strains facilitates the communication and integration of scientific knowledge about the laboratory mouse and supports effective and robust comparative genomic analysis. The International Committee on Standardized Genetic Nomenclature for Mice strives to develop unique and informative nomenclature for mouse genes, genetic markers, alleles, chromosome aberrations, genomic features, and strains. With some exceptions, we coordinate symbols and names of genes and genetic markers with the Human Gene Nomenclature Committee (HGNC) and the Rat Genome Database (RGD) and we reach out to interested investigators to develop appropriate nomenclature within the Nomenclature Committee's guidelines (https://www.informatics.jax.org/mgihome/nomen/gene.shtml). Taking advantage of the recently released paralogy data provided on the Alliance for Genome Resources (https://www.alliancegenome.org/) gene pages, we are focusing on giving informative nomenclature to gene models which belong in large gene families such as the zinc finger proteins and keratin associated proteins. Many potential members of these gene families have uninformative gene symbols that consist of sequence identifiers or a sequential gene model (GM#) designation. This poster will outline recent efforts to update uninformative mouse gene symbols and include them within gene family nomenclature.

MGI is supported by NIH HG000330

552T **Online databases and data integration in the RIKEN BioResource Research Center** Hiroshi Masuya[1], Toyoyuki Takada[1], Daiki Usuda[1], Naomi Yuhara[1], Keiko Kurihara[1], Yuri Namiki[1], Shigeru Iwase[1], Kenta Suzuki[1], Yuki Yamagata[2], Takeya Kasukawa[3], Hideya Kawaji[4], Shinya Oki[5], Tatsuya Kushida[1] [1]BioResource Research Center, RIKEN, [2]Head Office for Information Systems and Cybersecurity, RIKEN, [3]Center for Integrative Medical Sciences, RIKEN, [4]Research Center for Genome & Medical Sciences, Tokyo Metropolitan Institute of Medical Science, [5]Department of Drug Discovery Medicine, Kyoto University

Online databases are important infrastructures for facilitating the widespread, effective, and efficient use of biological genetic resources as experimental materials in life science. To improve the findability, accessibility, interoperability, and reusability of bioresource data, adding "metadata" with data integration with public biological data is one of the effective ways.

The RIKEN BioResource Research Center (BRC) is a public repository to collect, preserve, and provide experimental mice, *Arabidopsis thaliana* as a laboratory plant, cell culture lines derived from humans and animals, microorganisms, and associated genetic materials. The online catalog of these bioresources is available at https://brc.riken.jp, with a search function by resource name, species, disease, phenotype, and gene for keywords. The system is driven by an integrated knowledge base of publicly available data on bioresources, genes, orthologs, diseases, and ontologies that form a knowledge graph through Semantic Web technologies. Currently, data and metadata of 6,156 mice, 612,131 plants, 11,857 cells, 168,193 DNAs, and 19,777 microbes are openly available from https://knowledge.brc.riken.jp and searchable from https://brc.riken.jp.

Genome-centric data integration is also underway in the RIKEN BRC. We released a genomic variation database of mouse strains, MoG$^+$ (https://molossinus.brc.riken.jp/mogplus/) in which SNPs for multiple strains including Japanese wild mice-derived strains are openly available. In 2022, collaboration is started with a genome-wide integrated database for cis-regulatory elements (CRE), trans-factors, and epigenomes, INtegrated TRAnscriptional REgulation Data platform **(**INTRARED: https://www.intrared.org/) for promoting the understanding of the transcriptional regulations. Through these activities, we will contribute to improving the reproducibility of genetics studies through the expansion of the usability of bio-resources.

553T **Update of MoG+: a database of mouse genomic variations connecting bioresource and biomedical research** Toyoyuki Takada[1], Daiki Usuda[1], Tatsuya Kushida[1], Toshihiko Shiroishi[1], Takeya Kasukawa[2], Hiroshi Masuya[1] [1]RIKEN BioResource Research Center, [2]RIKEN Center for Integrative Medical Sciences

Genome information of living organisms has become indispensable not only for understanding biodiversity, evolution, and phenotypes, but also for strategic planning of biomedical research. Use of genome information of laboratory mouse (*Mus musculus*) is essential for production of genome-edited animals. The classical inbred mouse strains are known to have mosaic genomes derived from three or four different *M. musculus* subspecies. Recently, we have conducted a whole-genome resequencing of a group of 10 wild-derived inbred mouse strains originated from the above-mentioned different subspecies. More than 40 million nucleotide variations revealed from the analysis are open to public via a mouse genome database of RIKEN BRC, MoG+ (https://molossinus.brc.riken.jp/mogplus/). MoG+ enables users to visualize intuitively those nucleotide variations in genes and intergenic regions of interest for multiple mouse strains. We are also updating MoG+ to ensure high-resolution comparison of mouse and human genome variations in orthologous genes to promote comparative genomics. MoG+ has also been upgraded with new features to facilitate research in the field of medical biology, such as addition of the latest genome information for other strains, linking to publicly available genomic variants of commonly used strains,

and human disease-associated genome variants, as well as collaboration with INTRARED (https://www.intrared.org/), a data platform to identify genome variations that affect the transcriptional regulations.

554T **Spatial statistical tools applied to genome landscapes of mutations help to refine the mutational signature concept and uncover new mutational mechanisms** Kathleen A Hill[1], David Chen[1], Bin Luo[2], Joseph Butler[1], Freda Qi[1], Nicholas Boehler[3], Hailie Pavanel[3], Cornelia Tolg[4], Eva Turley[4], Reg Kulperger[3], Charmain Dean[5] [1]Biology, Western University, [2]Statistics and Actuarial Sciences, Western University, [3]Western University, [4]London Health Research Institute, [5]Waterloo University

Mutational signatures are valuable tools for classification of cancer types and the elucidation of both mutagen exposures and mutational mechanisms. However, the current conceptualization of mutational signatures fails to consider the associations between different mutation types across the spatial landscape of entire chromosomes. Novel statistical tools permit characterization of the spatial relationship between single nucleotide substitutions or variants (SNVs) and heterozygous loci and copy number variants (CNVs). We adapted the J statistic, a nonparametric test for spatial independence between genomic events, to examine the spatial associations between SNVs, heterozygosity and CNVs in contexts of germline and somatic mutagenesis. Our J statistic pipeline is packaged as an easy-to-use, standalone R package. The pipeline can be applied to a variety of statistical genomics scenarios that require tests of association between genomic regions and sets of genomic coordinates, and accepts input data produced by genotyping arrays, whole exome sequencing or whole genome sequencing. The package offers a range of features that allow users to design hypothesis-driven tests for genomic spatial association using the J statistic, including customization of the maximum genomic distance between genomic points and regions and the interval step size to test for spatial association. We applied our tool in the two case studies: 1] associations between heterozygosity and CNVs for diverse mouse genetic backgrounds differing in the extent and genome spacing of heterozygosity and 2] associations between *de novo* SNVs and CNVs with tumorigenesis and metastasis in a mouse model of breast cancer with metastasis. Our tool successfully detected nonrandom, proximal associations between heterozygosity and CNVs relevant to novel mutational mechanisms associated with meiosis and clustered heterozygosity. We also characterized distal associations between *de novo* SNVs and CNVs in the mouse model of tumorigenesis with metastasis. Mutational signatures that incorporate signature spatial landscapes of mutations are predicted to increase the resolution of mutational signatures and cancer type classifications and advance our mechanistic understanding of mutagenesis.

555T **A statistical model for inferring rates of meiotic and mitotic chromosome segregation using data from preimplantation human embryos** Qingya Yang, Sara A. Carioscia, Rajiv C. McCoy Johns Hopkins University

Embryonic arrest and miscarriage are common in humans and largely trace to the gain or loss of chromosomes (aneuploidies) during meiosis or mitosis. Preimplantation genetic testing for aneuploidy (PGT-A) seeks to improve the outcomes of in vitro fertilization (IVF) by prioritizing chromosomally normal (i.e., euploid) embryos for transfer. This procedure entails a biopsy of 5-10 cells from the trophectoderm of day 5 blastocyst-stage embryos, which are then sequenced and classified as euploid, aneuploid, or mosaic (composed of a mixture of cells with different karyotypes). It is expected that a meiotic error arising during egg formation will lead to uniform aneuploidy across all cells and that such embryos will be classified as aneuploid. In contrast, depending on the extent and spatial organization of aneuploid cells within mosaic embryos, mosaicism may or may not be detected based on the trophectoderm biopsy. Thus, while the relative incidences of euploid, aneuploid, and mosaic embryo biopsies are readily reported based on PGT-A data, the underlying rates of meiotic and mitotic errors remain unknown. Knowledge of the rates of these fundamental biological mechanisms would inform understanding of chromosome dynamics in human embryos, with implications for both the reliability and interpretation of PGT-A data as well as the basic biology underlying early human development.

To this end, we developed a simulation framework to facilitate inference of the rates of meiotic and mitotic chromosome mis-segregation in early-stage human development, testing the range of parameter space that best explains observed PGT-A data. Specifically, we simulated thousands of embryos with varying meiotic and mitotic error rates and conducted the process of multi-cell biopsy, mimicking the clinical procedure. We then applied approximate Bayesian computation (ABC) to identify the combination of meiotic and mitotic error rates that best explain the incidences of euploid, aneuploid, and mosaic biopsies reported in recent literature. Our results reveal that a 30-35% meiotic error rate and a 2-7% mitotic error rate best approximate the published data. These estimates facilitate quantitative understanding of chromosome mis-segregation rates in human preimplantation embryos, enhancing knowledge of human development and informing the use of PGT-A data in the clinic.

556T **The European Variation Archive: Genetic variation archiving and accessioning for all species** Thomas Keane, Tim Cezard, Dona Shaju, April Shen, Nithin Kumar EMBL-EBI

The European Variation Archive (EVA) is a primary open repository for archiving, accessioning, and distributing genome

variation including single nucleotide variants, short insertions and deletions (indels), and larger structural variants (SVs) in any species. The EVA has archived more than 4.2 billion variants across 2,569 studies and 250 species since its launch in 2014. A key function of the EVA as a long-term data archive is to provide globally unique persistent identifiers for all discovered variant loci (RS identifiers) so that they can be referenced in publications, cross-linked between databases, and integrated with successive reference genome builds. For recently sequenced species, the EVA provides a free resource to archive and share genetic variants for publication and cross referencing.

The EVA regularly releases versions of all the RS identifiers it creates. The fifth release (August 2023) featured 2.2 billion variants from 250 species (featuring 18 new species including European seabass, Millet, and Plasmodium vivax). Millions of loci have been updated to a newer assembly to synchronise with the assemblies supported by Ensembl and UCSC genome browsers. The release data is available primarily via FTP[1] but all the underlying RS identifiers are queryable on the EVA website[2] and the EVA REST API[3].

Other services for researchers include: standard variant annotation, calculation of population statistics, and an intuitive browser to view and download queried variants in either Variant Call Format (VCF) or Comma-Separated Value (CSV) files backed up by a comprehensive REST API to query and export variant and genotypes programmatically.

The EVA also contributes to the maintenance of the Variant Call Format (VCF) specification and has implemented a validation suite to ensure correctness of all the submissions made to the archive. This suite, as well as the rest of our software is freely available on GitHub[4] and has amassed ~7,300 downloads worldwide.

557T **Improving Laboratory Animal Genetic Reporting** Lydia Teboul[1], Guillaume Pavlovic[2] [1]MRC-UKRI, [2]Institut Clinique de la Souris

The biomedical research community acknowledges the challenges of reproducibility in biomedical research and has initiated efforts to address this issue. These efforts encompass nomenclature guidelines, enhancement and pre-registration of experimental designs, and open access initiatives. Crucial to this is the establishment of common documentation standards for animal experiments. The ARRIVE guidelines outline key aspects for documenting laboratory animals used in experiments, but a need remains for more comprehensive information on the genetics of research animals. We have started an initiative, involving members of key societies and consortia (IMGS, IMPC, ISTT) to assemble guidelines for the documentation of laboratory animal genetics. We also discuss how existing resources for standardisation of nomenclature are important frameworks that support research reproducibility.

558T **Differential and conditional elimination of marked homomorphic sex chromosomes in *Aedes aegypti* for disease vector population control** Melanie Hempel[1], Austin Compton[1], Atashi Sharma[1], Azadeh Aryan[1], Wanhao Chi[2], Xiaoxi Zhuang[2], Jake Tu[1] [1]Biochemistry, Virginia Tech, [2]Neurobiology, University of Chicago

Aedes aegypti mosquitos are the major vector for multiple viruses that cause diseases including dengue, yellow fever, and Zika. In contrast to other insect species such as *Drosophila melanogaster* and anopheline mosquitos, *Ae. aegypti* have *homomorphic sex-determining chromosomes*. On chromosome 1, there is a small (1.3 Mb), dominant, male determining locus (M-locus), while the rest of the chromosome is autosomal and susceptible to recombination. Within this M-locus resides two genes essential for male development: *Nix*, which is the male determining factor that is required and sufficient for male sex development; and *myosex*, which is responsible for male flight.

We take advantage of the homomorphic nature of the sex chromosomes and the extremely low recombination surrounding the sex locus to develop new ways to achieve effective separation of the non-biting males from the females, which is a *critical* bottleneck affecting all genetic control programs. These new methods were enabled by developing incompatible sex chromosomes and/or by conditional elimination of M- or m- bearing sex chromosomes. These methods are highly efficient and provide a diverse array of possibilities including the production of non-transgenic male mosquitoes.

One of the new approaches is a system of **D**ifferential **E**limination of **Mark**ed sex chromosomes (DeMark), which uses recessive lethal alleles to eliminate all transgenic male mosquitos, producing exclusively non transgenic males for release. We have

also created multiple lines of conditional lethality – both through selection and counterselection measures – that have the potential for the conditional selection of males. These diverse technologies can be applied to a wide array of genetic biocontrol measures to maximize disease prevention while improving efficiency, cost effectiveness, and catering to the needs of various communities.

559T **Developing a molecular toolkit for ecological, evolutionary, and functional genomics in *Daphnia*** Megan Maar[1], Jake Miller[1], Michael Lynch[2], Andrew C Zelhof[1] [1]Biology, Indiana University Bloomington, [2]Biodesign Center for Mechanisms of Evolution, Arizona State University

For most model species, little is known about the natural environment, significantly limiting our understanding of the evolutionary determinants of functional biological traits. In contrast, the aquatic microcrustacean *Daphnia* have been subject to more studies in ecology and ecotoxicology than any other organism and have led to many discoveries in functional biology, however, they are largely absent from the landscape of functional research at the gene level. We seek to develop *Daphnia pulex* as a model for testing hypotheses on functional biology through experimental manipulation at the gene level, bridging the genotype-phenotype gap. Our aim is to populate the Daphnia genome with attP sites for both PhiC31-mediated attP/attB exchange and recombinase-mediated cassette exchange, as well as develop a GAL4/UAS system for *Daphnia*. We are also generating and testing the delivery of Cas9 and sgRNAs on DNA plasmids under the control of endogenous heat shock and U6 promoters to establish a set of reagents for both generation of mutants and homologous recombination. Here, we will present our data on generating transgenic animals and improving the efficiency of CRISPR/Cas9 editing of the *Daphnia* genome.

560T **Applying machine learning to elucidate environmental components of microbial extremophilic genomic signatures** Joseph W Butler[1], Pablo Millan Arias[2], Gurjit S Randhawa[3], Maximillian PM Soltysiak[1], Lila Kari[2], Kathleen A Hill[1] [1]Biology, University of Western Ontario, [2]Computer Science, University of Waterloo, [3]Mathematical and Computational Sciences, University of Prince Edward Island

Next-generation sequencing has enabled whole genome sequencing, empowering big data analysis using bioinformatics and computation tools including machine learning (ML) algorithms. ML has been demonstrated to effectively analyze DNA sequence data for many applications including comparing and classifying sequences, and analyzing compositional patterns in DNA sequences in the context of genomic signatures. The genomic signature concept describes the patterns of oligonucleotide (*k*-mer) composition pervasive across the genome and associated with taxonomic classification even to the distinctions of species and subspecies taxa. The determinants of a genomic signature are not completely understood.

Extremophiles, organisms spanning all domains of life, are adapted to survive and sometimes thrive in extreme environments. These environments impose highly selective pressures that typically restrict life, such as extreme pH or temperature. Extremophiles are industrially relevant given their robust biocatalyst potential and useful as an emergent model organism for the study of astrobiology and early earth systems. Convergent adaptations have been observed within extremophiles groups, underlain by genomic and proteomic adaptations, such as anti-freeze proteins present in psychrophiles across all domains despite their distant phylogeny. Due to the selective pressures imposed on extremophiles by extreme environments, ML algorithms were employed to shed light on an environmental impact on prokaryotic genomic signature composition, unrelated to taxonomic contributions.

ML algorithm testing was initiated with the curation of a novel dataset of prokaryotic pH- and temperature-adapted extremophiles, including 693 genome assemblies (253 archaea, 440 bacteria) as the first iteration with dataset expansion as the curation continues. Representative sequences were constructed from the genome assemblies and labeled based on their adapted environment (i.e. thermophile, alkaliphile) and taxonomic rankings (domain-species name). Six classification algorithms were employed to assess *k*-mer profiles correlated with each group, enabling their classification taxonomically and environmentally with high and medium to medium-high accuracies, respectively. *K*-mer profiles were successfully compared to previously documented proteomic and genomic adaptations. Unsupervised approaches were undertaken and corroborated the existence of an environmental component of genomic signatures.

Overall, alignment-free ML methodologies have effectively identified macro-environmental imprints on prokaryotic extremophile genomic signatures, potentially aiding in understanding the resiliencies of extremophiles and characterizing environmental traits from metagenomic studies.

561T **Reliable estimation of tree branch lengths using deep neural networks** Anton Suvorov[1], Daniel R. Schrider[2] [1]Virginia Tech, [2]University of North Carolina at Chapel Hill

A phylogenetic tree represents hypothesized evolutionary history for a set of taxa. Besides the branching patterns (i.e., tree topology), phylogenies contain information about the evolutionary distances (i.e. branch lengths) between all taxa in

the tree, which include extant taxa (external nodes) and their last common ancestors (internal nodes). In phylogenetic tree inference, the branch lengths are typically co-estimated along with other phylogenetic parameters during tree topology space exploration. There are well-known regions of the branch length parameter space where accurate estimation of phylogenetic trees is especially difficult. Several novel studies have recently demonstrated that machine learning approaches have the potential to help solve phylogenetic problems with greater accuracy and computational efficiency. In this study, as a proof of concept, we sought to explore the possibility of machine learning models to predict branch lengths. To that end, we designed several deep learning frameworks to estimate branch lengths on fixed tree topologies from multiple sequence alignments or its representations. Our results show that deep learning methods can exhibit superior performance in some difficult regions of branch length parameter space. For example, in contrast to maximum likelihood inference, which is typically used for estimating branch lengths, deep learning methods are more efficient and accurate when inferring long branches that are associated with distantly related taxa and perform well in the aforementioned challenging regions of the parameter space. Together, our findings represent a next step toward accurate, fast, and reliable phylogenetic inference with machine learning approaches.

562T **An Improved Methodology for Sperm Cryopreservation in *Xenopus*** Carl Anderson[1], Lucia Arregui[2], Nikko-Ideen Shaidani[1], Terrence Tiersch[2], Marko Horb[1] [1]Marine Biological Laboratory, [2]Aquatic Germplasm and Genetic Resources Center

Cryopreservation of sperm from X. tropicalis and X. laevis improves the utility and availability of transgenic, mutant, and wild-type lines. Preserving distinct genetically modified lines through cryopreservation expands the ability of the National Xenopus Resource (NXR) to generate new lines by reducing demand for space. Using new methods developed in collaboration with the Aquatic Germplasm and Genetic Resources Center (AGGRC), we analyze Xenopus sperm to assess concentration, viability, and motility, along with testing fertilization rate. Prior to our shift in practices focusing on early process quality control and correction, we saw greater variation in sample quality, and a bottleneck resulting from testing fertilization rate. Changes to equipment, including the addition of a controlled-rate freezer, use of French straws, and a simplified cryoprotectant media, allow us to closely control crucial stages of the cryopreservation process. By adjusting samples prior to freezing based on these assessment tools we can ensure consistency and efficacy for users. Differences we have identified in sperm concentration between individuals further reinforces the importance of assessment metrics. Through use of these tools, we increase throughput by eliminating time spent producing and testing samples with subpar concentration, low viability, or poor motility. With the incorporation of these new practices, the Xenopus community will have increased access to cryopreserved lines, greater success using cryopreserved samples, and improved ability to generate new lines at the NXR. Steps we have taken to improve our cryopreservation program are a necessary part of addressing the ever-expanding demand of Xenopus as a research model.

563T **Intra-FCY1: a novel system to identify mutations that cause protein misfolding** Natalie Quan, Yuichi Eguchi, Kerry Geiler-Samerotte Arizona State University

Protein misfolding is a common intracellular occurrence. Most mutations to coding sequences increase the propensity of the encoded protein to misfold. These misfolded molecules can have devastating effects on cells. Despite the importance of protein misfolding in human disease and protein evolution, there are fundamental questions that remain unanswered, such as, which mutations cause the most misfolding? These questions are difficult to answer partially because we lack high-throughput methods to compare the destabilizing effects of different mutations. Commonly used systems to assess the stability of mutant proteins in vivo often rely upon essential proteins as sensors, but misfolded proteins can disrupt the function of the essential protein enough to kill the cell. This makes it difficult to identify and compare mutations that cause protein misfolding using these systems. Here, we present a novel in vivo system named Intra-FCY1 that we use to identify mutations that cause misfolding of a model protein (yellow fluorescent protein (YFP)) in Saccharomyces cerevisiae. The Intra-FCY1 system utilizes two complementary fragments of the yeast cytosine deaminase Fcy1, a toxic protein, into which YFP is inserted. When YFP folds, the Fcy1 fragments associate together to reconstitute their function, conferring toxicity in media containing 5-fluorocytosine and hindering growth. But mutations that make YFP misfold abrogate Fcy1 toxicity, thus strains possessing misfolded YFP variants rise to high frequency in growth competition experiments. This makes such strains easier to study. The Intra-FCY1 system cancels localization of the protein of interest, thus can be applied to study the relative stability of mutant versions of diverse cellular proteins. Here, we confirm this method can identify novel mutations that cause misfolding, highlighting the potential for Intra-FCY1 to illuminate the relationship between protein sequence and stability.

564T **Data Integration Through Allele Curation at SGD** Edith D Wong[1], Suzi Aleksander[1], Jodi Lew-Smith[1], Robert S Nash[1], Rahi Navelkar[2], Marek S Skrzypek[1], Stacia R Engel[1], J Michael Cherry[1], The SGD Project[1] [1]Genetics Department, Stanford University, [2]Harvard University

The *Saccharomyces* Genome Database (SGD; www.yeastgenome.org) is a model organism knowledgebase that aims to provide

a complete picture of eukaryotic cellular processes by curating a comprehensive and diverse collection of data types for the budding yeast *Saccharomyces cerevisiae*. In addition to other data, we also have been capturing single mutant phenotypes, as well as importing genetic and physical protein-protein interactions from BioGRID (thebiogrid.org) to help shed light on proteins' roles in cellular processes. While we have been collecting mutant types since we started annotating mutant phenotypes, we more recently decided to capture mutant alleles broadly and systematically. Users can now search for and find alleles associated with their genes of interest. In addition, pages dedicated to single alleles are now available and include information on allele type, molecular details of the mutation, alias names, and associated references, along with all phenotype and interaction annotations where specific alleles were used. Alleles that share phenotype and/or genetic interaction annotations are graphically represented in the 'Shared Alleles' section. Users will be able explore more fully previously unlinked data types using our new allele curation model to gain additional insight into cellular processes and pathways. This work is supported by a grant from the NHGRI (U41 HG001315).

565T **Determining the functional domains of the anti-CRISPR protein AcrIIA4 using a high-throughput deletion scan** Annette Iturralde[1], Cory Weller[2], Meru Sadhu[1] [1]National Human Genome Research Institute, National Institutes of Health, [2]Center for Alzheimer's and Related Dementias, National Institutes of Health

Determining the functionality of all parts of a protein is an important step to be able to fully comprehend how each building block of a gene contributes to its general function. By implementing a series of small to large scale deletions throughout a single gene, we can determine the significance of all parts of a protein. Many observed in-frame deletions within a protein have unknown effects, while mutational scans typically focus on indel mutations exclusively. To counter this, we have developed a method in which we can generate all possible deletions within a protein in a high throughput manner and evaluate the phenotypic result to determine critical regions. We have applied this method to AcrIIA4, an anti-CRISPR protein which inhibits Cas9. As a result, we have begun defining the functionally important parts of AcrIIA4 for the inhibition of Cas9. Notably, we have observed that the majority of deletions result in a complete loss of anti-CRISPR function. However, our data suggests that there are four potentially dispensable domains of AcrIIA4, of which we are in the process of verifying.

566T **Single cell ribosome profiling of yeast on whole populations using localized tag RNA** Ishan Maduka Gammadde Hewa[1], David Granas[2], Michael A White[3], Gary D Stormo[4] [1]Washington University in St Louis, [2]Genetics, Washington University in St Louis, [3]Genetics, Washington university in St Louis, [4]Genetics, Washington University in St. Louis

The ability to assay genetic perturbations at scale is a major source of recent progress in functional genomics. The use of sequence barcodes to perform assays on pooled libraries rather than arrays of individual samples has greatly increased the scale of genetic screens and functional assays. An important cellular phenotype that is assayed in pooled genetic screens is gene expression. However, a critical bottleneck is that gene expression is measured in pooled screens using single-cell RNA-seq technologies that require physically isolating single cells. These technologies are subject to significant technical noise and have high reagent costs. A method to perform RNA-seq on pooled samples without isolating single cells would eliminate this bottleneck in pooled genetic screens.

We are developing a method for pooled transcriptome analysis using RNA barcoding by proximity ligation. This method, called SCALoP (Single Cell Analysis of Localized RNA on whole Populations) avoids the need to isolate single cells by using a barcoding "tagRNA" molecule that stably associates with a localized pool of cellular RNAs *in vivo* via an RNA aptamer. After lysis of a pooled sample, cellular RNAs are labeled by proximity ligation to the barcoded tagRNA. The sequence barcode tags the mRNA molecules of individual cells, within a population, enables the identification of the originating cell of each transcript. We demonstrated this technology in *Saccharomyces cerevisiae* with a tagRNA directed to the ribosome.

We used SCALoP to perform ribosome profiling under multiple stress conditions. Stress conditions such as higher temperature and amino acid starvation represented nearly 1000-1500 differentially expressed genes compared to its normal conditions, which we reproducibility measured with SCALoP. Experiments will be carried out to generate single cell RNA sequencing data via unique barcode carrying tag RNA per cell. Therefore, our method addresses a promising solution which enables any large-scale genetic perturbations and RNA-seq experiments to perform without requiring physical isolation of single cells.

567T **Homology and Disease curation at *Saccharomyces* Genome Database: Budding yeast as a model for eukaryotic biology** Stacia R Engel, Robert S Nash, Edith D Wong, Suzi Aleksander, Shuai Weng, Kalpana Karra, Stuart Miyasato, J. Michael Cherry Genetics, Stanford University

The foundation for much of our understanding of basic cellular biology has been learned from the budding yeast *Saccharomyces cerevisiae*, and studies with yeast have provided powerful insights into human genetic diseases and the cellular pathways in which they are involved. This utility of yeast as a model for human disease arises from the biochemical unity that underlies all forms of life. Work with humanized yeast (in which yeast genes have been replaced with human

orthologs) and humanized yeast proteins (in which key residues have been altered to match the human sequence) has demonstrated extensive conservation of ancestral functions through time and across taxa. In order to promote and support the ways in which yeast and yeast research can inform genetic medicine, the *Saccharomyces* Genome Database (SGD; www.yeastgenome.org) is providing comprehensive curation for human disease-related genes and their yeast homologs, including high quality manually curated information regarding functional complementation and conserved function. Curated information for yeast genes is displayed on Homology pages and Disease pages at SGD in ways that allow data mining and encourage innovation for researchers studying both yeast and other organisms. These efforts are part of our continuing mission to educate students, enable bench researchers, and facilitate scientific discovery. SGD is supported by a grant from the NHGRI (U41 HG001315).

568T **Optogenetic activation of hypothalamic AgRP neurons in transgenic zebrafish larvae increased food intake** Pushkar Bansal, Erica E. Jung Mechanical Engineering, University of Illinois at Chicago

Agouti Related Protein (AgRP) neurons are located in the hypothalamus and upon stimulation, these neurons regulate hunger and hunger-mediated behaviors especially food-seeking and compulsive eating. AgRP neurons are naturally activated by ghrelin-binding onto the ghrelin receptors on the neuron surface during starvation or fasting state to evoke the aforementioned behaviors. In this study, we used channelrhodopsin (chR2), an optogenetic actuator to control AgRP neuron activity. For the first time, we observed feeding behavior in zebrafish larvae by optogenetically triggering AgRP neurons. We created a transgenic line, *Tg(agrp1:ChR2-Kaede*), where ChR2-Kaede is expressed in AgRP1 neurons. Transgenic zebrafish *Tg(agrp1:ChR2-Kaede)* larvae at 6 days post fertilization and wild-type (ABWT) larvae were used to compare the suction behavior. The food-intake response was recorded as food suction behavior in the partially immobilized larvae with mouth left to move freely and covered the larvae with fish water containing suspended food-particles. The suction-mediated food-particle movement (particle speed) was analyzed and quantified using Particle Image Velocimetry (PIV), which visualizes the traces of individual food particles. Our results show that acute post-photoactivation of AgRP-chR2-Kaede neuron complex increased food-suction behavior in transgenic zebrafish larvae compared to wild type larvae. These findings in this novel transgenic zebrafish model would be useful in studying various hunger-related behaviors, their underlying neural circuits and substrates subjected to different chemical stimuli including drugs of abuse

569T **A fluorescence integrated Zebrafish Larvae screening platform for whole body imaging** Yongwoon Kim, Madelyn Davis, Deborah Frenkel, Tom Mullins, Yifei Wang, Mariya Lomakina, Chris Bogan, Rock Pulak Union Biometrica, Inc.

Traditional techniques of preparing zebrafish larvae for imaging involve mounting them in agarose and manually rotating them to the desired viewing angle for microscopy. This process can be time consuming and tedious. Consistency is often dependent on the scientists' dexterity and focus. The throughput rate then limits the type and scale of possible experiments. The VAST BioImager is a high throughput screening platform capable of automatically handling and rotating larvae to desired positions and angles at a rate of 1 larva every 1.0 - 1.5 min at its fastest. A limitation of this system is the lack of fluorescence imaging. Typically, this is dealt with by combining the VAST BioImager with a fluorescent microscope. However, there are difficulties latent in integrating these two systems together such as microscope platform and software compatibility, and hardware constraints which can restrict activating or changing fluorescence filters to be a manual process rather than an automatic one.

Improving on the previous design of the VAST BioImager, zebrafish larvae can now be imaged with automated 3 color fluorescence plus brightfield and a 2.5x lens, enabling an all-in-one whole body imaging platform. This type of platform can be used to screen large numbers of zebrafish larvae as well as to evaluate any fluorescence properties across the entire length of the body. Rapid, repeatable rotations enable high throughput generation of optical projection tomography datasets (3D volumes of regions of interest). This whole-body imaging platform can then be used in a number of ways such as assaying development in an environmental contaminant screen or tracking cancer xenograft recession after exposure to different drugs.

570T **The International Mouse Phenotyping Consortium: a catalogue of mammalian gene function** Kalliopi Kostelidou[1], Stacy Brody[2], IMPC Consortium[1], Maya VanZanten[3] [1]IMPC, [2]National Institutes of Health Library, [3]National Human Genome Research Institute, National Institutes of Health

The International Mouse Phenotyping Consortium (IMPC mousephenotype.org) is an international effort by 21 research institutions to identify the function of every protein-coding gene in the mouse genome. The IMPC's mission is to create a comprehensive, standardised catalogue of mammalian gene function that is freely available for researchers. To achieve this, the IMPC is knocking out each of the roughly 20,000 genes that make up the mouse genome.

IMPC data is used to investigate basic biology mechanisms that can lead to new therapeutic targets or to narrow down a suspected list of genes in patients in rare or complex disease studies. IMPC has made major gene discoveries in deafness, diabetes, circadian rhythms, metabolism, vision, pain and rare disease genetics.

IMPC data is standardised, mutant phenotypes are annotated with mammalian phenotype (MP) ontology terms, and is highly quality controlled by experts and analysed using a reproducible analysis pipeline using the OpenStats BioConductor package. Data is released biannually via the IMPC portal (mousephenotype.org) and is also made available from the Mouse Genome Database and OpenTargets for model organism and translational users respectively. Data Release 20.1 (December 2023) comprises 9,393 phenotyped lines corresponding to 8,707 human orthologs.

IMPC's impact is tracked through curation of the scientific literature and via bibliometric analysis from the National Library of Medicine. These reveal >250,000 citations and ~7000 publications which use IMPC data or IMPC materials (ES cells, lines etc). IMPC will complete an additional 1800 gene knockouts by 2027.

571T **A synthetic biology approach for optimizing insulin production in yeast** Anna Rico, Lisa Scheifele Biology, Loyola University Maryland

Since the initial genetic engineering and recombinant expression of human insulin, pharmaceutical companies have developed more effective insulin analogs with fewer side effects. However, the patenting of these proteins and the processes by which to express them has allowed the insulin market to become an oligopoly and the price of insulin to rise to levels that are unaffordable to many who rely on insulin as life-sustaining medicine. The Open Insulin Foundation seeks to develop open-source genetic constructs and production methods that would enable the production and sale of the most advanced insulin analogs at prices just above the manufacturing cost. In conjunction with the Foundation, we have worked to optimize the production of a long-acting analog, glargine, in *Komagataella pastoris (Pichia pastoris)* cells. Using a synthetic biology approach, we have systematically tested and optimized promoters and secretion signals. Combined with improvements in media formulation, these have collectively raised the yield of glargine substantially over the most commonly used expression systems (the pAOX1 promoter and αMF secretion signal). While certain promoters and secretion signals were generally strong or weak, we revealed that the context in which they are expressed could significantly modulate their strengths and that the optimal combination of promoter and secretion signal needs to be experimentally determined for each new coding sequence tested. Taken together, these results demonstrate the utility of standardized and high-throughput approaches for the optimization of protein expression and the small-scale production of medically relevant biologics.

572T **Shining Light on Calcium-Mediated Morphogenesis: Forward Engineering Organ Development with Optogenetics and Mechanosensation** Mayesha S Mim[1], Nilay Kumar[1], Jeremiah Zartman[2] [1]University of Notre Dame, [2]Chemical and Biomolecular Engineering, University of Notre Dame

Cells communicate with each other to coordinate cellular processes across tissues during cell differentiation and tissue morphogenesis. This coded communication, facilitated by Calcium (Ca^{2+}) as a second messenger, controls cell mechanics to shape the growth of organs. Many unresolved questions remain about the complex morphogenetic process due to challenges in precisely perturbing and measuring cell mechanics and signaling dynamics. Thus, the overarching goal of this work is to program Ca^{2+} to elucidate the multi-layered steps of morphogenesis. To bridge this knowledge gap, we employed 1) CsChrimson as an optogenetic and 2) Piezo as a mechanosensitive tool to define relationships between signal transduction and downstream cellular responses during *Drosophila* larval development. These tools control intracellular Ca^{2+} levels at the single-cell or whole-tissue scale to direct subsequent cellular processes and define morphogenesis. We demonstrate that these channels regulate cytosolic Ca^{2+} dynamics, impacting the activities and growth-related biological pathways of several downstream proteins. We used Ca^{2+} indicator fluorescent proteins like GCaMP6f to study live Ca^{2+} dynamics, while fluorescent tagging through fixed tissue imaging provided information about subcellular processes and cytoskeletal regulation during tissue growth. Cumulatively, these findings will provide insights into the general design principles that spatiotemporally govern morphogenesis and practical applications for modulating the development of tissues and organs.

573F **TrakBox: An automated nematode tracking and analysis system** Christopher James[1,2] [1]EMbody Biosignals Ltd., [2]Biomedical Engineering Institute, University of Warwick

TrakBox is a low cost tracking system to track nematodes under a microscope, over long periods of time, and to automatically analyse and report on their behaviour. The system is made up of two parts; the low cost hardware which comprises an off the shelf USB microscope mounted on a tracking platform, and bespoke software that allows the tracking of single nematodes over long periods of time, and performs automatic analysis of behaviour. TrakBox will accommodate dishes of various sizes (as well as multi-well plates), provides its own white (LED) light source and it powered from a single USB connection (LED light source requires its own USB power source for maximum brightness).

Using off-the-shelf parts and bespoke hardware components keeps development costs (and hence final product costs) low. The tracking and analysis code is machine learning based and automatically produces high-fidelity objective data from consecutively recorded images. Whilst TrakBox can track individual worms and produce a multitude of behavioural

characteristics after analysis, it can also perform dispersal analysis as well as analysis on multiple experiments in multiwell plates.

574F **A high-throughput method for testing the impact of chemical exposure on *Drosophila* fecundity** Andreana Gomez[1], Sergio Gonzalez[2], Jaiyu Luo[2], Ashwini Oke[1], Raymond Esquerra[2], Jennifer Fung[1], Thomas Zimmerman[3], Sara Capponi[3], Todd Nystul[1] [1]UC San Francisco, [2]San Francisco State University, [3]IBM

Measurements of Drosophila fecundity are used in a wide variety of studies, such as investigations of aging, stem cell biology, nutrition, behavior, and toxicology. Fecundity assays have broad applicability because they are a readout for so many different aspects of adult fly biology, including inputs from the reproductive tract, intestine, and brain. In addition, because fecundity assays are performed on live flies, they are suitable for longitudinal studies such as investigations of aging or prolonged chemical exposure. However, because the rate of egg laying is so closely tied to the physiological state and environmental cues, fecundity assays must be carefully designed to ensure robust and reproducible results, and there are distinct challenges that arise when scaling this assay up to test multiple experimental conditions at once. We have overcome these challenges by combining a new multiwell fly culture strategy with a novel 3D-printed fly transfer device to rapidly and accurately transfer flies from one plate to another; a low-cost, custom built robotic camera to automatically capture images of the wells; and an image segmentation pipeline to automatically identify and quantify eggs. We show that this method is compatible with robust and consistent egg laying throughout the assay period, that the automated pipeline for quantifying fecundity is very accurate (r^2 = 0.98 for the correlation between the automated egg counts and the ground truth); and that this method can be used to detect effects on fecundity induce by dietary exposure to chemicals. Taken together, this strategy substantially increases the efficiency and reproducibility of high throughput egg laying assays that require exposing flies to multiple different media conditions. Our findings demonstrate a proof of principle for this approach, and we are currently using it to test for chemicals that are commonly found in modern households as well as in tobacco smoke that may pose a risk to reproductive health.

575F **Nickases and anti-CRISPR boost mosaic analysis in *Drosophila* by MAGIC** Yifan Shen[1], Ann Yeung[2], Rhiannon Clements[2], Michael Sheen[2], Kathy Wang[2], Chun Han[2] [1]Chemistry and Chemical Biology, Cornell University, [2]Molecular Biology and Genetics, Cornell University

Mosaic analysis is a powerful approach for studying tissue-specific gene function and cell-cell interaction in vivo. Besides Flippase (Flp)/FRT-based mosaic methods, we have previously developed a novel technique called Mosaic Analysis by gRNA-Induced Crossing-over (MAGIC), which utilizes CRISPR/Cas9 to induce homology-directed repair (HDR) and chromosomal crossover at a predetermined target site(s), thus avoiding the need for a FRT site. While developing and using MAGIC, we noticed some limitations: First, double strand breaks (DSBs) generated by Cas9 create a high frequency of non-homologous end-joining (NHEJ) events that mutate the target sequence, preventing subsequent cutting from occurring, and cause chromosomal aberrations, resulting in abnormal clones and cell ablation. Second, tissue specificity of Cas9 needs to be improved for more consistent clone induction. To avoid problems associated with DSBs, we explore the use of Cas9-derived mutant nickases, which create single strand cuts (nicks) and thus do not alter the original sequence. Using our existing gRNA-marker transgenes, we found that nickases can induce MAGIC clones. Currently, we are determining the factors influencing the efficiency of clone induction by nickases and comparing the frequency of cell ablation caused by nickases and Cas9. At the same time, we are applying tissue specific anti-CRISPR to increase Cas9 specificity. These attempts and results in this study will provide important insights for us to further optimize the MAGIC technique and benefit the Drosophila community by providing versatile and powerful tools for genome-wide and tissue-specific mosaic analysis.

576F **New technologies and resources from the Drosophila Research & Screening Center-Biomedical Technology Research Resource (DRSC-BTRR)** Stephanie Mohr[1], Muhammad Ahmad[1], Justin A Bosch[1], Matthew Butnaru[1], Adam Carte[1], Weihang Chen[1], Aram Comjean[1], Ben Ewen-Campen[1], Elizabeth Filine[1], Corey Foreman[1], Srishti Goswami[1], Myeonghoon Han[1], Yousuf Hashmi[1], Yanhui Hu[1], Neha Joshi[1], Ah-Ram Kim[1], Lu-Ping Liu[1], Raphael Lopes[1], Enzo Mameli[1], William Mckenna[1], Karim Rahimi[1], Alexandria Risbeck[1], Emily Stoneburner[1], Raghuvir Viswanatha[1], Baolong Xia[1], Jonathan Zirin[1], Norbert Perrimon[1,2] [1]Harvard Medical School, [2]Howard Hughes Medical Institute

The Drosophila Research & Screening Center-Biomedical Technology Research Resource (DRSC-BTRR) at Harvard Medical School (NIH NIGMS GM132087), the current iteration of what was originally founded as the Drosophila RNAi Screening Center and Transgenic RNAi Project (DRSC/TRiP), focuses on the development, optimization, and dissemination of technologies for the benefit of the *Drosophila* and broader research communities. Our areas of emphasis include (i) high-throughput screening in *Drosophila* and other insect cultured cells using CRISPR and other technologies; (ii) molecular genetic and protein technologies for use *in vivo* in *Drosophila*; and (iii) online resources for reagent design, ortholog identification, and other applications in *Drosophila*, common model species, and a growing number of arthropod species. Here, we will emphasize newly developed technologies and resources that facilitate use of cell culture to rapidly and efficiently interrogate topics that

can then be followed-up in vivo. We will also present how using *Drosophila* cells as a platform for technology testing and optimization has opened new doors to small- and large-scale studies that directly interrogate gene function in mosquitos or other non-model species. Altogether, this work is empowering studies relevant to a wide array of biological and biomedical topics, including studies of host-pathogen interactions, signal transduction, and other topics.

577F **Building Cell-type-specific Split-GAL4 Genetic Reagents Targeting *doublesex+* Neurons in Drosophila Central Nervous System** Hongzhou Gustave Li[1], Siqi April Li[2], Yu-Chieh David Chen[2], Claude Desplan[2] [1]New York University Shanghai, [2]New York University

A central goal in neuroscience is to understand how various neurons form neural circuits that produce complex innate behaviors, such as sexual dimorphic behaviors. The *doublesex* (*dsx*) gene is critical for *Drosophila* sexual dimorphic behaviors, such as female receptivity and male courtship song. Creating cell-type-specific tools for doublesex neurons facilitates our understanding of neural diversity and the role of individual *dsx*$^+$ cell types in sexually dimorphic behaviors.

The Desplan Lab recently developed the gene-specific split-GAL4 system that accurately labels specific neuron cell types in the *Drosophila* visual system in a predictable manner. One of the important features is that these gene-specific split-GAL4 lines can be used in other tissues as long as the genes are expressed in the tissue of interest. In this study, we collaborated with Dr. Yun Ding's lab (UPenn) to explore their single-cell RNA sequencing dataset of all *dsx*$^+$ neurons and designed a genetic crossing scheme to generate gene-specific split-GAL4 reagents targeting individual *dsx*$^+$ clusters/cell types.

We first selected the target gene pairs that label specific clusters based on the transcriptomic dataset of *dsx*$^+$ neurons. We leveraged the publicly available coding-intron MiMIC insertion lines and the T2A-split-GAL4 donor lines to insert the T2A-split-GAL4 donor to the target gene via trojan exon Recombinase-mediated Cassette Exchange (RMCE). The T2A-split-GAL4 construct was excised from the original locus and circularized by Cre recombinase, followed by in-vivo swapping with MiMIC via phiC31 integrase. As RMCE does not have orientation preference, genotyping PCR was performed to screen for flies with split-GAL4 insertion orientation the same as the target gene orientation. We have generated four gene-specific split-GAL4 lines and will test the validity of these split-GAL4 lines by crossing with flies carrying dsx-flp, UAS-FRT-STOP-FRT-EGFP constructs, and pan-neuronal DBD/AD hemi-driver. EGFP expression will be examined under fluorescence microscope.

Our work demonstrates the feasibility of generating gene-specific split-GAL4 lines by the Trojan-exon-mediated in vivo swapping scheme. It offers a cost-effective alternative to traditional microinjection methods for converting coding intronic MiMIC lines into gene-specific split-GAL4 lines. The split-GAL4 lines generated in this study will benefit the Drosophila *doublesex* neuron research community by providing genetic tools to label and manipulate individual *dsx* neuron types in the central brain.

578F **MLDAAPP: Machine Learning Data Acquisition for Assessing Population Phenotypes** Amir R Gabidulin Biology, Washington State University

MLDAAPP is a computer vision machine learning based script that utilizes a state of the art open-source machine learning algorithm called YOLOv8. The script is designed to assist in quantifying phenotypical traits of model organisms by reducing the time investment needed to collect data and opening new pathways to more intricate and efficient experimental designs. MLDAAPP uses cheaply available resources, and mainly focuses on collecting empirical data from non-standardized environments. It is an easy-to-implement method, that requires little to no investment in both time and monetary costs. MLDAAPP has already been successfully implemented in assessing various phenotypes such as locomotion, size, and count in *Drosophila melanogaster,* setting up the basis of its viability for current and future work.

579F **Optical system with blue LED light for multiple studies in *Drosophila melanogaster* cultures** Monica Andrea Lopez Bautista[1], Viviana Matilde Mesa Cornejo[1], Jorge Enrique Mejía Sánchez[1], Francisco Javier Ornelas Rodríguez[2] [1]Centro Universitario de los Lagos, Universidad de Guadalajara, [2]Centro de Investigación en Ciencia Aplicada y Tecnología Avanzada, Instituto Politécnico Nacional

Drosophila melanogaster has become a model organism widely studied for more than a hundred years by various research groups that has allowed to understand many behaviors, especially the circadian cycle, which regulates sleep-wake conditions in a 24-hour cycle day and depends closely on exposure to blue light short wavelength. Blue light represents the main entrainment signal of circadian rhythms and has been directly involved in the suppression of melatonin in humans as well as the extracellular and intracellular photosensitized production of reactive oxygen species (ROS), generating various general health implications. But one of the main drawbacks when carrying out experiments using this model organism exposed to light is the limitation of the population number that can be obtained. Therefore, in this work we present an optical assembly with a hexagonal arrangement equipped with blue LED light ($\boldsymbol{\lambda}$: 457.33 ± 45 nm) for the homogeneous irradiation of fly cultures,

which can be used for various applications depending on the study to be carried out; from retinal degeneration, longevity, reproduction, courtship, among others. For this arrangement, a space of 1.6 x 1.7 x 0.2 m was used, which resulted in the assembly of 95 blue light LEDs that provided us with a capacity of up to 153 flasks or fly cultures, which can be arranged randomly, allowing the development of assays of more than 5 generations with 5 repetitions in two strains simultaneously, depending on the experimental design. The illuminance of this assembly from 0 to 601.12 Lux can be programmed with the change of current injected into the system from the variable power source from 0 to 1.05 A, respectively. Its construction is cost-effective, providing a great tool that allows easy manipulation of a large population of flies across various generations and strains. In addition, it is programmed on a 12-hour light, 12-hour dark cycle with a timer in real time, with controlled temperature and humidity.

580F **New CRISPR-induced, loss-of-function mutations from the Fourth Chromosome Resource Project enabling clonal analysis of fourth chromosome protein-coding genes** Bonnie Weasner[1], Brandon Weasner[1], Robert Eisman[1], Kevin Cook[1], Justin Kumar[1], Stuart Newfeld[2] [1]Indiana University, [2]Arizona State University

The Fourth Chromosome Resources Project is generating stock resources for the analysis of fourth chromosome genes. One of our efforts is to induce at least one mutation in every protein-coding gene on an FRT-bearing fourth chromosome using CRISPR mutagenesis with a single guide RNA and to provide preliminary phenotypic characterizations of the new mutations. Our methods assure that the new mutations are established in a single genetic background, making these high-quality stocks particularly well suited for the analysis of background-sensitive phenotypes such as behavior and the influence of chromatin conformation on gene expression. We will present our progress in completing the screens, our molecular analyses of the new mutations, our assessments of recessive lethal, sterile and morphological phenotypes, our quality-control tests and our preliminary characterizations of eye-antennal imaginal disc phenotypes in FLP-induced mitotic clones. Completion of this work will provide a comprehensive set of molecularly characterized, loss-of-function mutations for the entire fourth chromosome.

581F **Predicting gene expression dynamics in *D. melanogaster* through super resolution live imaging and computational modeling system** Priyanshi Borad[1], Parisa Boodaghimalidarreh[2], Biraaj Rout[2], Mohammad Sadegh Nasr[2], Md Jillur Rahman Saurav[3], Kelli Fenelon[4], Jacob Luber[5], Theodora Koromila[6] [1]Biology, University of Texas at Arlington, [2]Computer Science, University of Texas at Arlington, [3]University of Texas at Arlington, [4]University of Texas Arlington, [5]Computer Science, University of Texas Arlington, [6]Biology, University of Texas Arlington

One of the major challenges of the modern genomics era is to better understand how gene expression is regulated to support spatiotemporal outputs that change over the course of development. It is known that multiple, transiently acting enhancers act sequentially to support changing outputs of expression for some genes. The early *Drosophila* embryo has served as a paradigm for how enhancers control patterning and has also demonstrated that the patterning process is dynamic, whereas other genes are controlled by enhancers that act over a longer period and support changing spatial outputs over time. For example, expression of the gene short gastrulation (*sog*) is driven by at least two co-acting enhancers that support temporally dynamic. Live imaging experiments offer the capacity to analyze gene expression dynamics with increased temporal resolution and linear quantification. However, genetic and live imaging techniques have outpaced analysis techniques to harvest the bountiful information contained within real-time movies of transcriptional dynamics with modern methods confined to static parameter cell and transcript tracking methods. To assess gene expression systematically, we developed a quantitative approach to measure the spatiotemporal outputs of enhancer-driven MS2-yellow reporter constructs as captured by *in vivo* imaging to provide information about the timing, levels, and spatial domains of expression. We introduce a pipeline based on Random Forest Regression to predict the future distribution of cells that are expressed by the *sog-D* gene in the *D. melanogaster*. This method provides insight about how cells and living organisms control gene expression and consists of three parts: 1) Super resolution imaging of whole embryo spatial transcriptomics imaging at sub cellular, single molecule resolution, 2) Image processing that includes resizing, segmentation, and identifying transcriptionally active cells, and 3) A Random Forest regression model that can predict the next stage active distribution based on the previous one. In conclusion, with super resolution live imaging technique and Random Forest Regression computational tool we can predict future spatially resolved gene expression using features from the spatial point processes which is analogous to RNA Velocity for spatially resolved developmental biology.

582F **Balancing competing effects of tissue growth and cytoskeletal regulation during *Drosophila* wing disc development** Nilay Kumar[1], Jennifer R Ambriz[2], Kevin Tsai[2], Mayesha S Mim[3], Marycruz Flores Flores[3], Weitao Chen[2], Mark Alber[2], Jeremiah Zartman[3] [1]Chemical and Biomolecular engineering, University of Notre Dame, [2]University of California, [3]University of Notre Dame

How a developing organ robustly coordinates the cellular mechanics and growth to reach a final size and shape remains poorly understood. Through iterations between experiments and new model simulations that include a mechanistic description of

interkinetic nuclear migration, we show that the local curvature, height, and nuclear positioning of cells in the *Drosophila* wing imaginal disc are defined by the concurrent patterning of actomyosin contractility, cell-ECM adhesion, ECM stiffness, and interfacial membrane tension. We show that increasing cell proliferation via different growth-promoting pathways results in two distinct phenotypes. Triggering proliferation through insulin signaling increases basal curvature, but an increase in growth through Dpp signaling and Myc causes tissue flattening. These distinct phenotypic outcomes arise from differences in how each growth pathway regulates the cellular cytoskeleton, including contractility and cell-ECM adhesion. The coupled regulation of proliferation and cytoskeletal regulators is a general strategy to meet the multiple context-dependent criteria defining tissue morphogenesis.

583F **Homeostatic behavior quantification of mice in a social context using machine vision** Jessica D Choi[1,2], Cayson Hamilton[3], Brian Geuther[4], Gautam Sabnis[4], Tom Sproule[4], Vivek Kumar[4] [1]Genetics, The Jackson Laboratory, [2]Tufts University, [3]Brigham Young University, [4]The Jackson Laboratory

Understanding nuances in feeding and drinking behaviors is crucial when assessing disorders such as obesity, diabetes, and metabolic syndrome. Obtaining a reliable and efficient method to assess these behaviors in mice can provide powerful insight into the effects of these disorders. Technological advances in the computer vision field have enabled studying mouse behavior with a higher degree of sensitivity. Our group has applied these techniques to study mice in a social context, which allows for more naturalistic behavior in group-housed animals with the potential to produce more relevant data. Using machine vision over 46 long-term, continuous four-day experiments with three mice in each arena, I capture feeding and drinking behaviors across the classic inbred strain C57BL/6J, the autism spectrum disorder model BTBR *T+ Itpr3^{tf}*/J (BTBR), heterozygous B6.BKS(D)-*Lepr^{db}*/J (Lepr) control mice, and homozygous Lepr diabetic mice.

We trained machine learning (ML) classifiers for feeding and drinking through supervised learning. To validate the drinking classifier, I ran a Lickometer experiment, which is a mechanical solution to measuring drinking behavior, that logs contact events with the water spout. I manually scored each contact bout as a drinking bout or a non-drinking contact bout. We validated the feeding classifier through a classical ML approach of densely annotating videos. We used these datasets as ground truth to measure precision, recall, and F1 scores.

Because BTBR mice are used as a model of autism spectrum disorder, we compared social feeding behavior where mice eat at overlapping times from the same food hopper. Interestingly, we find the C57BL/6J mice participating in more social feeding bouts with longer durations compared to BTBR mice, aligning with the BTBR strain's known antisocial tendencies, which have been previously characterized.

We also compared heterozygous and homozygous Lepr mice in terms of their feeding, drinking, and general activity. Activity levels are typically used as a measure of circadian rhythm. However, while homozygous Lepr mice have circadian rhythms that are extremely arrhythmic when looking at activity, they preserve diurnal feeding and drinking rhythms. This highlights the usefulness of measuring other homeostatic behaviors to glean circadian insights of less active mouse strains. These novel ML tools enable a new generation of assays that can use group-housed mice to produce more naturalistic data.

584F **Long-read sequencing with adaptive sampling for characterization of CRISPR/Cas9-generated transgenic mice** Zachary T Freeman[1], Weisheng Wu[2], Laura Burger[3], Elizabeth Hughes[1], Thomas L Saunders[1], Shipra Garg[4], Olivia Koues[4], Judith S Meyers[4], Suzanne M Moenter[5], Chris Gates[2] [1]Transgenic Animal Model Core, University of Michigan, [2]Bioinformatics Core, University of Michigan, [3]Molecular & Integrative Physiology, University of Michigan, [4]Advanced Genomics Core, University of Michigan, [5]Molecular and Integrative Physiology, University of Michigan

Complete characterization of CRISPR/Cas9-generated animal models presents many challenges that may require advanced sequencing methods. We previously used a long single stranded donor combined with a single gRNA strategy to generate an endogenous iCre knock in the *Npvf* gene in C57BL/6J mice. After breeding to wild type, candidate G1 founders were identified using a screen PCR, but spanning PCR across the insert were unsuccessful at fully characterizing the entire allele. We used Oxford Nanopore Technology (ONT) long-read sequencing (LRS) with adaptive sampling for Chromosome 6 on an individual G1 founder to determine if the entire insert sequence and arms of homology were correct as designed. Reads were aligned to mouse reference genome GRCm38 using the wf-alignment pipeline with the minimap2 v2.24 to align reads. Structural variants (SV) were then called using Sniffles and CuteSV and consensus SVs were called using SURVIVAL v1.0.7. Adaptive sequencing resulted in ~58X total with 30X coverage (51.7% allele frequency) of the targeted allele, which contained an SV at the expected site. All reads were then segregated into variant-supporting versus reference-supporting reads and assembled into separate consensus sequences using Flye v2.9.1. These two consensus sequences were then aligned individually to the megamer sequence with variant-supporting reads matching the megamer sequence in the correctly targeted location with no changes observed outside the arms of homology. We next used barcoding of 3 different G1 founders in equimolar concentrations to

examine the efficacy of LRS with adaptive sampling across pooled samples. Overall coverage decreased to 31X with a range of 8-13 reads per barcoded sample. Each barcoded sample contained only 2-3 reads with the expected SV, which was insufficient to resolve final sequence. These data support the use of ONT adaptive sequencing for the characterization of CRISPR/Cas9-generated animal models.

585F **Update of the Collaborative Cross Population in the UNC Systems Genetics Core Facility** Michelle E Allen[1,2], Madison A Drushal[1,2], Timothy A Bell[1], Matthew W. Blanchard[1,3], Jackie Brooks[1,3], Joe Farrington[1], Pablo Hock[1], Richard Austin Hodges[1,2], Darla R Miller[1,2], Ginger D Shaw[1], Fernando Pardo-Manuel de Villena[1,2,3,4], Martin T Ferris[1,2], Rachel Lynch[1,2,5], Jennifer Brennan[3] [1]Genetics, University of North Carolina at Chapel Hill, [2]Systems Genetics Core Facility, University of North Carolina at Chapel Hill, [3]MMRRC at UNC, University of North Carolina at Chapel Hill, [4]Lineberger CLineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, [5]3Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill

The Collaborative Cross (CC) is a multi-parental genetic reference mouse population derived from eight founder inbred strains, encompassing an extraordinary level of genetic diversity. The mission of the UNC Systems Genetics Core Facility (SGCF) is to maintain and distribute CC mice. CC mice, and their associated genomic data, are accessible to researchers with minimal conditions of use. The SGCF distributes mice to researchers at cost and functions on a first-come, first-served basis. The CC population at the SGCF has recently undergone significant changes. First, the set of CC strains currently distributed from the SGCF and the Mutant Mouse Resource and Research Center (MMRRC) at UNC is now complete at 63 strains, and every effort is being made to avoid extinction of any of these strains. Second, the majority of these strains were rederived into UNC's highest health status Barrier Facility. As of today, we have 59 strains in this Barrier Facility, specifically noting that CC038/GeniUnc has become distributable from the Barrier Facility in the last 6 months. Finally, CC strains have become significantly more inbred in the more than 9 years since the latest genetic characterization, and the strains have also undergone recent population bottlenecks). In 2021, we used these bottlenecks to define a new set of Most Recent Common Ancestors (MRCAs), and we used these animals to update our genetic characterization of the strains. DNA from 6-44 MRCAs per CC strain were individually genotyped with the MiniMUGA array (revealing a significant reduction in residual heterozygosity, with 21 strains inbred at the 99% cut off level) and pooled for whole genome sequencing (WGS). We plan on releasing strain-specific variant information after sufficient data has been generated, and after quality control is completed. We have partnered with the MMRRC at UNC to cryopreserve a majority of the extant strains as a secure reserve in case of extinction or disaster. With the MMRRC, efforts are still underway to rederive the last 4 CC strains into the Barrier Facility, with the ultimate goal of having all CC strains distributed through the Barrier Facility. In summary, this updated, uniform description of the entire CC colony at UNC will be a valuable resource to the research community, further increasing the value of the CC population.

586F **The mouse Gene Expression Database (GXD): a tool for accelerating insights into the molecular mechanisms of development and disease** Constance M Smith, Jacqueline H Finger, Terry F Hayamizu, Ingeborg J McCright, Jingxia Xu, David R Shaw, Richard M Baldarelli, Joel E Richardson, Martin Ringwald The Jackson Laboratory

The Gene Expression Database (GXD; www.informatics.jax.org/expression.shtml) provides detailed information about when and where genes are expressed in different mouse strains and mutants, with a particular emphasis on mouse development. As part of the Mouse Genome Informatics (MGI) resource, GXD combines its expression data with genetic, functional, phenotypic, and disease-oriented data, thus fostering insights into the molecular mechanisms of development, health, and disease.

GXD integrates data from RNA *in situ* hybridization, immunohistochemistry, knock-in reporter, RT-PCR , Western blot, and RNA seq experiments. The *in situ* and blot data are obtained via curation of the published literature and through collaborations with large-scale data providers; there are currently ~2 million such expression results for ~16,000 genes, with ~460,000 accompanying images. The RNA-seq data is imported from the EBI's Expression Atlas. The Expression Atlas generates uniformly processed TPM-level data sets for a select set of high-quality, bulk RNA-seq experiments. As part of its incorporation into GXD; these data are further processed and annotated, resulting in seamless integration with GXD's *in situ* and blot data. The result is an extensive database that enables search capabilities unavailable elsewhere using a wide variety of biologically- and biomedically-relevant parameters. Analysis of results from these searches is facilitated by interactive summaries and matrix views that have advanced filtering and export capabilities. Additionally, GXD provides an RNA-Seq and Microarray Experiment Search utility to reliably search for mouse tissue and cell type experiments deposited in NCBI's GEO and EBI's ArrayExpress. Searches using this tool are effective because they use standardized sample and experiment metadata annotations done by our curators; there are currently ~6,500 such indexed experiments in GXD. GXD is supported by NIH/NICHD grant HD062499.

587F **Crispant founder mice display recessive visible phenotypes** Rebekah Tillotson[1,2,3], Julie Ruston[2], Li-Hsin Chang[3], Marina Gertsenstein[4], Lauri Lintott[2,4], Christine Taylor[2], Lauryl M. J. Nutter[2,4], Monica J. Justice[2,5] [1]MRC Human Genetics Unit, University of Edinburgh, [2]The Hospital for Sick Children, [3]University of Oxford, [4]The Centre for Phenogenomics, [5]Department of Molecular Genetics, University of Toronto

CRISPR/Cas9 genome editing technology has revolutionised animal model production. In the mouse field, the gold standard for generating knock-outs is to introduce ribonucleoprotein (RNP, comprising Cas9 protein and synthetic guide RNA) into zygotes resulting in indels via the non-homologous end joining (NHEJ) repair pathway. The resulting founder mice are bred to establish pedigrees that undergo quality control assays prior to phenotyping. In contrast, the zebrafish and Xenopus communities have employed CRISPR technology in genetic screening pipelines that assess phenotypes in founders (F0), referred to as "crispants". We investigated the usefulness of crispant mouse founders for genetic screening by knocking out genes associated with recessive visible phenotypes, such as coat colour and ear morphology. Excitingly, we found that almost all crispant mice displayed the expected phenotypes. To establish the validity of phenotypic assessment of crispants, we addressed concerns in the field about the impact of genetic mosaicism. While many of our founders carried multiple small and large indels, wild-type (unedited) sequence was almost always absent, consistent with the displayed phenotype. Additionally, several founders were compound heterozygotes carrying a null mutation and a short in-frame mutation, the latter of which facilitated functional assessment of the mutated protein domain. Our results set the stage for using CRISPR/Cas9 technology for phenotypic screening in mice.

588F **Sequencing for Dummies: Using Nextflow Pipelines to Increase RNAseq Analysis Accessibility** Katy Martinson, Susan Deering, Sarah Lower Biology, Bucknell University

Differential gene expression (DGE) analysis of RNA sequencing (RNAseq) data is a useful tool for investigating where and when different genes are active. This analysis requires multiple computational steps; for example, filtering, aligning, and normalizing the sequencing data, before it can be used for experimental analysis. With technical advances in sequencing, large RNAseq projects are more affordable and feasible in non-model organisms that lack previous genomic resources, opening up DGE analysis as a tool in many more organismal systems. To increase the accessibility of this tool, it is important to make DGE analysis more easily done by biologists who are unfamiliar with computational science. To assist in this effort, we developed a computational pipeline that automatically cleans and filters the sequences to prepare a transcriptome assembly of given short read RNAseq data, and preprocesses it for analysis in R. This pipeline parallelizes the cleaning/filtering, assembly and analysis processes across multiple samples by using Nextflow's native ability to efficiently work in computing cluster systems. It also provides computational efficiency statistics to minimize wasted resources. We benchmarked the tool using RNAseq data from wild-caught Lucidota atra fireflies, an unlighted species for which there is no reference genome. We found that this tool vastly decreased the amount of time it takes to run DGE analysis, particularly for the novice user.

589F **NCBI GEO's GEO2R tool increases access to public genomics data with new visualization features and incorporation of RNA-seq studies** Emily Clough, Tanya Barrett, Steve E Wilhite, Pierre Ledoux, Carlos Evangelista, Irene F Kim, Maxim Tomashevsky, Kimberly A Marshall, Katherine H Phillippy, Patti M Sherman, Hyeseung Lee, Naigong Zhang, Nadezhda Serova, Lukas Wagner, Vadim Zalunin, Andrey Kochergin, Alexandra Soboleva NCBI, NLM, NIH

The Gene Expression Omnibus (GEO, http://www.ncbi.nlm.nih.gov/geo/) is an international public repository that archives gene expression and epigenomics data sets generated by next-generation sequencing and microarray technologies. The GEO repository is built and maintained by the National Center for Biotechnology Information (NCBI), a division of the National Library of Medicine (NLM). In addition to archiving data, GEO provides the web-based analysis tool GEO2R that enables users to analyze data stored in GEO within minutes. GEO2R facilitates access to and analysis of genomic gene expression data by removing the burden of data download and bioinformatic computation. GEO2R has recently been updated to include a wide variety of data visualization plots and can now be used to analyze more than 23,000 human RNA-seq studies available in GEO. The new data visualization plots include Volcano, Mean-difference, UMAP, box plot and Venn diagram, among others. These plots enable users to evaluate sample relatedness and analysis results. Some plots such as Volcano, Mean-difference and Venn diagram have interactive "explore and download" features where information on genes and statistics are visible by "mouseover" of points on the plot and interesting subsets of data (such as differentially expressed genes) can be downloaded. GEO2R has been expanded to include analysis of human RNA-seq data stored in GEO using DESeq2 software. The read counts for the RNA-seq samples utilized by GEO2R are calculated from submitter-provided raw reads with the NCBI Sequence Read Archive (SRA) RNA-seq Counts Pipeline (described at https://www.ncbi.nlm.nih.gov/geo/info/rnaseqcounts.html). The raw and normalized read count matrices for human RNA-seq studies are available for download directly from the GEO website. With the expansion of GEO2R for human RNA-seq samples, approximately 50% of studies in GEO can be analyzed with GEO2R. All studies that can be analyzed with GEO2R can be identified by searching GEO DataSets using the filter "geo2r"[Filter].

590F **Error-Free Single Molecule Nanopore Sequencing to Observe Evolving Viral Quasi-Species** Adam Zahm, Caleb Cranney, Alexa Gormick, Justin G English Biochemistry, University of Utah

We present ConSeqUMI, a computational pipeline for unique molecular indexing based Nanopore sequencing of long DNA and RNA molecules with base calling error rates below those observed for high fidelity PCR reactions. We have developed a range

of biochemical and computational benchmarks to vet and internally control the run-to-run accuracy of this platform. We have subsequently applied and validated this system for a range of applications including mapping the landscape of chemically-induced PCR mutagenesis, the contiguous identity of multiple plasmids during long term evolution in bacteria, the single molecule integrity of packaged transgenic AAV, the distributed genomic mutagenesis of Sindbis virus, and the quasi-species identity of patient SARS-CoV-2 and HIV samples. We further demonstrate that any single identified molecule can be extracted from the sample library via PCR and clonally expanded for further interrogation, obviating the need for synthesis and enabling rapid isolation and characterization of many unique molecular variants in a single sample library. ConSeqUMI is publicly available and ready for immediate use.

591F **Predicting Antibiotic Resistance in E. coli Using Machine Learning Models** Pleuni S. Pennings, Melika Teimouri Biology, San Francisco State University

Background: Antibiotic resistance in *Escherichia coli* (E. coli) presents a significant public health challenge. Swift and accurate identification of drug-resistant E. coli strains is crucial for optimizing patient treatment, reducing drug administration time, and curbing the spread of resistance. Machine learning holds the potential to expedite antibiotic resistance identification, leading to more efficient patient care.

Aim: This study aims to predict antibiotic resistance in E. coli through genomics. Our primary goal is to identify the most effective machine-learning technique for predicting drug resistance in *E. coli*. A recent one-year dataset from a hospital in the US provides a unique, high-quality source of labeled *E. coli* genomes. This dataset enables us to meticulously evaluate and select the optimal machine-learning approach for improving drug resistance prediction in *E. coli.*

We will employ gradient-boosted tree algorithms and neural networks for our machine-learning analysis, informed by prior research demonstrating their effectiveness with genomic data. Our main objective is to assess whether modern machine learning methodologies can outperform traditional rule-based approaches like CARD and ResFinder and if so, for which drugs and/ or which drug-resistance mechanism. If we find that these advanced machine-learning techniques can provide more precise predictions of antibiotic resistance, this could enhance patient care and treatment decisions.

592F **Using JBrowse 2 for multi-species genome browsing for the Alliance of Genome Resources** Scott Cain, Alliance of Genome Resources Consortium Stein Lab, Ontario Institute for Cancer Research

The Alliance of Genome Resources (https://alliancegenome.org) is a database that serves multiple model organism research communities to develop and maintain tools and datasets for comparative genomics. As part of this effort, we are deploying a new genome browser using JBrowse 2 (Diesh et. al., Genome Biol. 2023 Apr 17, PMID: 37069644) to provide a multi-species browser, capable of viewing synteny and genomic data tracks across multiple species. The new JBrowse 2 instance replaces the previous JBrowse 1 browser, adding new functionality, expanded data options, and a new user interface. All the same tracks available previously have been maintained, including the MODs' curated gene sets, curated variants and high throughput variants, and a considerable amount of data has been added to the new instance, including data tracks for each assembly from their home model organism databases, as well as tracks identifying orthology between genes in other Alliance genomes. These orthology tracks make use of the synteny view provided by JBrowse 2, which compares the locations of genes on two distinct genomes. The ability to open these synteny views alongside supplementary data has resulted in a powerful data exploration tool for users of the Alliance of Genome Resources.

593F **Predicting Escherichia coli Drug Resistance through Different Deep Learning-Based Approaches using a Comprehensive Pan-genome Assembly** Estefanos Kebebew[1], Gian Carlo L Baldonado[2], Abdoulfatah M Abdillahi[2], Juvenal F Barajas[2], Anagha Kulkarni[2], Ilmi Yoon[2], Pleuni S. Pennings[1] [1]Biology, San Francisco State University, [2]Computer Science, San Francisco State University

Drug resistance poses a significant challenge in combating pathogenic infections, as many pathogens can develop mechanisms to evade the drugs designed to eliminate them. This issue is exemplified by Escherichia coli (E. coli), a bacterium residing in the intestines of healthy individuals, which exhibits a remarkable capacity to accumulate resistance genes. Prior machine-learning based studies have shown that using single nucleotide polymorphisms (SNPs) or gene-presence absence tables from genome data yielded impressive results. However, it is unknown whether the use of both SNPs and gene-presence absence tables could improve performance. With recent advancements in sequencing technology, a comprehensive pan-genome assembly, containing information about both SNPs and gene-presence absence, was constructed to be employed in different deep-learning based approaches. Here we present three of these novel approaches in leveraging deep learning models and machine learning techniques using the pan-genome assembly as inputs for predicting drug resistance in E.coli. (1) The first approach leverages a simple multi-layer perceptron. (2) Our second approach builds on transforming these pan-genome assemblies into visual colormaps (images) and employs convolutional neural networks. (3) Lastly, our third approach uses extracted latent

genetic features from these images using autoencoders. All approaches will implement a multi-label classification model that predicts drug resistance of E.coli isolates across multiple antibiotics. The result of this work will help inform doctors the most appropriate antibiotics to prescribe to their patients and pave the way for deep-learning based drug resistance prediction for other pathogens.

594F **Xenbase: latest support for genomics and disease models.** Malcolm Fisher[1], Christina James-Zorn[1], Virgilio Ponferrada[1], Taejoon Kwon[2], Andrew Bell[1], Erik Segerdell[1], Konrad Thorner[1], Ngoc Ly[1], Vy Ngo[1], Stanley Chu[3], Sergei Agalakov[3], Bradley I Arshinoff[3], Dong Zhuo Wang[3], Troy Pells[3], Vaneet Lotay[3], Kamran Karimi[3], Peter Vize[3], Aaron Zorn[1] [1]Division of Developmental Biology, Cincinnati Children's Hospital Medical Center, [2]Department of Biomedical Engineering, Ulsan National Institute of Science and Technology (UNIST), [3]Department of Biological Sciences, University of Calgary

Xenbase (www.xenbase.org) supports biomedical, developmental and cell biology using *Xenopus*, the African and Western clawed frogs. Xenbase is the central repository for *Xenopus* genetics and genomics data and provides researchers with bioinformatic resources and tools for complex analysis. Our mission is to 1) provide the latest genomes linked to genes and orthologs; 2) curate published research/literature for disease models, experimental phenotypes, and gene expression; 3) annotate *Xenopus* genes with GO terms (molecular functions, biological processes and cellular components); and 4) collate diverse genomics data from high throughput sequencing in a central, searchable, database. *Xenopus* genomes, proteomes, genome annotation files and *Xenopus* gene-to-human gene ortholog mapping files are available from our download site. The backbone of *Xenopus* gene expression curation is the Xenopus Anatomy Ontology (XAO) and phenotype curation uses the Xenopus Phenotype Ontology (XPO), linking *Xenopus* disease models to Disease Ontology (DO) terms when appropriate. Xenbase also derives expression phenotype data from our standardized pipeline for processing high-throughput datasets from the NCBI Gene Expression Omnibus (GEO) repository. In addition, Xenbase has recently expanded our education resources including an anatomy atlas, normal tables of development, tables of anatomical staging landmarks, tables of key tissue and stage specific marker genes, high resolution images of developing and adult frogs, movies of embryonic development, and a set of open access illustrations of embryonic development. Aggregating all of this information in an easy to use and free to access web portal, Xenbase effectively connects *Xenopus* genes and phenotypes to human genes and diseases via multiple data resources including the Alliance of Genome Resources. Here we provide an overview of Xenbase resources, tools and curated *Xenopus* data, and data interconnectivity. Xenbase is funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD/NIH).

595F **CRIS-cross: Efficient Generation of Combinatorial Genetic Variant Libraries** Han-Ying Jhuang, Gregory Lang Lehigh University

CRISPR-based genome engineering allows for precise and efficient editing of genetic sequences. However, the process also requires a significant amount of time, labor, and financial resources. To overcome this limitation, we use a modified yeast mating machinery that utilizes the natural efficiency of yeast mating but avoids the formation of hybrid nuclei. This system allows us to achieve high editing efficiencies and quickly generate combinatorial libraries of genetic variants. We are validating our system with known genetic interactions, and are creating a 3-way combinatorial library of genetic variants from evolution experiments. Our work has the potential to greatly increase our understanding of genetic interactions and provide insight into the evolution of species.

596F **Yeast Pathways at Saccharomyces Genome Database: Transitioning to Noctua & Alliance Pathways** Suzanne Aleksander[1], Dustin Ebert[2], Stacia R Engel[1], Rob Nash[1], Edith D Wong[1], Paul D Thomas[2], J. Michael Cherry[1], The SGD Project[1] [1]Genetics, Stanford University, [2]Department of Population and Public Health Sciences, University of Southern California

The *Saccharomyces* Genome Database (SGD, http://www.yeastgenome.org) is the leading knowledgebase for *Saccharomyces cerevisiae*. SGD collects, organizes and presents biological information about the genes and proteins of the budding yeast, including information concerning metabolism and associated biochemical pathways. The yeast biochemical pathways were originally sourced from the YeastCyc Pathway/Genome Database, which uses the metabolic pathways from MetaCyc. YeastCyc Pathways were imported into SGD in 2002, then SGD biocurators edited them as necessary to make them specific to *S. cerevisiae*, using publications from the primary literature. This comprehensive curation ensured that only the reaction directions and pathways that are physiologically relevant to *S. cerevisiae* were included, and also provided written summaries for each pathway. Loading, editing, and maintaining YeastPathways displayed at SGD was accomplished using the Pathway Tools software.

YeastPathways have now been available at SGD for over 20 years, with the last major content update in 2019. Recently, YeastPathways have been transitioned from a curation system that uses Pathway Tools software to one that uses the Gene Ontology curation platform Noctua, the interface SGD already uses to curate GO annotations. Each of the 220 existing pathways in YeastPathways has been converted from Pathway Tools BioPAX format into separate GO-Causal Activity Models (GO-CAMs), which are available as Turtle (.ttl) files. The GOCAM structured framework allows multiple GO annotations to be linked, which is ideal for a metabolic pathway. Although many of the steps are automated, manual intervention was required throughout the process to complete the GOCAMs and to verify inferences made by the conversion tools. Using the Noctua curation interface for biochemical pathways, without the need for external software, will streamline curation. Additionally, each model's metadata is accessible to any interested party. GO-CAMs can be deconstructed into standard GO annotations, making the pathway information accessible for enrichment studies and other applications. YeastPathways as GO-CAMs will also be available through the Gene Ontology's GO-CAM browser and the Alliance of Genome Resources, as well as any other resources that display GO-CAMs. This upgrade to the SGD's curation process will also make YeastPathways more transparent and compliant with FAIR guidelines and TRUST principles.

597F **Single-cell DNA Sequencing via *in situ* Genomic Amplification & Combinatorial Barcoding** Parker E Crossland, Kara Schmidlin, Leandra Brettner, Isabella Valli-Doherty, Kerry Geiler-Samerotte Arizona State University

Single-cell DNA sequencing (scDNA-seq) can identify genetic differences between individual cells in a population, which has broad applications in studying cell biology. For example, because scDNAseq preserves haplotypes, it enables studying the fitness of combinations of mutations instead of just individual mutations. Current scDNA-seq methods require the physical separation of cells, which can be done manually or using machinery. Both are time-consuming and costly. Thus, most scDNA-seq studies are limited to a few hundred cells. These constraints make it challenging to multiplex samples and perform high throughput experiments. We are developing a novel method for sequencing the DNA of single cells in heterogeneous populations by using cells as their own container for *in situ* amplification and barcoding reactions, thus eliminating the need to isolate individual cells. To uniquely identify DNA from each cell, we use combinatorial barcoding, which creates cell-specific barcodes by using a unique combination of non-unique nucleotide sequences. Combinatorial barcoding allows for the pooling of cells, making the method multiplexable and enabling the analysis of dozens of samples containing thousands of cells each. Our flexible method allows for targeted sequencing of a region of interest and whole genome sequencing. We aim to optimize the method for various organisms and applications to make it accessible to many research groups.

598F **Extending the GRNsight application for visualizing small-to-medium gene regulatory networks to incorporate physical protein-protein interaction data from SGD** Kam D Dahlquist[1], Onariaginosa O Igbinedion[2], Ahmad R Mersaghian[1], Ngan N Tran[2], Deepa V Dabir[1], John David N Dionisio[2] [1]Biology, Loyola Marymount Univ, [2]Computer Science, Loyola Marymount Univ

A gene regulatory network (GRN) consists of genes, transcription factors, and the regulatory connections between them which govern the level of expression of mRNA and protein from genes. GRNmap is an open source MATLAB program that performs parameter estimation and forward simulation of a differential equations model of a GRN based on time course gene expression data. GRNsight is an open source web application for visualizing small-to-medium scale GRNs, especially models produced by GRNmap. GRNsight reads the Excel input and output workbooks from GRNmap and automatically displays the model data as a graph with colored nodes (expression data) and edges (estimated regulatory weights). We recently implemented a backend PostgreSQL database for GRNsight, populated with five public gene expression datasets and regulatory network data from the *Saccharomyces* Genome Database (SGD). A user can select genes to include in the GRN, and GRNsight will automatically layout the network using regulatory connections from SGD. The user can then select one of the time course gene expression datasets with which to color the nodes and export to a properly-formatted GRNmap input workbook. GRNmap can then be used to estimate the regulatory weights (activation vs. repression and magnitude of the relationship). Although GRNsight was originally designed for GRNs, it has the general applicability for displaying any appropriately-sized, weighted or unweighted network with directed edges. Previously, GRNsight was limited to only displaying graphs with directed edges and was unable to display protein-protein physical interaction (PPI) networks, as they are represented by undirected graphs. Thus a protein-protein physical interaction network mode was created to visualize these models in GRNsight. Additionally, a backend database

was added to store PPI data obtained from SGD, so that users can generate a PPI network within GRNsight the same way they can generate a GRN. The graphical user interface was updated to be able to toggle between these two graph modes, enabling comparison of these two types of data. GRNmap is available at http://kdahlquist.github.io/GRNmap/; GRNsight is available at http://dondi.github.io/GRNsight.

599F **Generating a transgenic fish for in vivo cell cycle studies in glial cells** Jenny R Lenkowski[1], Cas A Sturdivant[2], Edna A Ferreira[1] [1]Goucher College, [2]Biological Sciences, Goucher College

Glial cells in the central nervous system provide a variety of functions including homeostatic support of neurons and synapse regulation as well as acting as stem cells. Glia develop from the same neuroepithelia as neurons and in some animals can be reactivated to act as tissue-specific stem cells to regenerate destroyed neurons, an area of research in our lab. Therefore, we are developing a system to study cell cycle dynamics in glial cells in the zebrafish model system. In the zebrafish fluorescent ubiquitination-based cell cycle indicator (zFUCCI) system, the fluorescent protein mCherry is tagged with a fragment of chromatin licensing and DNA replication factor 1 (CDT1) and visible during G1 phase, while mAzamiGreen (mAG) is tagged with a fragment of geminin and visible S through M phase. We are generating a *gfap:zFUCCI* system with the glial fibrillary acidic protein (gfap) promoter, thus, *gfap:mCherry_Cdt1* and *gfap:mAG_Gem* constructs will only be expressed in glia. In the neural retina, this would allow Müller glia to be observed via fluorescent imaging after a neuronal lesion when they reenter the cell cycle and cell cycle dynamics quantified when genes or pathways are manipulated. We have confirmed the zFUCCI construct sequences by culturing *E. coli* carrying the construct to sequence and injected linearized constructs into fertilized zebrafish eggs to establish transgenic lines. These *gfap:zFUCCI* lines will be used to then study how cell signaling pathways regulate cell cycle dynamics during development and regeneration in the nervous system.

600F **Integrative 3D Zebrafish Microanatomical Atlas** Khai C Ang[1,2], Jean E Copper[1], Mee S Ngu[1], Daniel J Vanselow[1], Keith C Cheng[1] [1]Pathology, Penn State College of Medicine, [2]Penn State Functional Genomics Core, Penn State College of Medicine

The zebrafish is a vertebrate model organism with significant genetic, cellular, and physiological similarities with humans. Its powerful genetics and advanced imaging facilitate the elucidation of genetic functions, embryonic development, and disease mechanisms. Traditional 2D histology offers cellular and subcellular detail across cell types and is the cornerstone of histopathological diagnosis. Its inherent limitations include its two-dimensional perspective, under-sampling, and section-based artifact, which lead to inadequate understanding of the three-dimensional structure of cells (including volume, shape, texture) and spatial relationships between cells in different tissues and disease states. To enable the computational phenotyping of whole organisms without sampling bias, we developed a 3D form of histology, *histotomography*, that features centimeter field-of-view, and submicron voxel resolution. This enables volumetric measurements of cells and the relationships between cells and tissue structures in the context of the whole organism.

The 2D histology component of existing atlases includes high-resolution images of the organisms' cells, tissues, and organs. We propose to add a microCT component to atlases that will add 3D representations of cells and organs, allowing researchers to interrogate the spatial relationships between the structures and exploration of microanatomy in virtual environments. Integrative atlas resources will allow access to multi-omic data in the context of the whole organism. MicroCT images will serve an integrative role, anchoring histology, fluorescence and ultrastructural imaging, and large-scale "-omic" data across length scales. Integrating "-omics" data elevates atlases to dynamic anatomical guides for molecular data in the context of the whole organism platform to elucidate how genetic variation and external perturbations cascade through multiple biological scales to influence phenotype.

The tools of the 3D zebrafish atlas resource are being created as a foundation for future application across model organisms and human atlases to anchor research and educational advances in our understanding of biology, disease, and development.

601F **Improving toxicology data compatibility within and across species and advancing a community-led zebrafish toxicology phenotype atlas.** Anne E. Thessen[1], Melissa Haendel[1], Alexa Burger[2], Sabrina Toro[1] [1]Department of Biomedical Informatics, University of Colorado, Anschutz, [2]Department of Pediatrics, Section of Developmental Biology, University of Colorado, Anschutz

Zebrafish have greatly advanced toxicology and environmental studies as a valuable animal model because they are easy to manipulate, breed, and observe during development. However, the absence of universal standards for toxicology data significantly impedes scientific progress and therefore human and environmental health.

The Zebrafish Toxicology Phenotype Atlas is a new, community-built standard for annotating zebrafish toxicological exposure and their phenotypic outcomes (toxicophenotypes). We are designing a toxicophenotype data model that enables comprehensive representation of toxicological exposures, including time course, toxicants, and concentrations; genotype and

genetic manipulations; phenotypic endpoints. This data model is developed with the community and leverages a variety of different toxicological use cases, from multiple species. Ensuring that the core of this data model is applicable across organisms will allow data integration and interoperability across species and across toxicological studies.

We will create a toxicophenotype annotation toolkit that will allow users to annotate their data based on the data model, and will instantiate a zebrafish toxicophenotype atlas web application. This atlas will serve as a visual definition of the standards and their documentation for examining variations of specific phenotypes by laboratories in the community. Users will be able to explore and query exposures and phenotypes of interest and see example images demonstrating the phenotypes.

This project is governed and driven by the community, which includes diverse stakeholders in toxicology and environmental health sciences, ensuring fit-for-purpose design and sustainability.

Realizing interoperable toxicophenotypic data is crucial to improving data integration across scale and granularity, and across species; thereby accelerating our understanding of environmental influences on human health.

602S **Assessing behaviour across organisms through patterns in multi-variate data** Christopher James[1,2], Christopher James[3] [1]EMbody Biosignals Ltd., [2]Biomedical Engineering Institute, University of Warwick, [3]EMbody Biosignals LTD

Whether its tracking human behaviour through activity monitoring or nematode behaviour on a dish, AI and machine learning based data analysis solutions provide a powerful way to undertake real-time monitoring to gain insight on trends, history and prediction, as well as to detect problems quickly.

Of the various methods in the literature a) Rules based systems take time and extensive knowledge of the end user and b) Statistical approaches are fast but rely on one-size fits all techniques. Machine learning based methods remove these limitations by automatically learning behaviour patterns for each individual organism. Crucially, these methods provide a data source agnostic approach that can work on any numeric, categorical or event based data. For example, through the use of a video microscope, longitudinal patterns in C.elegans can be captured and examined over very long periods of time resulting in learned generative models to predict behaviour in both individual as well as population models. The same methods can be used to assess multi-sensor scenarios in more complex organisms yet with similar, detailed measures of complex behaviour as outcomes.

603S **High-Efficiency Integration of Large DNA Fragments by Cas9 Cleavage and Single-Strand Annealing in *Drosophila*** Jeff Sekelsky, Susan McMahan Biology, University of North Carolina

Numerous types of genome editing with CRISPR/Cas9 have been described. One goal that remains difficult is integration of large DNA fragments, as this challenges the processivity of homology-directed repair (HDR). The single-strand annealing (SSA) repair pathway should allow pasting in of large fragments without the need for a copying step as in typical HDR. When a DNA double-strand break (DSB) is made, the first step in HDR is resection of the ends to generate long 3’-ended single-strand overhangs. If the DSB is between direct repeats, this resection exposes complementary sequences that are efficiently annealed. In this chromosomal SSA the result is collapse to a single repeat with loss of intervening sequences.

In our approach, a payload to be integrated into the genome is flanked by homology arms (HAs) that match sequences adjacent to the genomic target site(s). The [HAleft] + payload + [HA right] unit is cut out of the plasmid when the genomic target site is cut. Resection of both the chromosomal site and the linear fragment released from the plasmid exposes complementarity between the HAs and the target site, promoting SSA to integrates the payload. This approach was developed independently by Oguz Kanca to integrate smaller fragments into thousands of Drosophila genes (PMC9239680).

We built a vector that allows (1) introduction of one or more gRNA sequences for targeting the genome (these are added downstream of the gRNA to cut the vector, which is already present); (2) simultaneous cloning of both HAs; and (3) sites for the payload between the HAs. Each step is done by highly efficient GoldenGate cloning. For the payload step the vector can function as a GoldenBraid omega vector to allow assembly of two or more pieces from plasmids or fragments. Additional vectors we’ve made include one with chromatin insulators, versions with eGFP or mCherry as payloads (just add gRNA and HAs), and variants that have additional gRNA sites for downstream engineering in the fly.

We tested our strategy by targeting a site in ebony. The vector carried a 12.5-kb payload including eGFP and used ~400-bp HAs. Among G0 flies after injection, 18 of 29 (62%) had ebony progeny, and 51% of ebony flies (27% of all progeny) expressed eGFP. We are now testing larger payloads and precise editing by replacing a genomic region after two cuts. We’ve also domesticated many parts (Drosophila promoters, genes, recombination target sites, etc.) that can be used in GoldenBraid cloning.

604S **New from the TRiP: large scale resources for gene perturbation, gene expression, and protein detection** Jonathan

Zirin[1], Ben Ewen-Campen[1], Justin A Bosch[1], Ah-Ram Kim[1], Raphael Lopes[1], Neha Joshi[1], Barbara Jusiak[2], Lu-ping Liu[1], Christians Villalta[1], Alexandria Risbeck[1], Elizabeth Filine[1], Yousuf Hashmi[1], Corey Forman[1], Aram Comjean[1], Yanhui Hu[1], Stephanie Mohr[1], Norbert Perrimon[1,3] [1]Genetics, Harvard Medical School, [2]Physiology and Biophysics, University of California, Irvine, [3]Howard Hughes Medical Institute

The Transgenic RNAi Project (TRiP) is an in vivo functional genetics platform that has generated >20,000 shRNA and sgRNA fly stocks for the research community. These resources, distributed to the community by the BDSC, provide powerful, versatile, and transformative tools for gene knockdown, knockout, and activation. Researchers can now easily access fly stocks useful to "dial down" or "dial up" genes covered by the collection, in a variety of developmental stages and tissues. Here we describe new in vivo resources designed to enable: 1) combinatorial studies using multiple binary expression systems. Focusing on genes with well-characterized GAL4 expression patterns, we generated a set of more than 40 LexA-GAD and QF2 insertions by CRISPR knock-in and verified their tissue-specificity in larvae; 2) validation of scRNA gene clusters using split-Gal4 lines. Using an algorithm that determines the smallest unique set of marker genes that define a cluster, we are generating and validating several hundred highly specific Gal80-repressible split-Gal4 knock-in lines; 3) detection of fly proteins. We are inserting a NanoTag epitope at the C-terminus of more than 300 high confidence Drosophila orthologs of human mitochondrial disease genes, which can then be recognized by an existing high-affinity nanobody against the NanoTag. These new resources will dramatically expand the scope of available reagents for gene expression and detection of fly proteins.

605S **Optogenetics for All: NinaB Cleavage of *Beta*-Carotene as a Source of *all-trans* Retinal** Karen L Hibbard[1], Ilya Vilinsky[2], Thomas A Ravenscroft[1], Glenn Turner[1], Yoshi Aso[1] [1]HHMI Janelia Research Campus, [2]University of Cincinnati

Optogenetics has become a valuable tool for investigating memory, learning, and behaviours in *Drosophila* and many other species. It also has become an exciting science educational tool that has been successfully implemented in elementary and secondary schools. There are many different variants of opsins: ion channels (channelrhodopsin), pumps (halorhodopsins), or coupled G-Proteins (visual opsins). All opsins share a similar structure of 7 transmembrane domains and bind a retinal molecule (chromophore) within the 7th transmembrane domain. The retinal chromophore absorbs a photon of light and rapidly isomerize inducing a structural change in the protein. *Drosophila* are unable to synthesize retinal and it must be derived from carotenoids in their diet. In the majority of channelrhodopsin variants, the amounts of carotenoids obtained from standard cornmeal fly food is insufficient to supply both the visual system and the transgenic channelrhodopsins. Fly food is usually supplemented for optogenetic experiments in the range of 0.2 -0.4 uM of *all-trans*-retinal which is costly. NinaB, a *beta, beta*-carotene-15,15'-oxygenase, cleaves carotenoids into two retinal molecules. Confocal imaging of *ninaB-GAL4/UAS-GFP*, identified glial cells as the putative site of *ninaB* expression. We are investigating the efficacy of pan glial over-expressed NinaB cleaved *beta*-carotene as the source of *all-trans* retinal for optogenetic experiments. Current experiments are comparing the cost-effective *beta*-carotene supplementation versus *all-trans* retinal in optogenetic behaviors and electrophysiology (e.g., Moonwalker behavior, learning within the mushroom body, and excitatory junction potentials at the larval neuromuscular junctions).

606S **Selective depletion of histone transcripts to interrogate histone residue function** Oscar M Arroyo, Daniel J McKay University of North Carolina - Chapel Hill

At the earliest stages of metazoan development, a single diploid nucleus begins dividing and eventually creates a diversity of cell types with specialized functions in the adult. No genetic information is gained or lost during development; rather, epigenetic mechanisms are responsible for maintenance of gene expression programs underlying cell identity. Post-translational modifications on histones, the main protein component of chromatin, are a major source of epigenetic information. Despite their importance, direct examination of histone function in metazoans is challenging due to their high copy number and location on multiple chromosomes. *Drosophila melanogaster* provides an excellent experimental system for studying histones in epigenetic gene regulation as all 100 copies of the canonical histone genes exist at a single locus in a tandem array. Homozygous deletion of the histone gene locus is lethal but can be rescued by a transgene carrying 12 copies of the wild-type histone repeat unit. By mutating the transgenic histone genes to encode target residues that cannot be post-translationally modified, we have engineered mutant genotypes to directly test histone residue function. Although this "histone replacement platform" has expanded our understanding of epigenetic gene regulation, the scope of experimental approaches that can be employed remains limited because many histone mutations are lethal and can only be studied by generating small clonal populations of mutant cells. Here, we present an approach that further expands our ability to interrogate histone function by improving spatiotemporal control over histone depletion. Utilizing the GAL4/UAS system to express transgenic siRNAs targeting the 3'UTR of the *D. melanogaster* histone H3, we can selectively deplete endogenous histone gene expression in a targeted manner. We find that H3 depletion results in a severe proliferation defect. However, we can rescue this defect by providing transgenic H3 bearing the 3'UTR from the *Drosophila simulans* H3 gene, which renders it insensitive to siRNA-mediated knockdown. Coupling H3 depletion with a knockdown-insensitive mutant transgene allows us

to generate entire tissues expressing mutant histones, thus expanding the scope of experimental approaches beyond those employed in small populations of cells. We propose to use this genetic platform to generate fully mutant tissues or embryos to further interrogate the requirement of specific histone residues.

607S **Repurposing synthesized homology donor intermediates to generate novel genetic reagents** Oguz Kanca[1,2], Catherine Grace Burns[1,2], Megan Cooper[1,2], Ali Hosseini Bereshneh[1,2], Wen-wen Lin[1,2], Liwen Ma[1,2], Ming Ge[1,2], Robert W. Levis[3], Hugo J. Bellen[1,2,4] [1]M & H Genetics, Baylor College of Medicine, [2]Duncan Neurological Research Institute, Texas Children Hospital, [3]Department of Embryology, Carnegie Institution for Science, [4]Department of Neuroscience, Baylor College of Medicine

The Gene Disruption Project (GDP) aims to generate versatile reagents to facilitate in depth functional characterization of fly genes with an emphasis on fly genes that are conserved in humans. The GDP has generated thousands of alleles with transposable elements and more recently CRISPR-mediated homologous recombination (CRIMIC). We have developed streamlined methodologies to accomplish CRIMIC transgenesis to make targeting thousands of genes feasible. Our current methodology uses commercial DNA synthesis to generate a homology donor intermediate vector which contains sgRNA coding sequences that both guide the cutting of the target locus and the linearization of the circular homology donor construct *in vivo* in the Cas9-expressing germline. It contains short homology arms that enable homologous recombination. This construct design allows single step directional cloning of any payload in the homology donor intermediate vector to generate a donor construct containing all the components required for successful homologous recombination. To date, we have generated over 3000 transgenic alleles that express GAL4 in the expression pattern and dynamics of the targeted gene. These transgenes not only generate strong loss of function alleles but also are useful to determine the expression pattern of the targeted gene by using the GAL4 to drive the expression of a UAS-RFP reporter. Furthermore, the GAL4 can be used to drive a cDNA of the human orthologue of the target gene to test whether the human orthologue can rescue the fly mutant phenotype. Recently, we started to repurpose the synthesized homology donor intermediate vectors to generate GFP protein trap alleles for over 80 genes. These GFP alleles are very versatile and allow detection of the subcellular localization of the targeted gene product, immunopurification of the gene product and its interactors using anti-GFP antibodies. The GFP tag allows removal of the gene product by using genetic tools such as DegradFP or iGFPi. Repurposing the homology donor intermediates offers many advantages compared to RMCE based approaches. First, the homology donor intermediates contain all the components required for homologous recombination. Second, it allows using the same injection stock to create different reagents. Third, if the CRIMIC allele is in an essential gene, only half of the injected embryos are viable whereas injection in wildtype stocks do not suffer from this effect. We are also currently testing whether it is possible to replace the target gene with human cDNA directly at the endogenous locus. Replacing the fly gene with human cDNA directly in the locus will allow more precise matching of expression levels, which may increase the success rate of functional replacement of the fly gene with the human gene. Hence, repurposing the homology donor intermediates opens new avenues to easily develop novel applications to manipulate fly genes.

608S **Higher-resolution pooled genome-wide CRISPR knockout screening in insect cell lines using integration and anti-CRISPR (IntAC)** Raghuvir Viswanatha[1], Samuel Entwisle[1], Claire Hu[1], Stephanie E Mohr[1], Norbert Perrimon[1,1,2] [1]Genetics, Harvard Medical School, [2]Howard Hughes Medical Institute

CRISPR screens provide a systematic, scalable approach for linking genotype to phenotype. We have successfully conduct CRISPR screens in insect cells (*Drosophila* or *Anopheles*) using plasmid transfection and site-specific integration to introduce sgRNA libraries, followed by PCR and sequencing of integrated sgRNAs at the end of the assay. Although the method is highly effective, quantitative analysis revealed room for improvement. With our approach, constitutive Cas9 activity is important. However, having Cas9 activity present early in the screen workflow could be problematic, because immediately after library transfection many active sgRNA expression plasmids are present in cells but only one or a few of sgRNAs will become integrated, creating the potential for a mismatch between genome edits that result in a phenotype and the sgRNA sequence detected. To avoid this, we previously used a weak promoter (*DmU62*) for sgRNAs, which likely delayed activity, favoring recovery of edits attributable to integrated sgRNAs but also reducing efficiency. Here, we asked if suppressing Cas9 activity in the early post-transfection period would allow us to combine constitutive Cas9 expression with use of a stronger promoter for sgRNAs for improved screen quality. To do this, we co-transfected a plasmid expressing the anti-CRISPR protein AcrIIa4 at the time we introduced the sgRNA library, now driven by the higher-strength *DmU63* promoter, and the integrase that mediates integration of the sgRNA. Early on, we expect that sgRNAs are expressed but Cas9 activity is suppressed by anti-CRISPR. Later, when the anti-CRISPR plasmid has been lost, Cas9 acts together with the integrated sgRNA to edit the target gene. This approach, which we call “intAC” for integrase with anti-CRISPR, successfully delayed CRISPR activity and, when tested in combination with a new machine learning-based genome-wide sgRNA library, dramatically increased the number of high-confidence fitness genes detected in a ‘drop-out’ screen. This dataset provides the most complete set of cell fitness genes yet assembled for *Drosophila*. We also used the intAC approach together with a targeted sgRNA sub-library for positive selection

of nucleoside transporters. Overall, we demonstrate that the introduction of anti-CRISPR along with sgRNAs outperforms existing virus-free pooled CRISPR screening strategies.

609S **Drosophila Community Strains Pangenome: A Pangenome Resource Built From Highly Contiguous Genome Assemblies Of *Drosophila melanogaster* Community Strains** Mahul Chakraborty Department of Biology, Texas A&M University

Understanding the genotype-to-phenotype relationship in model organisms relies on community strains that various laboratories have developed. These strains often carry mutations and transgenes for genetic mapping and reverse genetics experiments, such as RNAi and CRISPR. However, in most cases, the genetic background of these strains is unknown. When interpreting the functional consequences of genetic perturbations in these strains, we assume that the study strains share a “more-or-less” same genome as the community reference genome. I have recently shown that the presence of genome structural variants, such as copy number changes, deletions or insertions, insertion of transposable elements, and inversions in widely used *Drosophila melanogaster* community strains can severely mislead our understanding of genotype-to-phenotype relationships. The ideal solution to this problem would be to build a reference genome of all laboratory strains used by the members of a model organism community. However, sequencing the genomes of all laboratory strains in *D. melanogaster* is unnecessary because the genetic background of many strains are derived from a few strains. A pangenome of these strains would be sufficient for the majority of experiments investigating the sequence-to-phenotype relationship. I initiated the Drosophila Community Strains Pangenome (DCSP) project to build such a resource. It is a publicly available pangenome constructed with highly contiguous, reference-quality genome assemblies of commonly used *D. melanogaster* strains, including wild-type and transgenic strains. The genome assemblies are built with Pacific Biosciences HiFi reads, which ensures high sequence accuracy across the assembled genome, including the repetitive sequences. The pangenome can be downloaded and searched using alignment tools. The initial release of DCSP features the genomes of 12 popular *D. melanogaster* strains, including the genetic background of commonly used CRISPR and RNAi stocks, with plans for further expansion based on community feedback. Annotation of comprehensive structural variants in these genomes revealed several variants with potential phenotypic effects that can confound the interpretation of functional experiments involving these strains or their genetic background. The DCSP project will be a valuable resource for *Drosophila* researchers, enabling accurate interpretation of results and advancing our understanding of genotype-to-phenotype relationships.

610S **Characterization of shock wave effects using nanoparticles in syncytial embryos of *Drosophila melanogaster*** Daniel Tapia Merino, Achim Max Loske Mehling, Pedro Salas Castillo, Juan Rafael Riesgo Escovar Universidad Nacional Autonoma de Mexico

In this work, nanoparticles have been used as fiducial markers to evidence the insertion of exogenous material in the early embryo of *Drosophila melanogaster*, which is a syncytium. The aim is to achieve the insertion of nanoparticles through the application of underwater shock waves, a method that has been used successfully to create pores in other cell membranes and cell walls, such as those of fungal cells. In our shock wave protocol, the majority of embryos treated with shock waves in a suspension of nanoparticles survived to adulthood. We used carbon quantum dots and gold nanoparticles to evaluate whether they can be seen in sections of *Drosophila* larva by microscopy (fluorescence and electron transmission), after treatment with shock waves. In a complementary test, larva showed transient expression with a plasmid encoding GFP after underwater shock wave treatment when they were syncytial early embryos. The demonstration that exogenous material can penetrate the outer layers (chorion and vitelline membranes) as well as the cellular membrane of the early *Drosophila* embryo applying this regime, may open the door to diverse biological applications.

611S **Single-embryo ‘omics to monitor gene expression and metabolite changes in a sex-specific manner during early *Drosophila* development** J. Eduardo Pérez-Mojica[1], Zachary Madaj[2], Christine Isaguirre[3], Kin Lau[2], Joe Roy[1], Krittika Sudhakar[1], Ryan Sheldon[3], Adelheid Lempradl[1] [1]Department of Metabolism and Nutritional Programming, Van Andel Institute, [2]Bioinformatics and Biostatistics Core, Van Andel Institute, [3]Mass Spectrometry Core, Van Andel Institute

Early embryonic development lays the foundation for embryo structure and cellular differentiation. While the underlying transcriptional events have been widely studied, little is known about the concurrent metabolic processes. To study early embryo metabolism and understand its relationship with gene expression, we developed a method to simultaneously measure RNA and metabolites from individual embryos in *Drosophila melanogaster*. This method utilizes single-embryo RNA-sequencing data to establish a high-resolution developmental trajectory (pseudo-time). Single-embryo metabolomics data are then matched, enabling continuous metabolite analysis during early embryonic development. The resulting dataset provides a detailed picture of early embryo development up to the onset of gastrulation (≤3 hours) in *Drosophila*. The high resolution and sensitivity of this method allows for the identification of subtle changes in both transcripts and metabolites. As an example, our data show that deoxyribonucleotide metabolism is highly dynamic, showing a marked and rapid decreased in deoxyribonucleoside triphosphates at the onset of the zygote genome activation. Due to a high-resolution data, we identified novel transcripts with significantly different expression between males and females. Together, our method provides a new tool

with higher sensitivity to investigate the metabolism-transcription axis in the embryo. Beyond normal embryo development, this method can be used to characterize the role of developmental/metabolic genes during early embryonic development and investigate the mechanisms underlying embryo re-programming by maternal exposures.

612S **Upgraded genome browsers at the Rat Genome Database support comparative and translational studies** Jennifer Smith[1], Stanley JF Laulederkind[1], G Thomas Hayman[1], Shur-Jen Wang[1], Monika Tutaj[1], Mary L Kaldunski[1], Mahima Vedi[1], Wendy M Demos[1], Marek A Tutaj[1], Jyothi Thota[1], Logan Lamers[1], Adam C Gibson[1], Akhilanand Kundurthi[1], Varun Reddy Gollapally[1], Kent C Brodie[2], Stacy Zacher[3], Jeffrey L De Pons[1], Melinda R Dwinell[1], Anne E Kwitek[1] [1]Physiology, Medical College of Wisconsin, [2]Clinical and Translational Science Institute, Medical College of Wisconsin, [3]Finance and Administration, Medical College of Wisconsin

The Rat Genome Database (RGD, https://rgd.mcw.edu), a cross-species knowledgebase and the premier online resource for rat genetic and physiologic data, has recently added two advanced comparative genome browsers to our suite of innovative analysis tools--JBrowse 2 and VCMap. JBrowse 2 (https://rgd.mcw.edu/jbrowse2/) is a newly developed genome browser with improved functionality for structural variant and comparative genomics visualization. JBrowse 2 shares many features with its predecessors GBrowse and JBrowse 1, such as the ability to select and view multiple data types in a single view, easy zooming and navigation across a chromosome, and the ability to search for the name or ID of a genome feature, for example a gene or QTL, and go directly to that region of the genome. In addition, it provides expanded functionality designed to facilitate comparative studies, including the linear synteny viewer for cross-species analyses, the breakpoint split view and circular plot for structural variants, and a dot plot viewer for whole genome alignments.

JBrowse 2 browsers have been set up for all ten RGD species, including browsers for multiple assemblies for each species where those are available. For rat in particular, a substantial set of tracks is available. In addition to gene, QTL and strain tracks, RGD's JBrowse 2 provides tracks for RNA-Seq BAM alignments, strain-specific variants, and ATAC-Seq and ChIP-Seq epigenetics data aligned onto the mRatBN7.2 assembly. Tracks for consolidated variants from the European Variant Archive are available for all applicable species, including rat, mouse, dog, pig and green monkey, allowing comparisons with human variants from ClinVar and the GWAS Catalog for a gene or region of interest.

For those interested in synteny across more than two species, RGD is developing the Virtual Comparative Map tool (VCMap, https://rgd.mcw.edu/vcmap/). VCMap, currently released as a beta version, provides a bird's eye view of synteny between two or more species/assemblies, whereas the synteny viewer in JBrowse 2 is limited to only two. Since the original version of VCMap, substantial improvements have been made to the performance and navigation for comparisons of syntenic regions across species. In addition to genes, tracks for data such as genomic variant densities can be added to the display. In conclusion, RGD's JBrowse 2 and VCMap provide valuable functionality for researchers engaging in comparative genomics and translational medicine.

613S **Pseudorabies virus upregulates low-density lipoprotein receptors to facilitate viral entry** ming shengli Henan Agricultural University

Pseudorabies virus (PRV) is the causative agent of Aujeszky's disease in pigs. The low-density lipoprotein receptor (LDLR) is a transcriptional target of the sterol-regulatory element-binding proteins (SREBPs) and participates in the uptake of LDL-derived cholesterol. However, the involvement of LDLR in PRV infection has not been well characterized. We observed an increased expression level of LDLR mRNA in PRV-infected 3D4/21, PK-15, HeLa, RAW264.7, and L929 cells. The LDLR protein level was also upregulated by PRV infection in PK-15 cells and in murine lung and brain. The treatment of cells with the SREBP inhibitor, fatostatin, or with SREBP2-specific small interfering RNA prevented the PRV-induced upregulation of LDLR expression as well as viral protein expression and progeny virus production. This suggested that PRV activated SREBPs to induce LDLR expression. Furthermore, interference in LDLR expression affected PRV proliferation, while LDLR overexpression promoted it. This indicated that LDLR was involved in PRV infection. The study also demonstrated that LDLR participated in PRV invasions. The overexpression of LDLR or inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9), which binds to LDLR and targets it for lysosomal degradation, significantly enhanced PRV attachment and entry. Mechanistically, LDLR interacted with PRV on the plasma membrane, and pretreatment of cells with LDLR antibodies was able to neutralize viral entry. An in vivo study indicated that the treatment of mice with the PCSK9 inhibitor SBC-115076 promoted PRV proliferation. The data from the study indicate that PRV hijacks LDLR for viral entry through the activation of SREBPs.

614S **RNA-Seq Technologies Identify Causal Mutations in Mice with Mendelian Disorders** David Bergstrom[1], Son Yong Karst[1], Belinda S Harris[1], Melissa L Berry[1], Whitney Martin[1], Heather E Fairfield[2], Narayanan Raghupathy[3], Laura G Reinholdt[1] [1]The Jackson Laboratory, [2]MaineHealth Institute for Research, [3]Bristol Myers Squibb

To investigate disease manifestation seen among patients and across mouse strains with Mendelian disorders, the identification of causal mutations is fundamental. Within The Jackson Laboratory's Comparative Mendelian Disease Genomics (CMDG) program (R24 OD021325/OD/NIH HHS/United States), we are exploring alternative technologies to identify disease-causative mutations where whole-exome sequencing alone has been insufficient. One such technology is transcriptome sequencing (RNA-Seq). Here, we report the analysis of sequenced transcriptomes from disease-relevant tissues for forty-seven (47) mouse models across a broad spectrum of Mendelian disorders (*e.g.*, those affecting craniofacial development, metabolism, neurological function, pigmentation, skeletal morphogenesis, *etc*.). Our analyses include the detection of single-nucleotide polymorphisms (SNPs) and an analysis of differential (gene) expression (DE), as well as an interrogation of changes among transcript isoforms. In many instances, confirmation of causation has been provided through CRISPR modeling and complementation testing. Our analyses highlight many instances where transcriptome sequencing has succeeded in identifying disease-causative mutations where other technologies have not, and suggests a further role for RNA-Seq, not only for mutation discovery in model organisms, but also in the diagnosis of Mendelian disease among patient populations.

615S **Can AI Outperform Well-Established Antimicrobial Resistance Gene Databases such as ResFinder and CARD?** Kristiene Recto, Pleuni S. Pennings Biology, San Francisco State University

The rise in antimicrobial resistance genes among microbes is a significant global health threat. This rise means that the antibiotics we use to treat infections become less effective, making it harder to fight these harmful microorganisms.

To combat infections and customize effective treatments, it's essential to know whether an infection is resistant to a certain drug. Machine learning combined with genomic data is a promising tool for proving valuable insight in this field. While machine learning has demonstrated efficient predictions in drug resistance, achieving the desired higher accuracy values remains a challenge. E coli is a species with a lot of diversity and can be divided into so-called phylogroups (A, B1, B2, C, D, E and F). It's currently unclear whether phylogroups affect prediction accuracies. In this study, we aim to bridge this knowledge gap by investigating the relationship between phylogroups and ML prediction accuracies in hopes of improving the ability to combat drug-resistant infections.

This study utilizes an openly accessible dataset of E. coli genomes from the UK to evaluate the prediction accuracies of the Gradient Boosted Tree Machine Learning model against ResFinder and Comprehensive Antibiotic Resistance Database (CARD). Gradient Boosted Tree is a branch of machine learning that combines predictions of multiple decision trees, with each tree correcting the errors of the previous tree to improve overall predictive accuracy. ResFinder is a database identifying acquired genes and finding chromosomal mutations mediating antimicrobial resistance in bacteria's total or partial DNA sequences. CARD offers analysis tools for molecular sequences, such as BLAST and the Resistance Gene Identifier (RGI) software, which utilize homology and SNP models to predict the resistome. In predicting the accuracies of antibiotic resistance profiles in E. coli, we will compare each model with five distinct E. coli Phylogroups (A, B1, B2, D and F) and apply our method to six antibiotic drugs. For each combination of drug and phylogroup, we will determine whether machine learning or the traditional CARD/Resfinder approach yield better results. Our project is dedicated to enhancing machine learning methods for quickly and accurately predicting antibiotic resistance. This advancement holds the potential to improve patient health outcomes significantly.

617S **Empowering disease knowledge representation with the Disease Ontology Knowledge (DO-KB)** J. Allen Baron, Claudia M. Sanchez-Beato Johnson, Lynn M. Schriml University of Maryland School of Medicine

The Human Disease Ontology (DO) is a FAIR genomic resource fostering cross-domain disease data integration and analysis, at model organism databases (e.g., FlyBase, MGD, RGD, SGD, WormBase, Xenbase, ZFIN) and by the broader biomedical community. It provides expertly curated, human-readable, and machine-actionable disease data with a comprehensive etiological disease classification spanning genetic, infectious, cancer, environmental, complex, rare, and common diseases. It links across authoritative biomedical resources with over 37,000 clinical vocabulary cross mappings and semantically represents diseases with mechanistic drivers and characteristics like mode of inheritance, phenotypes, chemical and environmental exposure, anatomy, and infectious agents.

The DO is a collaborative project that assists with disease data standardization and supports a growing disease data ecosystem, having been incorporated into over 390 biomedical resources and used in thousands of individual research projects since its inception in 2003. To expand this ecosystem and help researchers actionably leverage the DO in their research, genomic and machine learning applications and tools at disease-ontology.org that aid in exploration, access, connection, and search of disease data are highlighted. These tools include the Disease Ontology browser and new Disease Ontology Knowledgebase (DO-KB) SPARQL service and faceted search interface. The DO-KB SPARQL service empowers data discovery, extraction, and connection to diverse data across the web through the addition of DO-specific and federated query options, while the DO-KB

faceted search interface simplifies and enhances accessibility to the disease-defining semantic data in the DO, eliminating the need for users to have knowledge of programming and semantic logic to explore disease relationships.

Disease knowledge within the Disease Ontology and the disease data ecosystem it supports is continually updated and expanding. Greater collaboration will foster FAIR-er disease data access and open new avenues in biomedical research.

618S **Employing tRNA Mutations for Enhanced Non-canonical Amino Acid Incorporation** Berenice Guerra[1], Evan Kalb[2] [1]Health and Sciences School, Universidad del Sagrado Corazón, [2]University of Minnesota

Transfer RNAs (tRNAs) are essential for protein synthesis by delivering amino acids to the ribosome. Wild-type translation favors L-**α**-amino acids because of the specificity of aminoacyl-tRNA synthetases (AARs), EF-Tu binding, and ribosomal interactions. Tryptophanyl-tRNA synthetase has been observed to aminoacylate both D-tryptophan and *N*-**α**-methyl-tryptophan onto native $tRNA^{trp}$, but these substrates are unable to be incorporated in translation. Our hypothesis suggests that this incompatibility is due to reduced binding to EF- Tu and delivery to the ribosome. To overcome this, we introduced mutations in the T-stem of a native E. coli $tRNA^{Trp}$ and replaced it with the high affinity T- stem of $tRNA^{Asp}$. We overexpressed and purified the $tRNA^{TrpAsp}$ mutant using a hybridization probe purification scheme and confirmed its purity using a combination of Urea-PAGE and MALDI-TOF mass spectrometry. We found the overexpressed tRNA was hypomodified compared to wild type $tRNA^{Trp}$. Further, MALDI-TOF suggests $tRNA^{TrpAsp}$ is charged with L-Tryptophan. Our results suggest that wild type tRNAs can be mutated for the increased incorporation of noncanonical amino acids in native translation.

619S **Genome-wide CRISPR screening in a non-model Anopheles mosquito cell line** Enzo Mameli[1], Raghuvir Viswanatha[1], Claire Y Hu[1], William P Robins[2], John J Mekalanos[2], Stephanie E Mohr[1], Norbert Perrimon[1,3] [1]Genetics, Harvard Medical School, [2]Department of Microbiology and Immunobiology, Harvard Medical School, [3]Genetics, Howard Hughes Medical Institute

CRISPR screens are unbiased, systematic, linearly scalable approaches for linking genotype to phenotype. These screens had previously been restricted to mammals due to challenges in high-throughput delivery of a sgRNA library into non-mammalian cell line genomes. We previously showed that pooled, genome-wide CRISPR screens can be conducted in *Drosophila* S2R+ cells using plasmid transfection in combination with site-specific integration of an sgRNA-expressing cassette. Here, we report application of this approach to the *Anopheles* mosquito cell line Sua-5B. First, using optimized Polymerase III promoters to drive sgRNA expression, we conducted pilot screens of 7 genes that, as expected, rediscovered known genetic interactions with the drugs rapamycin or trametinib and the molting hormone ecdysone. Next, we scaled the approach to include all predicted *Anopheles* open reading frames based on the *Anopheles gambiae* PEST reference genome. In designing the library, we also optimized sgRNA designs for the Sua-5B cell line genome sequence and prioritized designs based on a machine-learning algorithm developed based on *Drosophila* CRISPR screen datasets. We then delivered the genome-wide library into Sua-5B cells at scale and determined which sgRNAs dropped out of the population over time, leading to identification of approximately 1,300 predicted fitness genes. As expected, these genes include most of the known or predicted components of essential complexes such as the ribosome, proteasome, and spliceosome. Lastly, we conducted proof-of-principle genome-wide positive selection screens to discover genes necessary for intoxication or infection of insects by pathogens. In one such screen, we identified a receptor and components of a putative internalization mechanism for an insect-crustacean toxin, and in another, we identified genes important for infection by an arthropod-born virus. Application of our approach has made genome-wide CRISPR knockout screens possible in cultured *Anopheles* mosquito cells for the first time, and provide a straightforward approach for conducting forward genetic screens in any organism for which derived cell lines are available.

620S **Gene-language are whole-genome representation learners** Charles Chen Biochemistry and Molecular Biology, Oklahoma State University

The language of genetic code embodies a complex grammar and rich syntax of interacting molecular elements. Recent advances in self-supervision and feature learning suggest that statistical learning techniques can identify high-quality quantitative representations from inherent semantic structure. We present a gene-based language model that generates whole-genome vector representations from a population of 16 disease-causing bacterial species by leveraging natural contrastive characteristics between individuals. To achieve this, we developed a set-based learning objective, AB learning, that compares the annotated gene content of two population subsets for use in optimization. Using this foundational objective, we trained a Transformer model to backpropagate information into dense genome vector representations. The resulting bacterial representations, or embeddings, captured important population structure characteristics, like delineations across serotypes and host specificity preferences. Their vector quantities encoded the relevant functional information necessary to achieve state-of-the-art genomic supervised prediction accuracy in 11 out of 12 antibiotic resistance phenotypes.

621S **Identification of Phytochemicals from Medicinal Plants as Strong Binders to SARS-CoV-2 Proteases ($3CL^{Pro}$ and PL^{Pro})**

and RNA-dependent RNA polymerase (RdRp) by Molecular Docking and Dynamic Simulation Studies Quaiser Saquib[1], Ahmed H Bakheit[2], Sarfaraz Ahmed[3], Sabiha M Ansari[4], Abdullah M AlSalem[5], Abdulaziz A AlKhedhairy[5] [1]Zoology Department, College of Science, King Saud University, [2]Pharmaceutical Chemistry, College of Pharmacy, King Saud University, [3]Pharmacognosy, College of Pharmacy, King Saud University, [4]Botany and Microbiology, King Saud University, [5]Zoology Department, College of Sciences, King Saud University

COVID-19, a disease caused by SARS-CoV-2, has caused a huge loss of human life, and the number of deaths is still continuing. Despite the presence of a few repurposed drugs and vaccines, the search for potential small molecules to inhibit SARS-CoV-2 is in demand. We provide promising computational (*in silico*) data on phytochemicals (compounds **1**-**10**) from Saudi medicinal plants as strong binders, targeting 3-chymotrypsin-like protease ($3CL^{Pro}$) and papain-like proteases (PL^{Pro}) and RNA-dependent RNA polymerase (RdRp) of SARS-CoV-2. Compounds **1**-**10** followed the Lipinski rules of five (RO5) and ADMET analysis, exhibiting drug-like characters. Non-covalent (reversible) docking of compounds **1**-**10** demonstrated their binding in the active pocket with the catalytic dyad (CYS145 and HIS41) of $3CL^{Pro}$, catalytic triad (CYS111, HIS272, and ASP286) of PL^{Pro}, template primer nucleotides (A and U) and key amino acid residues (ASP623, LYS545, ARG555, ASN691, SER682, and ARG553) of RdRp. Moreover, the implementation of the covalent (irreversible) docking protocol revealed that only compounds **7**, **8**, and **9** possess the covalent warheads, which allowed the formation of the covalent bond with the catalytic dyad (CYS145) in $3CL^{Pro}$, catalytic triad (CYS111) in PL^{Pro}, and a crucial amino acid (CYS813) in the palm domain of RdRP. Root mean square deviation (RMSD), root mean square fluctuation (RMSF), and radius of gyration (Rg) analysis from molecular dynamic (MD) simulations revealed that complexation between ligands (compounds **7**, **8**, and **9**) $3CL^{Pro}$, PL^{Pro} and RdRP was stable, and there was less deviation of ligands. Overall, the *in silico* data on the inherent properties of the above phytochemicals unravels the fact that they may act as inhibitors for $3CL^{Pro}$ and PL^{Pro}. Also, the studied compounds exhibit non-nucleoside and irreversible interaction capabilities to inhibit RdRp that shed new scaffolds as antivirals against SARS-CoV-2. Nonetheless, to confirm the theoretical findings here, the effectiveness of the above compounds as inhibitors of $3CL^{Pro}$, PL^{Pro}, and RdRp warrants future investigations using suitable *in vitro* and *in vivo* tests.

Keywords: SARS-CoV-2; COVID-19; medicinal plants; $3CL^{Pro}$; PL^{Pro}; RdRp; docking; MD simulation; phytochemicals.

Funding: This research was funded by King Abdulaziz City for Science and Technology (KACST) via the Fast Track Funding Path for COVID-19 Research Projects, grant number 5-21-01-001-0025.

622S **Development of a Computational Pipeline for Identifying Haplotype-Aware Genomic Variation in *Saccharomyces cerevisiae*** Joy A Love, Joseph A Stewart, Mackenzie A Wienke, Juan Lucas Argueso Environmental and Radiological Sciences, Colorado State University

Loss of Heterozygosity (LOH) is a class of chromosomal structural mutation that has important implications in the development of numerous genetic diseases, including cancer. LOH tracts occur when heterozygous genomic regions become homozygous for either one of the two available alleles. While using *Saccharomyces cerevisiae* as a model organism, we have identified LOH tracts in a mutation accumulation experiment. Accurate and efficient identification of LOH events from short-read whole genome sequencing (WGS) data is crucial for understanding these mutations. Currently, our group uses Nexus Copy Number to detect LOH tracts. However, this program has limitations: (1) it lacks haplotype phasing awareness, making it challenging to determine which allele a LOH clone tract became homozygous for, and (2) its commercial license is costly. The goal of this project is to develop a haplotype-aware and cost-effective LOH calling solution, leveraging Python and CLC Genomics Workbench. We conducted experiments to obtain LOH tracts in a hybrid heterozygous diploid strain background. We derived multiple yeast clones carrying genome-wide LOH tracts from this hybrid parent, and characterized them using the standard analysis above. These known LOH clones serve as the validation set for the new pipeline we are developing. To perform our new method, we first created a complete list of heterozygous single nucleotide polymorphisms (HetSNPs) in the parent strain. We validated this list by mapping reads from the fully heterozygous parent diploid to one of the haploid parents (our reference genome). We then derived a list of variants shared by the two sets and removed variants present at repetitive regions of the genome to arrive at a high-confidence HetSNP list. This enabled us to generate a custom variant tract in CLC. Subsequently, we mapped WGS reads from the known LOH clones above to the reference, creating a variant list for each LOH clone. These mapping variants were interrogated against the high-confidence HetSNP variant tract. CLC provided allelic identity and frequency outputs at all HetSNP positions, which were used in a custom Python code to make haplotype-aware phased genotyping calls. These calls were validated against known LOH tracts initially identified in Nexus. Our initial results show that this approach can reveal the full complexity of LOH tracts, including discontinuities in gene conversion segments near the recombination endpoints. As our study progresses, we will incorporate further insights and data into our presentation, providing a comprehensive overview and outlook of our research findings.

623S **Finding a function for Aim33 in *Saccharomyces cerevisiae*** Julia Iacovella, Thientrinh V Nguyen, Deborah Duong,

Analise Sulentic, John Giovinco, Julia Y Lee-Soety Biology, Saint Joseph›s University

Yeast *AIM33* encodes a protein with unknown molecular function, biological process, or cellular location. It is, however, 27% similar to human cytochrome b5 reductase CYB5R4, known for elongation of fatty acids, protection against oxidative stress, and cholesterol biosynthesis. *PGA3*, *AIM33*'s paralog, shares 55% similarity, and also encodes a cytochrome b5 reductase. Pga3 is able to extend chronological lifespan (CLS) under caloric restriction (CR) conditions, which limits typical caloric intake in nutrient-exhausted media without malnutrition. We compared the responses to CR between *aim33Δ* mutants and WT cells and observed that both cell types extended CLS in low sugar conditions indicating that Aim33 is not involved in caloric restriction responses. Interestingly, the *aim33Δ* mutants grew better than WT cells in minimal medium (SD) but grew similarly well in rich YPAD and synthetic complete (SC) media. Since Aim33 is likely a cytochrome b5 reductase with NAD and FAD binding domains, we measured and compared levels of NADH in WT and *aim33Δ* mutants and found that NADH levels were significantly lower in the mutants. Because *aim33Δ* mutants showed mitochondrial inheritance abnormalities, we stained for mitochondria in WT and mutant cells; no differences were observed. We did find that the *aim33Δ* mutation led to cells lingering longer in the S phase of the cell cycle and had decreased sporulation efficiency compared to cells with intact *AIM33*. In further exploration of *AIM33*, we discovered that it has genetic interactions with several genes with roles in telomere maintenance and in RNA processing. We generated *aim33Δ* haploid cells including deletions in *TLC1* which encodes the RNA template of telomerase and/or *NPL3* which encodes for an RNA processing protein involved in telomere maintenance. We measured and compared the rate of senescence which occurs when progressively shortened telomeres signal DNA damage and cause cell cycle arrest. While *tlc1Δ npl3Δ* double mutants senesced faster than *tlc1Δ* cells, the rates of senescence were similar between the *tlc1Δ* and *tlc1Δ aim33Δ* mutants and between *tlc1Δ npl3Δ* double and *tlc1Δ npl3Δ aim33Δ* triple mutants. Therefore, Aim33 likely does not have a role in supporting telomere maintenance. Furthermore, while genome-wide studies showed *aim33Δ* restoring the growth of *npl3Δ* cells at low temperature, we did not observe any differences in the rates of population doubling in *npl3Δ aim33Δ* mutants in standard growing conditions.

624S **Development of a yeast platform for expression and optimization of PET plastic degrading enzymes** Raphael Loll-Krippleber, Grant W Brown Department of Biochemistry and Donnelly Centre, University of Toronto

Over the past 70 years since the introduction of plastic into everyday items, plastic waste has become an increasing problem. With over 400 million tonnes of plastics produced every year, solutions for plastic recycling and plastic waste reduction are sorely needed. Recently, multiple enzymes capable of degrading PET (PolyEthylene Teraphthalate) plastic have been identified and engineered. In particular, the enzymes PETase and MHETase from *Ideonella sakaiensis*, have been shown to allow depolymerization of PET into the two precursors used for its synthesis, ethylene glycol (EG) and terephthalic acid (TPA). We have recently established a platform using *Saccharomyces cerevisiae* to develop a whole-cell catalyst expressing the MHETase enzyme, which converts MHET (monohydroxyethyl terephthalate) into TPA and EG, on the cell surface (PMID: 36587193). Following a similar strategy, we have now generated and assessed multiple construct architectures for efficient expression of PETase which acts upstream of MHETase and convert PET into MHET. Using a newly developed high-throughput plate assay that allows quantitative measurement of enzymatic activity, we demonstrate that despite differences between construct architectures, all PETase constructs are active against a model substrate. Importantly, expression of a published improved variant of PETase (FAST-PETase) increased activity of all PETase constructs, demonstrating that our plate assay and expression system recapitulates enzyme improvements characterized with purified enzymes. Using Synthetic Genetic Array (SGA), we introduced ~ 4200 non-essential gene deletions in our two best performing FAST-PETase expressing strains and measured PETase activity in the resulting strains using our high-throughput plate assay. We identified 54 gene deletions resulting in a robust increase in FAST-PETase activity, demonstrating the usefulness of our screening pipeline for PET-degrading strain improvement. Our current work aims to understand the mechanism by which gains in activity are achieved in these strains as well as screening gain-of-function and thermosensitive yeast essential genes libraries to identify further genetic alteration leading to PETase activity increases.

625S **Accelerated assembly of synthetic yeast chromosomes *in vivo* using DNA fragments with extensive synonymous recoding** Cara B Hull, Elizabeth Moore, Daniel Lusk, Ian Ehrenreich Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California

Homologous recombination in the budding yeast *Saccharomyces cerevisiae* is often used to assemble megabase-scale DNA molecules from smaller fragments. While this process works extremely well with DNA that has low identity to the *S. cerevisiae* genome, assembly of synthetic *S. cerevisiae* DNA *in vivo* poses unique challenges due to homologous sequences in the yeast genome. We hypothesized that a DNA synthesis strategy involving extensive synonymous recoding of protein-coding genes and use of recoded genes as assembly junctions could overcome this constraint. To test this hypothesis, we designed *in silico* a segment of *S. cerevisiae* Chromosome I that had identical intergenic regions and protein sequences to the natural chromosome but also possessed coding regions that differed at ~37% of nucleotides relative to natural homologs. We

then divided this design into 21 partially overlapping DNA fragments that were amenable to synthesis, with overlaps between fragments entirely restricted to coding regions. These DNA fragments were synthesized and co-transformed into yeast cells to assemble them with each other and a BAC/YAC vector. Here, we report the properties of this complex DNA assembly reaction and discuss our larger objective to use synonymous recoding schemes to build completely synthetic *S. cerevisiae* chromosomes in single assembly reactions involving large numbers of DNA fragments.

626S **What You Probably Didn't Learn When You Began Your Research Career – The Logic and Other Thoughts About How To Do Successful Research - Cliffnotes for Graduate Students and Post-Docs** Terrance G. Cooper Microbiology, Immunology & Biochemistry, University of Tennessee Health Science Center

The motivation for this work emanated from conversations with many graduate students and post-doctoral fellows. A simple question. How did you learn to do research? The answers were remarkably uniform. "Here's the project, here's the background, here are the techniques, let's begin." My objective has been to improve on that beginning. There is a logic to doing successful research, which graduate students and indeed post-doctoral fellows and young independent investigators often learn only with experience sometimes at their cost. The purpose of this work is to share the product of that experience and advice, working in nitrogen catabolite repression, Gln3, Gat1, Gcn2, and TorC1 as they begin their training and careers. In short, "CliffsNotes™" on how to think about and conduct a successful research program along with comments that have been guideposts for me as I have pursued the wonderful and winding road of nitrogen regulation in *Saccharomyces cerevisiae*. Anyone can walk on water if someone shows you where the stones are. Herein are some of the stones. FEMS Yeast Research FEMS Yeast Res. 23:foac065. doi: 10.1093/femsyr/foac065. PMID: 36881669 https://doi.org/10.1093/femsyr/foac065Supported by the Harriet S. VanVleet Chair of Excellence and NIH GM35642.

627S **A zebrafish model for whole-organism quantitative phenotyping of pleiotropy** Alex Y Lin[1], Maksim A Yakovlev[1], Ke Liang[2], Caroline R Zaino[1], Daniel J Vanselow[1], Andrew L Sugarman[1], Patrick La Riviere[3], Yuxi Zheng[4], Justin D Silverman[2], John C Leichty[5], Sharon X Huang[2], Damian B van Rossum[1], Victor A Canfield[1], KhaiChung L Ang[1], Keith C Cheng[1] [1]Pathology, Pennsylvania State University College of Medicine, [2]Information Sciences and Technology, Pennsylvania State University, [3]Radiology, University of Chicago, [4]Mathematics, Pennsylvania State University, [5]Marketing, Pennsylvania State University

Whole-organism phenotyping is necessary for the detection of pleiotropy, a frequent outcome of single-gene mutation and single chemical exposure. We are working towards a computational mechanism for microanatomic "histopathological" phenotyping of whole organisms, which would lead to a better understanding of the mechanisms underlying pleiotropy, gene function, chemical toxicity, and environmental influences such as nutrition, temperature, and disease. Since cells and tissues are 3-dimensional, a 3D histology has been needed to make such computational phenotyping possible. As a model for the objective evaluation of pleiotropic phenotypes, we are characterizing the dynamic phenotypes across organ systems in a null zebrafish mutant, *huli hutu* (*hht*) of the B subunit of DNA polymerase α, *pola2.* Homozygotes for this mutation evolve a complex pleiotropy associated with DNA damage and S phase arrest across multiple organ systems over 5-7 days, including nuclear atypia, a common cellular feature in human cancers and pre-cancers, in gastrointestinal organs, nuclear fragmentation in the eye and brain. As a first step toward quantitative, computational tissue phenotyping that includes pleiotropic phenotypes, physical characteristics of wild-type and *hht* blood cells were examined by micro-CT customized for histopathology, or X-ray histotomography, which generates 3D images of whole larvae at cellular resolution. Computer-assisted quantification revealed that the distribution of blood cells in the fish is conserved between wild-type and *hht* mutants, but significant, quantifiable differences were detected in cell count and cell dimensions. The application of geometric modeling across cell types and across organisms and sample types may serve as a computational foundation for more open, informative, rapid, quantitative, and reproducible whole-organism phenotyping.

628S **Process for developing optimized siRNA conjugates for *in vivo* delivery.** Sean F McCauley[1], Hannah McCauley[1], Kathleen Tran[1], Alexey Wolfson[1], Per Lindell[2] [1]ADViRNA, [2]Panther Therapeutics

siRNA conjugates are quickly becoming the leading approach in oligonucleotide drug development. This relatively new class of therapeutics informational drugs, consist of two different modalities; where functionality and gene specificity are provided by the sequence of the siRNA and *in vivo* targeting is achieved by the nature of the conjugate. As a result, delivery of siRNA conjugates to their target tissues *in vivo* does not require any additional formulation. To reach their targets *in vivo* and produce a long-term biological effect, the siRNA requires a heavily chemically modified backbone to confer nuclease resistance and functional longevity. However, these same chemical modifications significantly restrict the sequence space available for functional siRNAs. Consequently, their design presents a challenging task.

We present here a process for the efficient design, screening, characterization, and optimization of siRNA conjugates for

the discovery of maximally functional entities for research applications and therapeutic development. Using the example of VEGF-A siRNA design we will discuss potential pitfalls and complications associated with this process.

629S **The Monarch Initiative: An analytic platform integrating phenotypes, genes, and diseases across species** Monica C Munoz-Torres[1], Christopher J Mungall[2], Peter N Robinson[3], Melissa A Haendel[1] [1]Biomedical Informatics, University of Colorado Anschutz Medical Campus, [2]Biosystems Data Science, Lawrence Berkeley National Laboratory, [3]Berlin Institute of Health, Charité – Universitätsmedizin

Bridging the gap between genetic variations, environmental determinants, and phenotypic outcomes is critical for supporting clinical diagnosis and understanding mechanisms of diseases. It requires integrating open data at a global scale. The Monarch Initiative, an international consortium that aims to harmonize data across scientific disciplines to reveal disease mechanisms and aid disease diagnosis, advances these goals by developing open ontologies, semantic data models, and knowledge graphs for translational research. The Monarch App (monarchinitiative.org) is an integrated platform combining data about genes, phenotypes, and diseases across species. Monarch's APIs enable access to carefully curated datasets and advanced analysis tools that support the understanding and diagnosis of disease for diverse applications such as variant prioritization, deep phenotyping, and patient profile-matching. Monarch features a scalable, cloud-based infrastructure; simplified data ingestion and knowledge graph integration systems; enhanced data mapping and integration standards; and a recently refreshed user interface with novel search and graph navigation features. Furthermore, we have advanced Monarch's analytic tools by developing a customized plugin for OpenAI's ChatGPT to increase the reliability of its responses about phenotypic data, allowing us to interrogate the knowledge in the Monarch graph using state-of-the-art Large Language Models. The resources of the Monarch Initiative can be found at monarchinitiative.org and its corresponding code repository at github.com/monarch-initiative/monarch-app.

630S **Positional cloning of a chemically induced zebrafish mutant line with altered yolk lipid export** Nainika Pansari, McKenna Feltes, Steven A Farber Department of Biology, Johns Hopkins University

Lipids are essential nutrients for life and are needed for energy, act as chemical messengers, are signaling molecules and are integral components of cell membranes. Lipoproteins transport these hydrophobic molecules through the aqueous environments of metazoans (from insects to humans). In vertebrates, dietary lipids are absorbed/synthesized by the intestine and liver and are subsequently packaged into Apolipoprotein B-containing lipoproteins (B-lps). We still have an incomplete understanding of the genetic factors that influence B-lp biogenesis and metabolism. This is especially important since dysregulation of B-lp metabolism plays a major role in cardiovascular and metabolic diseases, that ultimately kill 25% of the human population. A large-scale forward genetic screen for a "dark yolk" phenotype associated with abnormal B-lp biosynthesis, in zebrafish, identified 27 mutant families. Here we report on the characterization and positional cloning of Mutant 5, which, in preliminary studies, was shown to have decreased B-lp levels. Using recombinant gene mapping and CRISPR/Cas9 editing, we identify the amino acid transporter ***slc3a2a*** gene as the molecular locus in the Mutant 5 line that produces the dark yolk phenotype. The identification of ***slc3a2a*****,** a gene previously unlinked to B-lp metabolism, that is conserved in humans**,** provides potentially new insight into the molecular players involved in regulation of vertebrate B-lps.

631V **REDfly: Uses of the Regulatory Element Database for *Drosophila* and other insects** Soile V. E. Keränen[1], Xinbo Huang[2], Marc S. Halfon[3,3,4] [1]None, [2]Center for Computational Research, University at Buffalo-State University of New York, [3]NY State Center of Excellence in Bioinformatics & Life Sciences, [4]Departments of Biochemistry, Biomedical Informatics, and Biological Sciences, University at Buffalo-State University of New York

REDfly is a knowledgebase of experimentally validated *cis*-regulatory modules (CRMs) and transcription factor binding sites (TFBSs) for *Drosophila melanogaster* and other insects, including the mosquitoes *Anopheles gambiae* and *Aedes aegypti* and the beetle *Tribolium castaneum*.

REDfly (v9.6.2 update) contains data on about 58,900 tested or predicted regulatory sequences and about 2700 TFBSs or their variants, with more being curated. We also have implemented JBrowse, which allows inspection of REDfly *D. melanogaster* data against the FlyBase reference genome, and UCSC PhastCons and PhyloP. The uses of REDfly vary from detailing the regulatory structure of a single locus, to large-scale studies of the regulatory genome, to providing training and/or validation data for machine-learning analyses of gene regulation. In other words, the REDfly data can be used for studying gene regulation for its fundamental rules and for developing methodology, both of which are applicable beyond *Drosophila* to metazoans in general.

CRM data in REDfly are broadly segregated into three categories: reporter gene analysis (CRM, RC), deletion of potential regulatory sequences from the genome (CRM segment), and predictions based on, e.g., ChIP-seq, ATAC-seq and/or computational modeling (pCRM). Also, we use the CRM data internally to infer minimally active sequences from tested CRMs

(iCRM). Transcription factor binding sites are mapped to overlapping CRMs.

CRMs or gene loci can be searched at http://redfly.ccr.buffalo.edu/search.php by entering a gene or CRM name. As REDfly CRM activity is annotated using structured ontologies, it is possible to search by using anatomy or GO terms to find CRMs active in specific organs or under certain conditions.

Search results can be downloaded in various formats or opened in individual palettes, which contain data and metadata for the regulatory element including sequence, activity profile, links to the source papers of the data, and links to our dedicated JBrowse genome browser, allowing the user to further explore the data. REDfly also curates silencers, which inhibit gene transcription, often while acting as enhancers for some other location or condition. Searching 'Including silencer' will return CRMs with silencing function, whereas 'Excluding enhancer' will return CRMs with only silencing function recorded.

REDfly is freely accessible at http://redfly.ccr.buffalo.edu and can be followed at @REDfly_database ("X") or at @REDfly@mstdn.science.

632V **split-intein Gal4: a potent intersectional genetic labeling system which can be controlled temporally via Gal80** Benjamin Ewen-Campen[1], Haojiang Luan[2], Jun Xu[3], Rohit Singh[4], Neha Joshi[1], Tanuj Thakkar[1], Bonnie Berger[5], Benjamin White[2], Norbert Perrimon[1] [1]Harvard Medical School, [2]National Institute of Mental Health, NIH, [3]CAS Key Laboratory of Insect Developmental and Evolutionary Biology, [4]Duke, [5]Massachusetts Institute of Technology

The existing split-Gal4 system allows for intersectional genetic labeling of specific cell types with exquisite spatial control. However, unlike native Gal4, it cannot be controlled temporarily because it cannot be repressed by Gal80. We have developed a split-Gal4 system based on a self-excising split-intein, which drives transgene expression as strongly as the current split-Gal4 system and Gal4 reagents, yet which is repressible by Gal80. We call this system "split-intein Gal4" and demonstrate its broad applicability in vivo. Further, we show that our split-intein Gal4 can be extended to the drug-inducible GeneSwitch system, providing an independent method for intersectional labeling with inducible control. We demonstrate that the split-intein Gal4 system can be used to generate highly cell type–specific genetic drivers based on in silico predictions generated by single-cell RNAseq (scRNAseq) datasets, and we describe an algorithm ("Two Against Background" or TAB) to predict cluster-specific gene pairs across multiple tissue-specific scRNA datasets. We have created a publicly available plasmid toolkit to efficiently create split-intein Gal4 drivers based on either CRISPR knock-ins to target genes or using enhancer fragments. Altogether, the split-intein Gal4 system allows for highly specific intersectional genetic drivers that are inducible/repressible.

633V **A Simple Assay for the Detection of Late-Stage Apoptosis Features in *Saccharomyces cerevisiae*** Narendra K Bairwa[1,2], Heena Shoket[3], Monika Pandita[3], Meenu Sharma[3] [1]Shri Mata Vaishno Devi University, [2]Central University of Jammu, [3]Genome Stability Regulation Lab, School of Biotechnology, Shri Mata Vaishno Devi University

Unicellular eukaryotic organisms such as yeast and protozoa serve as useful models for studying the impact of chemicals on cell physiology, cellular growth, and genome duplication. The yeast Saccharomyces cerevisiae has been widely used to assess apoptosis induced by chemicals due to its genetic tractability, ease of evaluation, and readily available impact assessment tools. Apoptosis in S. cerevisiae is characterized by many features, including increased cell death, loss of membrane integrity, release of caspases, chromatin condensation, and nuclear fragmentation, which are similar to the ones observed in mammalian cells. Current methods of apoptosis assessment typically require specialized equipment and reagents, which limits wide adoption. Here, we describe a rapid, inexpensive, and easy-to-perform assay in yeast for the analysis of late-stage apoptotic features in cells treated with a chemical. We describe a protocol for assessing loss of cell survival and changes in the nucleus. We demonstrate the approach by using acetic acid and hydrogen peroxide as test chemicals. This assay for the study of late-stage apoptotic features in *S. cerevisiae* can be performed reliably and rapidly by any laboratory with basic equipment and may be extended for studying apoptosis in similar single-cell organisms after treatment with toxicological agents

Keywords: *Saccharomyces cerevisiae,* DAPI staining; acetic acid; apoptosis; fluorescence microscopy; hydrogen peroxide

634V **AVITI nucleic acid sequencing and its application** Jianhua Luo[1], Silvia Liu[2], Yanping Yu[1] [1]Pathology, University of Pittsburgh, [2]University of Pittsburgh

DNA sequencing is a critical tool in modern biology. Over the last two decades, it has been revolutionized by the advent of massively parallel sequencing, leading to significant advances in the genome and transcriptome sequencing of various

organisms. Nevertheless, challenges with accuracy, lack of competitive options and prohibitive costs associated with high throughput parallel short-read sequencing persist. Here, we conduct a comparative analysis using matched DNA and RNA short-reads assays between Element Biosciences' AVITI chemistry and Illumina's NextSeq 550. Similar comparisons were evaluated for synthetic long-read sequencing for RNA and targeted single-cell transcripts between the AVITI and Illumina's NovaSeq 6000. For both DNA and RNA short-read applications, the study found that the AVITI produced significantly higher per sequence quality scores. For PCR-free DNA libraries, we observed up to a 10-fold lower experimentally determined error rate for using the AVITI chemistry compared to the NextSeq 550. For short-read RNA quantification, both AVITI and the NextSeq 550 demonstrated comparable accuracy. With regards to synthetic long-read mRNA and targeted synthetic long read single cell mRNA sequencing, both platforms' respective chemistries performed comparably in quantification of genes and isoforms. The AVITI displayed a marginally lower error rate for long reads, with fewer chemistry-specific errors and a higher mutation detection rate. These results point to the potential of the AVITI platform as a competitive candidate in high-throughput short read sequencing analyses when juxtaposed with the Illumina NextSeq 550.

635V **Rareinsight: a collaborative rare disease report generator empowering clinicians and patients** Kimberly C Coetzer[1], Olaitan Awe[2,3] [1]Biomedical Sciences, Stellenbosch University, [2]African Society of Bioinformatics and Computational Biology, [3]University of Ibadan

The scarcity of knowledge surrounding rare diseases underscores the critical necessity for collaborative research efforts to unravel their complexities and improve diagnostic and therapeutic outcomes. This research introduces RareInsight, an effort focused on developing an open-source, interactive dashboard tailored for clinicians and patients. Its primary objective is to transform the interpretation of genetic variant data into flexible and detailed reports, aiming to ease rare disease diagnosis and research.

RareInsight will be designed to process genetic variant data into customizable, interactive reports. These files are preferably generated by nf-core's raredisease pipeline as it employs some level of filtering and prioritization from whole genome or whole exome sequencing data. The resulting VCF files will be used as input into the dashboard which is equipped with advanced filtering options, statistical analysis capabilities, and diverse export formats, empowering users to explore detailed data and seamlessly collaborate with peers for further analysis and interpretation. The final interactive dashboard will be developed using Shiny and tested using rare disease data from esteemed sources such as the Undiagnosed Disease Program and NHGRI GREGOR Consortium datasets found in dbGaP.

By encapsulating clinical relevance, genetic implications, ACMG classification, and essential resources within these reports, RareInsight will aid in informed decision-making for both clinicians and patients. Employing visual aids such as charts and graphs will further enhance comprehension and clarity. RareInsight will eliminate the proprietary limitations often present in existing tools. By adopting an open-source environment, it strives to encourage transparency and customization tailored to specific clinical or research requirements. The dashboard will also prioritize stringent data privacy and security measures to ensure the protection of sensitive genetic data.

Overall, this dashboard thrives on collaboration, by allowing researchers and clinicians to seamlessly share and collaborate on reports, fostering knowledge exchange and enriching the collective understanding of rare diseases. In essence, RareInsight is poised to redefine rare disease diagnosis and research by inviting collaboration and innovation to enhance healthcare outcomes in an open-source format.

636V **Resource-explicit interactions in spatial population models** Samuel Champer[1], Bryan Chae[1], Benjamin Haller[1], Jackson Champer[2], Philipp Messer[1] [1]Computational Biology, Cornell University, [2]Center for Bioinformatics, Peking University

Continuous-space population models can yield significantly different results from their panmictic counterparts when assessing evolutionary, ecological, or population-genetic processes . However, the computational burden of simulating spatial models is typically much greater than that of panmictic models due to the overhead of determining which individuals interact with one another and how strongly they interact. Though these calculations are necessary to model local competition that regulates the population density, they can lead to prohibitively long runtimes. Here, we present a novel modeling method in which the resources available to a population are abstractly represented as an additional layer of the simulation. Instead of interacting directly with one another, individuals interact indirectly via this resource layer. We find that this method closely matches other spatial models , yet can increase the speed of the model by an order of magnitude, allowing the simulation of much larger populations. Additionally, models structured in this manner exhibit other desirable characteristics, including more realistic spatial dynamics near the edge of the simulated area, and an efficient route for implementing more complex heterogeneous landscapes.

637T **Metabolic-based Polyclonality in Genetically-induced Intestinal Tumors** Pierre S Delamotte CNRS - I2BC

Cancers are usually considered of monoclonal origin, i.e arising from a unique cell, and their energy metabolism considered to rely on glucose fermentation to lactate and not on mitochondrial respiration. Either characteristics have been challenged by a number of studies. The goal of the present study is to decipher tumor metabolism and to demonstrate polyclonality using a Drosophila midgut tumor model. These tumors are induced at a chosen time and express GFP. They result from the loss of the tumor suppressor Apc (Adenomatous polyposis coli) and express an oncogenic form of Ras(RasV12). These two genetic events are typically found in human colorectal cancers. Here, we generated fly lines to evaluate the role of metabolic enzymes in those tumors and to follow their polyclonality based on a metabolic heterogeneity. We showed by cytometry that glycolysis, lactic fermentation, mitochondrial respiration, fatty acid synthesis, neoglucogenesis and glutamin-dependant anapleurosis are necessary to tumoral growth. We observed in microscopy that tumors are always formed by several clones and display a metabolic diversity. Furthermore, single cell RNAseq reveals several clusters of metabolically distinct tumor cell subpopulations. Finally, recent live imaging, both using flybow and biosensors suggests a high motility of the already metabolically-specialized tumor clones. The hypothesis, based on these results, is that several clones from different midgut locations have to associate and cooperate to ensure complementary metabolic functions. Demonstrating mandatory polyclonality in tumors, that are systematically generated with the same genetic modifications, will bring a novel vision to adapt to each cancer type the appropriate therapeutic treatment.

638T **Characterization of bacterial dynamics within the *Caenorhabditis elegans* intestine** Andrew N Moore, Justin Ellis, Erin Nishimura, Jessica Hill Biochemistry and Molecular Biology, Colorado State University

The gut microbiome is a key regulator of health, modulating various aspects of host physiology such as immunity and metabolism. However, our understanding of fundamental processes underlying interactions between the gut microbial community and host cells remains incomplete. *Caenorhabditis elegans* is an attractive model organism for studying host-microbe interactions in the gut, featuring stereotyped development of a 20-cell intestine which lacks an adaptive immune system. Previous work has profiled the natural microbiome of the nematode using 16S rRNA analysis, and a core microbial community of 12 bacterial strains known as CeMbio is available for studies of the *C. elegans* microbiome. Here, we characterize the spatial dynamics of bacterial colonization in the intestinal lumen of JUb66 (*L. amnigena*, a CeMbio community member) as both a monoculture and as a part of the CeMbio community. We transformed the CeMbio community members using a mini-Tn7 insertion system to create RFP reporter bacteria. We then fed *C. elegans* these bacteria to image using fluorescence microscopy and processed the images using tools from WormBiome Viewer to determine bacterial spatial patterning in the intestinal lumen. We found that JUb66 preferentially colonizes the mid to posterior region of the intestinal lumen as a monoculture, while its localization shifts primarily to the middle with reduced abundance as part of the community. This suggests that coordination of the microbiome and colonization by specific bacteria or a simplified bacterial community may not be finely localized to select intestinal cells throughout the intestine, but rather to larger regions of the intestine. In comparison, *E. coli* (OP50), the standard lab diet, showed similar spatial preference throughout the intestinal lumen but displayed decreased abundance when compared with JUb66, suggesting a reduced ability to colonize the host. Overall, these data provide a glimpse into whether bacteria maintained within the *C. elegans* intestine display spatial preference. Together, this system allows for future experiments which modulate the host transcriptome to observe effects in the microbiome and is a first step in understanding the underlying mechanisms of microbiome selection and maintenance.

639T **WormCat 2.0 defines characteristics and conservation of poorly annotated genes in *Caenorhabditis elegans*** Amy K Walker[1], Daniel Higgins[2] [1]Program in Molecular Medicine, UMASS Medical School, [2]PMM, UMASS Medical School

In today's post-genomic era, we know that most metazoans genomes encode around 20K genes. It is striking that nearly half of these genes are sparsely annotated, and many others are described by domain conservation. This profoundly biases gene enrichment studies, as the most well studied pathways have the most annotations per gene and limits studies into less well understood systems. For example, of 621 C. elegans transcription factors, the top 20 account for 40% of papers and have more than 2X the number of GO terms per gene.

We developed WormCat, a gene categorization tool for identifying and visualizing enrichment in genome-scale data, which depended on a custom annotation of the C. elegans genome. The WormCat annotation strategy differed from GO in two major ways. First, each gene received a single nested annotation with broad to more specific functions. These categories were based on physiological function, molecular or location-based category. Second, genes with little associated information were placed in a specialized category, UNASSIGNED. This allows poorly annotated genes (PAGS: UNASSIGNED and domain-based categories, such as TRANSMEMBRANE DOMAIN) to be tracked in transcriptomic experiments. We noted that nearly half the genes expressed in neurons or intestine from published studies were poorly annotated. One hypothesis is lineage specificity; however, we find that PAGs may have orthologs outside of C. elegans, which also lacked functional characterization. We find several indications that some of these genes may be amenable to functional characterization, such as phenotypes in large scale RNAi screens, which suggest functional testing has not been saturated. Using WormCat to interrogate a wide variety

of published RNA seq data, we also find that UNASSIGNED genes may be enriched in specific tissues or stress conditions, suggesting response to specific regulatory cures. In order to classify these understudied genes, we are using machine learning tools to cluster PAGs with genes of known function for detailed phenotyping studies. Conserved but functionally uncharacterized genes may function outside the lab environment, contain redundant functions, or support robustness. Many -omics studies depend on pathway analysis or previous annotation to select genes for functional analysis. Developing tools to improve functional gene annotation is critical for evaluating -omics data and identification of the most biologically relevant candidates for future study.

640T **A comparative study of piRNA evolution in *Drosophila simulans*.** Prakash Narayanan[1], Sarah Signor[2] [1]North Dakota State University, [2]Biological Science, North Dakota State University

Transposable elements (TE) are selfish genetic elements, capable of replicating themselves in a host genome. In germ cells TE replication is repressed by a special class of non-coding small RNA called piRNA, which originate from discrete loci in the genome called piRNA clusters (piCs). These loci harbor remnants of TEs that play an important role in defense against TE invasion. While there are many studies that have clarified the transcription and specification of piRNA clusters, little is known about the evolution of piRNA clusters. The two popularly proposed models of piRNA cluster evolution are the 'de novo' and 'trap' models. The 'de novo' model suggests that a newly inserted active TE can be transformed into a piRNA cluster by the production of small amounts of cognate piRNA. This new TE insertion turned piRNA cluster will prevent future invasions of the particular sequence of TE. The 'trap' model proposes that large evolutionarily conserved piRNA clusters act as traps for TEs, thus a TE invasion is stopped when one invading TE copy jumps into the piRNA cluster at random , leading to the cluster producing piRNAs. This ability of the cluster remains for long-term and hence piCs can produce more piRNAs that stop future invasion of related TEs . Recent evidence suggests that piRNA clusters evolve along a continuum of these models with aspects of each in *Drosophila melanogaster*. However, in *Drosophila simulans* , the model organism we are interested in studying, we see different patterns in piRNA cluster evolution compared to *D. melanogaster*. For example, only few classes of TEs seem to nucleate the formation of piRNA clusters in *Drosophila melanogaster. In contrast*, a large variety of classes of TEs seem to nucleate piRNA clusters. PiRNA production is more diffuse than in *D. melanogaster*, and we see more aspects of the *de novo* model in general. A common factor shared between the species seems to be that many piRNA clusters are genotype-specific. Overall our study looks to bring an evolutionary perspective to piRNA clusters, this will help us to understand what is necessary for TE suppression, what is expendable, and how TE suppression system evolve in response to new invasions.

641T ***m6A* patterns are consistent across different *Drosophila* datasets and regulates alternate splicing** George Boateng-Sarfo[1], Lijuan Kan[2], Sarah Signor[3], Eric Lai[2,2] [1]Genomics, Phenomics and Bioinformatics, North Dakota States University, [2]Developmental Biology Program, Memorial Sloan Kattering Cancer Center, [3]Biological Science, North Dakota States University

Methylation of adenosine at the *N*-6 position (m^6A) is the most common internal RNA modification in eukaryotes. It has been hypothesized to play significant biological roles including alternate splicing, RNA decay, neural function, and sex determination. However, there are many artifacts in m^6A data that potentially preclude these conclusions. Here, we are developing an atlas of m^6A from publicly available data. We mapped m^6A genomic regions in wild-type and knocked-out samples of Whole fly, Head, Neuron, Neuroblast, Schneider cells (S2 cells), and Embryo samples. Each dataset is assessed for quality and excluded from the meta-analysis if the data collection was flawed. The included datasets are cross-referenced to identify artifacts affecting m6a calling. Using this approach we have identified a number of different patterns in m^6A data that alter some of the existing conclusions about RNA modifications. First, we have found that in Drosophila m^6A modifications are primarily enriched in the 5' Untranslated Regions (5' UTR). Second, we showed that m^6A modification patterns do not vary significantly across samples or tissue although biological roles and mechanisms vary. We finally provide an atlas that represents the distribution of m^6A across the epitranscriptome of varying tissues. In conclusion, we show that m6A is significantly enriched in 5'UTR of flies compared to mammalian cells although the methylome pattern is consistent across different datasets.

642T **The *Drosophila melanogaster* microbiome is modified by parasitic nematode infection** Raymond Yau[1], Ioannis Eleftherianos[2] [1]Biological Sciences, George Washington University, [2]George Washington University

The gut microbiome is found in the gastrointestinal system and provides its host with health advantages, particularly by controlling immunological homeostasis. The fruit fly *Drosophila melanogaster* is a vital model for studying the microbiome due to the availability of genetic resources and procedures. To understand the importance of microbial composition in shaping immune modulation, it is imperative to investigate the functional role of the microbiota through parasitic infection. To achieve this, we use entomopathogenic nematodes (EPN) of the genus *Steinernema* which exhibit remarkable ability to swiftly and efficiently infect a diverse array of insect species, facilitated by the mutualistic bacteria found within their gut. *Steinernema carpocapsae* forms an obligate mutualistic association with the Gram-negative bacteria *Xenorhabdus nematophila*, which is an excellent model to study pathogen infection processes and host anti-nematode and antibacterial immune

responses. *Steinernema hermaphroditum* harbors the mutualistic bacteria *Xenorhabdus griffiniae* and this nematode produces hermaphrodites in the first generation and males and females in the second generation. This study aims to examine the microbiome changes in *D. melanogaster* larvae in response to *S. carpocapsae* and *S. hermaphroditum* nematode infection. For this, *D. melanogaster* late second to early third instar Oregon-R larvae were exposed separately to *S. carpocapsae* TT01 and *S. hermaphroditum* CS34 in 96 well plates using our standard EPN infection assay. We have found that *S. carpocapsae* infective juveniles are more pathogenic to *D. melanogaster* larvae compared to the closely related *S. hermaphroditum*. Our preliminary analysis also indicates substantial changes in the size and composition of the *D. melanogaster* larval microbiome during infection with EPN nematodes compared to the uninfected controls. The obtained results serve as a foundation for succeeding studies to elucidate the EPN-specific effector molecules that alter the *D. melanogaster* microbiome and understand the role of the microbiome in regulating insect anti-nematode immune processes.

643T **R-loop formation at transposable and repetitive elements in *Drosophila melanogaster* ovaries** Timothy J Stanek, Adam Kneebone, Weihuan Cao, Christopher E Ellison Genetics, Rutgers University

R-loops are three-stranded nucleotide structures consisting of a DNA:RNA hybrid and a displaced ssDNA non-template strand. Originally viewed as byproducts of transcription, R-loops are now recognized as important regulators of gene expression and genomic stability. Persistent dysregulation of R-loop maintenance can result in replication stress, DNA double-strand breaks, and chromosomal rearrangements that contribute to diseases such as neurological disorders and cancer. However, the full scope of R-loop-mediated contributions to genomic instability have not yet been explored.

Aberrant activation of transposable elements (TEs) has been a well-documented source of genomic instability and disease, including their insertion into genes and their imposition of epigenetic effects on nearby loci. However, the extent to which their disruptive effects involve concomitant or subsequent formation of R-loops remains unknown.

Here we used DNA:RNA immunoprecipitation followed by high-throughput sequencing (DRIP-seq) to map the R-loop profiles of *D. melanogaster* at TEs and repetitive DNA elements. To ensure detection of *cis* R-loops at active TEs, we performed DRIP-seq in the germline of control and *rhino* knockout flies, whose loss of piwi-interacting RNA (piRNA) expression results in derepression of TEs. We observe that R-loops form primarily in LTR-type retrotransposons from the Gypsy family, which contain DNA sequence motifs favorable to R-loop formation. Moreover, derepression of TEs in $rhi^{-/-}$ ovaries correlates with R-loop formation, with *rhi*-induced R-loops forming primarily in the LTR region of specific LTR-type TEs. In the Drosophila Genetic Reference Panel (DGRP), polymorphic copies of these same R-loop-forming TEs show reduced frequencies compared to non-R-loop forming TEs, suggesting they are under increased purifying selection, potentially due to detrimental effects of R-loop formation on genome stability. We also detect significant R-loop formation at many satellite repeats, yet in contrast to TEs, *rhi*-induced changes in satellite expression appear to occur independently of R-loop formation. Collectively, these results reveal a specialized relationship between TE expression, TE activity, and R-loop formation.

644T **Transcriptome Analysis of the Effects of Loss of ft and Deletion of Conserved Domains in Imaginal Wing Disc** Nattapon Thanintorn[1], Cole Julick[1], Jannette Rusch[1], Megan Glaser[1], Yonit Tsatskis[2], Yi Qu[3], Hongtao Zhang[3], Hyunseo Oh[4], Helen McNeill[1] [1]Developmental Biology, Washington University School of Medicine, [2]Cell Biology, The Hospital for Sick Children, [3]Lunenfeld-Tanenbaum Research Institute, [4]University of Toronto

During animal development, Fat (Ft), an enormous cadherin with extracellular domains of 32 cadherin repeats, contributes to precisely controlled organization at the cellular and tissue level by regulating growth of a tissue and establishing orientation of cells within the tissue. Drosophila Fat and its human ortholog FAT4 share 6 highly conserved cytoplasmic regions. Loss of *ft* in flies leads to pupal lethality, massive overgrowth of imaginal discs, and loss of planar cell polarity in tissue. Mutations in FAT4 in human causes cancer and Van Maldergem and Hennekam syndromes. Extensive studies from our group and others revealed that *ft* can reduce tissue overgrowth via the Hippo signaling pathway. However, little is known about how the critical regions of *ft* contribute to mechanisms in growth control and cell polarity. We have used an extensive CRISPR-based mutagenesis of Drosophila Ft to dissect Ft function *in vivo*. Here we present transcriptome analysis of CRISPR-based mutagenesis of Ft in imaginal wing disc. Understanding how Fat regulates tissue growth and organization will generate new hypotheses to better understand how mutations of Fat cause human diseases.

645T **Roles of Transposable Elements in rewiring 3D genome architecture** Harsh Girish Shukla, Grace Yuh Chwen Lee Ecology and Evolutionary Biology, University of California, Irvine

The entirety of an organism's genetic material needs to fit into a very tight space in the cell nucleus. Understanding the underlying principles for the intricate 3D folding of genetic material is of utmost importance since it influences a wide variety of genome functions. This study aims to investigate the contribution of transposable elements (TEs) in shaping this 3D nuclear architecture. TEs are genomic parasites that promote their own spread at the expense of host fitness. In concert, the host

has evolved a variety of mechanisms to suppress this selfish behavior, in particular, the enrichment of suppressive repressive marks, such as H3K9me2/3. These marks enriched at TEs oftentimes spread into adjacent regions, including genes, turning the TE local regions into an island of heterochromatin within euchromatin. Previous studies have shown that H3K9me2/3-enriched regions, including TEs, in the euchromatin can spatially interact with pericentromeric heterochromatin (PCH) even though large linear distances might separate them. In Drosophila populations, most TE insertions are polymorphic, and many of them are found in few individuals. We thus hypothesize that this polymorphic nature of TEs can drive polymorphic 3D nuclear structure through their spatial interactions with PCH. To test our hypothesis, we generated Hi-C libraries for two inbred D. melanogaster strains. In order to mitigate mapping biases arising from using a single reference, we generated reference quality assemblies using highly accurate Pacbio HiFi for these two strains. The assemblies have a more complete representation of PCH regions than the current Drosophila reference. We developed a novel computational method to rescue some of the multi-mapped HiC reads originating from the highly repetitive PCH and derived normalized PCH-contact frequencies to compare homologous alleles with and without TE insertions between the two strains. Our analysis indeed identified TE-adjacent regions showing significantly more frequent interactions with PCH than the TE-free homologous allele. We are in the process of identifying biological attributes, such as type of TEs and H3K9me2/3 enrichment level, that make these regions more likely to be in 3D contact with PCH. Our investigation will reveal how TEs contribute to varying 3D genome organization, paving the way for further in-depth studies investigating their functional effects.

646T **Activity of a *Drosophila teissieri* I-element retrotransposon in *D. melanogaster*** Denise Clark, Lauren Miller Biology, Univ New Brunswick

I-elements are non-LTR (long terminal repeat) retrotransposons found in Drosophila species. Like human LINE1 elements, they have an internal promoter and two open reading frames encoding an RNA-binding protein (ORF1) and an endonuclease/ reverse transcriptase (ORF2). The binding of human LINE1 ORF1 protein (ORF1p) to RNAs other than its own can lead to gene duplications (retrocopies). Retrocopies can then evolve into either functional genes or pseudogenes. Although retrocopies have been detected in *D. melanogaster*, it is not known if I-element activity contributes to their production. Notably, the piRNA pathway typically represses I-element activity in *D. melanogaster*. However, crosses between females lacking I-elements (responder strain) and males with I-elements (inducer strain) can produce sterile F1 females that have elevated I -element transposition—a phenomenon known as I-R dysgenesis. Moreover, I-element de-repression can occur in Drosophila interspecific crosses. Earlier research showed that a *D. teissieri* I-element transformed into a *D. melanogaster* responder strain could transpose and induce I-R dysgenesis.

Our interest lies in further understanding I-element activity in the germline, particularly its potential role in retrocopy generation. To this end, we cloned a *D. teissieri* I-element (*Dt-I*), revealing a 99% similarity to an element isolated by others. We generated both epitope-tagged *HA-ORF1* and non-tagged transgenes to study expression, activity, and localization in the *D. melanogaster* female germline. We found the full-length untagged *Dt-I*, transformed into the responder strain w^K, is transcribed and capable of transposition, demonstrating its functional autonomy. The expression of HA-ORF1p in oogenesis, in the context of a full-length I-element, localizes to oocytes during stages 2-10 of egg chamber development, consistent with previous studies. *nanos-GAL4*-induced HA-ORF1p expression, without the context of the full-length I-element, is similarly localized. To determine if HA-ORF1p binds to its own RNA and other RNAs during oogenesis, as observed with LINE1 ORF1p in human cells, we conducted RNA immunoprecipitation (RIP) followed by next-generation sequencing. The RIP using an anti-HA antibody showed specific enrichment for *HA-ORF1* RNA compared to input RNA and non-specific antibody RIP. Collectively, these findings suggest that transport of *D. teissieri* ORF1p to the oocyte is specifically accompanied by its own RNA.

647T **High-throughput transposition analysis of hybrid dysgenesis in *Drosophila virilis* using Oxford nanopore sequencing** Ekta Mohanty, Chris Stillman, Justin Blumenstiel Ecology and Evolutionary Biology, University of Kansas

Transposable elements (TE) are genetic parasites that can cause DNA damage and genome instability by replicating themselves within the host genome. To study the genomic causes and impacts of transposition we use hybrid dysgenesis (HD) in *Drosophila virilis* as a model. HD is a phenomenon of sterility that occurs when a TE family present in the paternal genome, but absent in the maternal genome, becomes activated in the germline. If a female lacks a particular TE family in her genome, she is unable to provision corresponding piRNAs to her offspring. In the absence of these piRNAs, TEs from this paternally inherited family become mobilized in the germline, causing chromosome breaks and dysgenesis. Unlike other syndromes of hybrid dysgenesis, the *D. virilis* syndrome is associated with mobilization of multiple TE families. It is not clear if this joint mobilization is driven through the same mechanism (lack of maternal piRNAs) or whether the activation of some TEs triggers the activation of others. To characterize the global transposition profile during hybrid dysgenesis in *D. virilis*, we are employing Oxford nanopore sequencing. In our first pass, we used pooled sequencing of backcross progeny to identify new TE insertions. We are now developing an approach that uses single flies to characterize both insertions and excisions to compare transposition rates in the germlines of flies under dysgenic and non-dysgenic conditions. This transposition analysis will be

performed to further determine if piRNA asymmetry is globally predictive of transposition rates and what explains variation in the transposition rate across individuals.

648T **Live Imaging Analysis of Akirin/NuRD Complex Interactions During Cardiac Development** Ariana Craft[1], Belle Lea[2], Scott Nowak[2] [1]Cellular and Molecular Biology, Kennesaw State University, [2]Kennesaw State University

Congenital heart disease is one of the most widely reported human congenital malformations, yet the exact genetics behind this spectrum of maladies remains unknown. The severity of heart defects can range from minor to severe, with some of the most severe cases being deformed or missing heart valves. Previous studies have identified the conserved nuclear protein Akirin as an important yet relatively unstudied regulator of gene expression for cardiac development. Our data suggests Akirin works with the Nucleosome Remodeling and Deacetylase (NuRD/CHD) complex to effectively control the cardiac developmental program. We are currently conducting an analysis of genetic interactions between akirin and components of the NuRD/CHD complex. Our data indicates that akirin genetically works with several components of this multiprotein complex including MTA-like to properly regulate the cardiac gene expression program during development. Using a combination of fixed and live microscopic imaging techniques, we have determined that these interactions are critical for proper cardiac function in akirin mutants.

649T **Long-range spatial interactions of transposable elements impose trans epigenetic effects** Yi Gao, Grace YC Lee Ecology and Evolutionary Biology, University of California, Irvine

The spatial organization of the genome plays a critical role in gene regulation and genome stability. However, highly abundant selfish genetic elements, transposable elements (TEs), can challenge the integrity of such spatial organization. TEs copy and move themselves to other genomic positions, which could disrupt functional elements while contributing to genetic variation. Due to the disruptive nature of TEs, eukaryotic hosts evolve strategies to epigenetically silence euchromatic TEs by enriching them with repressive epigenetic marks, particularly H3K9me2/3. Recent studies across eukaryotes reveal that the repressive epigenetic marks can spread from euchromatic TEs into adjacent genes and perturb gene expression. In addition, H3K9me2/3 enriched euchromatic TEs were shown to be involved in long-range spatial interactions with the pericentromeric heterochromatin (PCH) domain through phase separation mechanisms. Building upon these observations, we hypothesize that TEs' spatial interactions with PCH domains will drive the silencing of both homologous alleles throughout the genome. This is because of the somatic pairing of the homologous chromosome, which can lead to both homologous alleles coming into contact with the PCH domain through TE-PCH spatial interactions. Thus, TEs could impose "trans-silencing" effects on both homologous alleles even when they are present in only one of the two homologous chromosomes. To test the presence of our proposed trans epigenetic effects, we crossed two DSPR founder lines that have distinct TE insertion profiles to generate F1 with heterozygous TE insertion sites. We performed CUTnTAG on the embryo to assay genome-wide H3K9me3 enrichment levels on the parent-offspring trio. We are currently developing approaches to identify evidence of trans-epigenetic effects by comparing the epigenetic states of parental homozygous TE insertion with the F1 heterozygous TE insertion site. We will also perform transcriptome analysis to test if such trans-epigenetic effects result in trans-silencing. Our study will provide new insight into how the epigenetic silencing of TEs may have inadvertent harmful consequences not only in cis but also in trans. Moreover, if true, this TE-induced trans-silencing should be incorporated to study how TEs shape the evolution of the genome landscape.

650T **Extending the GENCODE long non-coding RNA catalogue in human and mouse** Adam Frankish[1], Toby Hunt[1], Jose Manuel Gonzalez[1], Silvia Carbonell-Sala[2], Gazaldeep Kaur[2], Jonathan Mudge[1], Roderic Guigó[2] [1]EMBL-EBI, [2]Centro de Regulación Genómica

The GENCODE consortium produces detailed reference annotation of all human and mouse protein-coding genes, pseudogenes, long non-coding RNAs (lncRNAs) and small RNAs. Accurate gene annotation is of fundamental importance for genome biology and clinical genomics; annotation that is incorrect or incomplete impacts downstream analysis and introduces potentially significant errors.

As part of the consortium's efforts, the CapTrap-seq protocol has been developed to achieve reliable end-to-end production of long-read RNA sequences using both PacBio and ONT platforms. Combining CapTrap and oligo(dT) priming to detect 5'-capped, full-length transcripts with the Capture Long Seq (CLS) method's targeted capture of putative lncRNA transcription, we have been able to identify more than 100,000 novel human and mouse lncRNA transcripts. These highly accurate transcripts are then integrated into the GENCODE geneset via a manually supervised computational pipeline.

These significant efforts to expand the GENCODE catalogue of full-length lncRNA transcripts in human and mouse support both intra- and inter-species analysis giving additional insights into the biology of lncRNAs.

The GENCODE genesets are the default Human and Mouse annotation used in the Ensembl and UCSC genome browsers and can be downloaded from www.gencodegenes.org.

651T **Mouse Regulatory Regions and Their Alleles and Sequence Variants at MGI and The Alliance** Laurens G Wilming, Sophia Zhu, Paul Hale, Richard Baldarelli, Joel Richardson, Cynthia Smith, Carol J Bult MGI, The Jackson Laboratory

The role of regulatory regions, such as enhancers, silencers, locus control regions, and imprinting control regions, in genetic networks is subject to increasing interest. To gain more insight into the role of these elements in the complex gene expression networks guiding normal development and disease, researchers are targeting regulatory sequences through genetic engineering to study natural variation and disease association. Mouse Genome Informatics (MGI) at The Jackson Laboratory has imported mouse regulatory region data from Ensembl and the VISTA enhancer database to assist the community in their efforts. The more than 365,000 imported regulatory region markers, named as *Rr* followed by a sequential number (*e.g. Rr123456*), are classified into five categories: enhancers, promoters, promoter flanking regions, CTCF-binding sites, and transcription factor binding sites. In addition to these imported putative regulatory region markers, we manually curate regulatory markers in these categories and more (*e.g.* insulators, silencers, ICRs, LCRs, *etc.*) based on reports in scientific publications. Regulatory region alleles are annotated to the coordinates of the associated allele's underlying molecular sequence variation (deletion, point mutation, *etc.*) where possible. The regulatory region markers and associated allele records are available from MGI (**www.informatics.jax.org**) and from the Alliance of Genome Resources (Alliance) (**www.alliancegenome.org**), where the associated allele genome sequence variants are also available. Examples we will discuss include regulatory elements associated with the *Sox10* gene and the *Klr* the *Hox* gene clusters.

Funded by HG000330 and HD102534

652T **Improving annotation of introgressions in the laboratory mouse using the Collaborative Cross** Sam Ardery[1,2], Anwica Kashfeen[1], Paul Cotney[1], Colton L Linnertz[1], Md Taksir Hasan Majumder[1], Martin T Ferris[1,3], Fernando Pardo-Manuel de Villena[1,4] [1]Department of Genetics, University of North Carolina-Chapel Hill, [2]Program in Genetics and Molecular Biology, University of North Carolina-Chapel Hill, [3]Systems Genetics Core Facility, University of North Carolina-Chapel Hill, [4]Lineberger Comprehensive Cancer Center, University of North Carolina-Chapel Hill

An introgressed sequence is a region of the genome transferred across two divergent taxa and maintained despite repeated backcrossing to the recipient species. This process introduces contiguous regions of a higher-than-average amount of genetic diversity that show an ability to exchange DNA between taxa, or hybridization Analysis of these regions can be used to date this genome exchange and measure the selective forces maintaining the introgression. Introgressions can be identified by scanning the genome for regions with phylogenetic histories that are inconsistent with the global phylogeny. However, this task is complicated by the dynamic nature of introgressed regions as well as challenges with technical analyses of whole-genome sequencing, making analyses of introgressions difficult in outbred populations. The mouse presents an attractive model for these studies for several reasons: their natural species ranges are known, we have extensive and detailed records of laboratory mice since the beginning of their use as a model in classical biomedical research, and we have detailed genetic/sequencing data from both wild and laboratory mouse strains. We also have ample evidence of introgressed regions in both classical inbred laboratory mouse strains, as well as in wild mouse populations. Here, we utilize whole-genome sequencing data from the Collaborative Cross (CC) mouse population to improve our annotation of introgressed genome regions of the mouse genome. We take advantage of our recently described methodology for identification of endogenous retrovirus (ERV) insertions that segregate within the CC population. ERV insertion is a type of mutation which has attributes that are complementary to classical single nucleotide variant (SNV) analyses. As an example, we have already refined a region on Chromosome 14 from 44 Mb to 46 Mb in NZO/HILtJ where the subspecific origin is not the canonical *M.m.domesticus*, but rather *M.m.musculus*, extending this region of introgression in NZO. As such, we can use these insertions to refine the boundaries of classically annotated introgressed regions, identify novel introgressed regions, and also better understand the extent of incomplete lineage sorting between *Mus musculus castaneous*, *M.m. domesticus*, and *M.m. musculus* subspecies of mouse.

653T **Molecular Characteristics and Computational Analysis to Investigate Genetic Diversity and its impact on Post Translational Modifications** Muhammad Saleem University of the Punjab

Various strains of Sordaria fimicola were collected from the south-facing African Slope (AS) and north-facing European Slope (ES) microsites within the Evolution Canyon valley. A comprehensive array of molecular, genetic, and in silico analyses were executed to delineate distinctive genetic markers for the purpose of investigating genetic variations and post-translational modifications. These markers encompassed two non-histone methyltransferases (EFM6 and EFM7), three histone methyltransferases (RKM1, RKM4, and Set 9), and five genes encoding industrially significant enzymes, namely endo-1,4-β xylanase, β-xylanase, carboxypeptidase, dipeptidyl-aminopeptidase (DAPD), and Serine protease endopeptidase (SP2). The

primary objective was to examine whether harsh environment accelerates the occurrence of genetic variations.
In this study, 10-kilobase genomic DNA from Sordaria strains was subjected to amplification, resulting in the identification of 32 nucleotide variations across all strains when compared to the consensus sequence. Furthermore, a total of 30 and 38 potential post-translational modification (PTM) sites, along with 10 and 7 inter-strain polymorphic sites, were predicted for AS and ES strains, respectively. In the case of EFM7, the analysis of genetic variations unveiled 54 sites leading to changes in amino acids at 16 sites spanning 9 positions in the protein sequence. Notably, the investigation predicted 67 potential sites for significant PTMs within the EFM7 domain, which could potentially enhance its catalytic activity.
Moving on to the RKM1 and RKM4 genes, seven single nucleotide polymorphisms (SNPs) were identified in the former and nine in the latter, with a subset of SNPs being unique to AS strains. A parallel trend was observed in SP2, where six polymorphic sites and 35 potential PTM sites were found in AS strains. Similarly, AS strains displayed a higher degree of genetic variation in genes associated with endo-1,4-β xylanase, β-xylanase, carboxypeptidase, and DAPD in comparison to the relatively stable ES strains. In short, this study elucidates that mutations resulting from natural genetic variations under environmental stress conditions gradually reshape the genetic composition of species, particularly in the case of Sordaria fungi at microsites. This research contributes to unraveling the mysteries surrounding the process of evolution.
Keywords: Genetic variations, Sordaria fimicola, EFMs, RKM4, Post-translational modifications (PTMs).

654T **Genome-wide overexpression screens in *Saccharomyces cerevisiae* identify novel antifungal drug-resistance mechanisms** Akriti Agrawal[1], Ina Suresh[2], Chris Jackson[2], David Gresham[2] [1]Biology, NYU, [2]NYU

Fungal infections pose a critical global health crisis, affecting more than a billion people and killing more than a million people annually. A central challenge to treating eukaryotic pathogens is the limited number of fungal-specific drug targets. Identifying the genetic basis of drug resistance is critical for devising effective treatment strategies. Previously, genome-wide studies of alleles that confer resistance to antifungals have used gene deletion collections to identify loss of function that confer resistance. However, the genetic basis of drug resistance in many clinical strains results from gain of function mutations such as copy number variants (CNVs) of the *ERG11* gene, which result in increased gene expression and resistance to fluconazole (an azole drug that interrupts ergosterol synthesis). Therefore, we screened the *Saccharomyces cerevisiae* diploid YETI collection, genome-wide mutation collection in which each gene is inducibly overexpressed, to identify genes which confer antifungal drug resistance when overexpressed. Using a time-series experimental design we quantified the fitness effect of each overexpression allele in the presence and absence of fluconazole. We identified known genes and pathways that result in increased fluconazole resistance, including multiple components of the ergosterol biosynthesis (*ERG11*, *ERG13*) and efflux pathway (*PDR5 and PDR3*). In addition, we identified several previously unknown genes that increase resistance to fluconazole revealing multiple possible mechanisms of resistance, including the oxidative stress sensors *YAP1 and MGE1*. Interestingly, we also identified genes that increase sensitivity to antifungals when overexpressed, such as *AUS1*, a sterol-importing transporter. Extension of our approach to other antifungal drugs will enable identification of common and drug-specific mechanisms of resistance.

655T **How repeats rearrange chromosomes in deer mice** Landen Gozashti, Olivia Harringmeyer, Hopi E Hoekstra Department of Organismic & Evolutionary Biology, Department of Molecular & Cellular Biology, Museum of Comparative Zoology, Harvard University

The origin and evolution of karyotypic diversity has long interested evolutionary biologists and geneticists. Large chromosomal rearrangements, such as chromosomal inversions, often underlie karyotype variability, but the mechanisms by which these rearrangements arise remains poorly understood. The deer mouse (*Peromyscus maniculatus*) is an excellent model system for studying karyotypic evolution because wild populations of deer mice display widespread variation in their number of biarmed chromosomes (indicative of large chromosomal rearrangements), yet a highly conserved total number of chromosomes. Recent work has shown that mega-base scale inversion polymorphisms underlie much of the karyotypic variability found within deer mice, including re-positioning centromeres from acrocentric to metacentric positions, raising the question of how these inversions arise within the deer mouse genome. Here, we investigate the genomic basis of deer mouse inversion polymorphisms. We first employed a combination of long-read (PacBio Hifi) and proximity ligation (Hi-C) sequencing of two F1 hybrid mice to create phased chromosome-level de novo genome assemblies for four deer mouse subspecies. Through comparisons of these genomes, we identified ~8,000 inversion polymorphisms, which together affect over 30% of the genome. We next investigated inversion breakpoints, and found that smaller inversions are often flanked by retrotransposons, suggesting they primarily arose via ectopic recombination between these retrotransposons. In contrast, the breakpoint regions of large (>1Mb) inversions are primarily enriched for segmental duplications (long repeats ranging from kilo- to mega-bases in length). Interestingly, we found evidence that retrotransposons may drive segmental duplication formation, suggesting that retrotransposons may indirectly facilitate the formation of mega-base scale inversions. Furthermore, we were interested in why inversion breakpoints often occur near centromeres. We found that pericentromeric regions exhibit a recent accumulation

of retrotransposons, which likely facilitated an expansion of pericentromeric segmental duplications. By comparing inversion breakpoints as well as fully assembled centromeres between ancestral and derived karyotypes, we highlight the evolutionary processes that give rise to intraspecific karyotypic variation with unprecedented resolution. Together, our results are consistent with a model whereby retrotransposable element activity and distribution directly and indirectly influences mammalian karyotypic evolution.

656T **Assembly and characterization of W chromosome in monarch butterfly (*Danaus plexippus*)** Martina Dalikova[1], Daniel Portik[2], Sarah B. Kingan[2], Hayley Mangelson[3], Liuqi Gu[1], James R. Walters[1] [1]Department of Ecology and Evolutionary Biology, University of Kansas, [2]Pacific Biosciences, [3]Phase Genomics

Degenerated sex chromosomes have a precedent of being notoriously difficult to assemble. Recent advances in long-read sequencing are catalyzing increases in the number and quality of W and Y assemblies, providing novel insights concerning the content and evolution of these elusive chromosomes. Here we report a novel genome assembly for the monarch butterfly (*Danaus plexippus*), focusing on the W chromosome. This species harbors a neo-Z chromosome, arising from the fusion of the ancestral Z with an autosome. Previous cytogenetic analyses indicated a similarly large and bipartite W chromosome, suggesting the possibility of a comparable neo-W, but much ambiguity remains concerning the sequence and history of the monarch W chromosome. We generated PacBio HiFi reads with Hi-C data from females to support *de novo* assemblies of maternal and paternal haplotypes using Trio binning. This produced chromosomal-level scaffolds for the Z and all autosomes. Approximately 14 Mbp of W-linked contigs from the maternal genome were identified based on male-to-female coverage and sex-specific k-mers. The W chromosome scaffold length was around 10 Mbp, thus leaving about one-third of this chromosome in unscaffolded contigs. We used this new assembly to investigate the gene and repeat content as well as population genetic diversity of the monarch W chromosome. The W is highly repetitive and contains very few protein-coding genes, which mainly arose through retroposition or segmental duplication from other chromosomes. Exons of these W-linked copies retain high sequence identity compared to their Z-linked and autosomal counterparts despite substantial divergence in intergenic regions, suggesting strong stabilizing selection on protein-coding regions for these W genes. Moreover, at least some W genes appear to be expressed in female tissues, especially ovaries. The prevalent repetitive content of the W chromosome is formed by transposable elements (TEs) from the LINE and LTR retrotransposon groups. Surprisingly, the TEs on the W chromosome have strikingly lower divergence compared to the rest of the genome, which we suggest results from gene conversion arising from TEs occurring in tandem arrays. Population genetic analyses revealed nucleotide diversity is about ten times lower on the W chromosome compared to autosomes. Finally, despite this novel W assembly, strong evidence for or against a neo-W chromosome origin remains elusive.

657T **Altered hydroxymethylation of imprinted genes in male infertility** Rajender Singh, Sujit Mohanty Endocrinology, Central Drug Research Institute

Methylation of imprinted genes has been correlated with low sperm count and motility, but since methylation analysis cannot discriminate between methylation and hydroxymethylation, the contribution of hydroxymethylation to such correlations remains completely unknown. Changes in hydroxymethylation in male infertility have not been investigated in depth. We undertook the present study to investigate changes in hydroxymethylation in male infertility. We analysed hydroxymethylation of imprinted genes in infertile cases and fertile controls. This was followed by the analysis of DNA methyltransferases (DNMT) and ten-eleven translocation methylcytosine dioxygenases (TETs) transcript and protein levels in cases and controls. In total, this case-control study used spermatozoal DNA, RNA, and protein from 135 oligozoospermic, 45 normozoospermic, and 66 fertile controls, respectively. Imprinting-controlling regions of imprinted genes were analysed for methylation using deep sequencing on spermatozoal DNA from 32 oligo/oligoastheno-zoospermic infertile patients and 20 normozoospermic fertile men. Further, hydroxymethylation analysis of the same imprinted genes was carried out using real-time PCR based on the spermatozoal DNA from 15 Normozoospermic infertile, 31 Oligo/Oligoasthenozoospermic infertile patients, and 15 Normozoospermic fertile. We observed that the hydroxymethylation level in the H19, IGF2, and LIT1 genes was significantly higher, while those of the MEST and PEG3 genes were lower in the cases in comparison to controls. Within the case groups, H19 and LIT1 hydroxymethylation showed direct correlation with sperm count, IGF2 and MEST showed direct correlation with some exceptions, and PEG3 showed inverse correlation. We also analyzed DNA methyltransferases (DNMTs) and found higher expressions of DNMT1 and DNMT3B in the cases in comparison to controls, and within the case group, DNMT1 showed an inverse correlation with sperm count. Analysis of ten-eleven translocation methylcytosine dioxygenases (TETs) showed that TETs were significantly higher in cases in comparison to controls. Within the case groups, TET1 and TET3 increased with an increase in sperm count. In conclusion, aberrant hydroxymethylation of the imprinted genes, i.e., *H19, IGF2, IGF2*, and *MEST,* correlates with reduced sperm count and fertility.

658T **A chromosome scale reference genome of house fly *Musca domestica*** Yesbol Manat[1], Perot Saelao[2], Richard Meisel[1] [1]Biology and Biochemistry, University of Houston, [2]US Department of Agriculture

Sex chromosomes play an important role in the evolution of sexually reproducing species. Studying sex chromosome evolution provides insights into broader principles of evolution, adaptation, and speciation. Investigating relatively young and undifferentiated sex chromosomes is essential for understanding how natural selection, intersexual conflict, and recombination landscapes affect the establishment of new sex chromosomes. The house fly, *Musca domestica*possesses a highly polymorphic sex determination mechanism, where the male-determining locus can be found on multiple different chromosomes. This makes it well suited system for studying the evolution of new sex chromosomes. However, the lack of a chromosome-scale male genome makes it challenging to use the house fly as a model system to study X and Y chromosome evolution. Here, we generated a chromosome scale assembly of *M. domestica* males carrying two different Y chromosomes. We used this chromosome-level genome of *M. domestica* to determine how gene content and recombination rates evolve in shortly after the formation of new sex chromosomes.

659T **Horizontal Gene Transfer in Staphylococcus Epidermis shows evidence of function of phage proteins in the bacteria** Gaurav S Arora, Matthew Thompson Gallaudet University

Horizontal Gene Transfer or HGT is the transfer of genes from one organism to another. HGT can occur between bacteria and bacteriophages. In bacteria, genes received from HGT are quickly removed unless they serve some beneficial purpose.

Prior work has found evidence of HGT of a tail tape measure protein (TMP) in bacteria. TMP occurs in tailed phages and controls the tail length of the virus.*Staphylococcus epidermis* or *S. epidermis* is a ubiquitous inhabitant of human skin and mucous membranes. Originally *S.epidermis* did not cause infections but over the years the number of infections caused by *S. epidermis* have increased.The phage that infects *S.epidermis* belongs to the *Caudovirales* order.

Using Bioinformatics tools, we show evidence of transfer of the TMP in *S. epidermis.* We also see that the protein is conserved in several strains of *S. epidermis.* RNA-seq data from published studies, show that the TMP is expressed in several of these strains.

By gaining the knowledge of conserved genetic information, further insight into the evolution of *S.epidermis* are gained. Also, it will lead to further understanding of the interaction between virus and bacteria. It may also help understand the changes that may have caused the pathogenic nature of the bacteria.

660T **Long-read *de novo* assembly and comparative analysis of six howler monkey genomes within genus *Alouatta*** Bide Chen[1], Patrícia Domingues de Freitas[2], Luana Portela[2], Victor Yunes[3], Lilian Catennacci[4], Alcides Pissinatti[5], Amy Goldberg[1] [1]Evolutionary anthropology, Duke University, [2]Federal University of São Carlos, [3]São Paulo State University, [4]Federal University of Piauí, [5]Primatology Center of Rio de Janeiro

As our closest relatives, primates are an ideal system to understand human evolution, and mechanisms generating genetic variation broadly across animals. Though only one species in the genus *Homo* exists today, multiple monkeys have wide radiations, allowing us to compare closely related species within a genus. Despite a growing number of primate genomes available, most genera are represented by a single reference genome. Here, we generate *de novo* reference assemblies using long-read sequencing for 6 Howler monkeys (genus *Alouatta*) to understand within-genus, between-species evolution. With between 9 to 14 species howler monkeys are some of the most widely distributed platyrrhines, extending from southern Mexico to northern Argentina, inhabiting a range of environments. Prior phylogenetic investigations into howler monkeys have exhibited discrepancies across studies or remained inconclusive, based on a mix of cytogenetic, morphological traits, and a restricted set of molecular markers. Attempts to address these questions have been limited because only a single poor-quality reference genome of mantled howler monkey (*Alouatta palliata*, Mexico) is currently available (assembly contig count: 1152695; N50: 51.304 Kbp). Our assemblies contain roughly ~2000 contigs, with N50 of ~15Mb and L50 of ~60. Based on phylogeny constructed with OrthoFinder, IQtree, and ASTRALL, we find the clade grouping *A. seniculus* and and *A. guariba* as sister taxa, with *A. caraya* and *A. belzebul* as respective sister lineages to this clade. We identify loci that show species-specific signatures of selection, as well as adaptive loci shared across the genus.

661T **Characterization of the Structure and Stability of Wild-Type FGF2 and Mutant Design of Wild-Type FGF2 to Enhance Wild-Type FGF2 Stability** Aisha Al-Rizzo, Suresh Thallapuranam, Patience Okoto Chemistry and Biochemistry, University of Arkansas

FGF2 is a multifunctional growth factor, part of the highly conserved superfamily of fibroblast growth factors. FGF2, along with other growth factors, belongs within a vast family of polypeptide growth factors which exhibit mitogenetic and cell proliferative properties. In the process of embryonic development, some fibroblast growth factors can play numerous roles in cell proliferation, migration, and differentiation. Other FGFs can present as homeostatic factors in adulthood, which help function in tissue repair, angiogenesis, and injury response, while other factors can present in embryonic development. FGFs

accomplish such biological and pathophysiological processes via paracrine, intracrine or endocrine signaling. FGF2 acts through tyrosine kinase receptors and exhibits cell self-renewal, cell differentiation and migration, wound healing, and angiogenesis, important properties in upkeeping homeostasis within the body. In particular, FGF2 confers its functions through paracrine signaling. FGF2 is found in embryonic and adult cell types, plays a significant role in the development and function of multiple organ systems. Furthermore, FGF2 plays roles in angiogenesis (blood vessel formation) and wound healing, which shows promise in medical applications and tissue engineering. Although promising in its potential, wild-type FGF2 itself poses issues of inherent instability, which affect its overall function. In our group, we are designing mutants of wild-type FGF2 using single point mutations to enhance FGF2 stability. By eradicating this issue, a higher stability in FGF2 can be applied to biochemical and medical industries, to name a few. For example, thermal instability wouldn't be an issue with a more stable FGF2 protein when considering external factors, such as the supply chain when transporting for further biochemical research. Thermal stability also indicates a longer shelf life, if used in medical applications. Overall, the aim of this project is to improve the stability of wild-type FGF2, a potent but unstable fibroblast growth factor, thus improving its function via experimentative methods of small-scale and large-scale expression, purification, and characterization of structure and stability. In short, the goal of the experimental design is to compare cell proliferation activity of wild-type FGF2. The ability to solve the problem of instability in FGF2 by fabricating a more stable and functional growth factor can open new doors for further research and breakthroughs in the fields of biochemistry and medicine.

662T **Unexpectedly simple and powerful relationships exist between genome composition and DNA Methylation, mRNA and Protein Expression in *Arabidopsis thaliana* rosettes** Richard Mott[1], Ziming Zhong[2], Mark Bailey[3], Yong-In Kim[4], Briony Parker[3], Nazanin Pesaran-Afsharyan[3], Kirsty Hassell[3], Gancho Slavov[5], Keywan Hassani-Pak[3], Kathryn Lilley[4], Frederica Theodoulou[6] [1]University College London, [2]Genetics, Evolution and Enviroment, University college London, [3]Rothamsted Research, [4]Dept Biochemistry, University of Cambridge, [5]IBERS, University of Aberwrystwyth, [6]Plant Sciences and the Bioeconomy, Rothamsted Research

The variation in expression across the proteome and transcriptome from a single plant tissue varies by over four orders of magnitude, despite most nuclear genes being encoded only once. The generally accepted explanation is that the observed expression of a given transcript reflects a specific balance between the rates of transcription and degradation, and that the expression of the corresponding protein is further modulated by a similar balance between translation and turnover. We set out to understand how much of variation of these omic levels within a single tissue can be explained by simple genomic features when genetic and environmental variation is absent. Specifically we investigated the impact of gene-body CpG methylation (gbM) and codon composition on these higher omic levels.

We performed detailed genomic profiling of the two *Arabidopsis thaliana* accessions Col-0 and Can-0. We re-assembled their genomes using long reads, from which we also calculated baseline gbM for each gene, and measured rosette gene and protein expression in multiple biological replicates grown under tightly controlled conditions, and which produced highly reproducible results.

We re-annotated the gene and transposon content of each assembled genome to produce accurate data across omic levels. We fitted models to explain variation in methylation, gene and protein expression in terms of lower omic levels. We find that the single best predictor of any omic level in one accession is to measure the corresponding level in the other accession, despite their 0.5% sequence divergence, and the presence of many differentially expressed genes. Looking within an accession, the impact of baseline gbM on either mRNA or protein expression can be almost entirely explained by variation in that gene's codon composition. Thus, absent environmental perturbation, gbM is determined by local sequence features.

We also find very similar impacts of any given codon on both mRNA and protein composition. These impacts are highly significant and unrelated to genome-wide codon abundance. About 44% of the variation in protein expression is explained by a combination of mRNA and sequence composition, each contributing distinct information. Codon composition alone explains 27% of protein expression and 44% of transcript variation. These statistics suggest that these simple models are important, but by no means the only, drivers of expression variation.

663T **Comparative genome analysis of *Quercus rubra* and *Q. ellipsoidalis*** Swapan Chakrabarty[1,2], Carsten Külheim[1] [1]College of Forest Resources and Environmental Science, Michigan Technological University, [2]College of Computing, Department of Computer Science, Michigan Technological University

Oaks (*Quercus spp.*) are the most abundant hardwood tree genus in the Northern Hemisphere, and they are widely distributed in the Americas, Asia, Europe, and North Africa. The rapid change in climatic and edaphic factors pose severe threats to the growth and survival of oak populations. Northern red oak (*Quercus rubra*) has a broad geographic distribution in easter North America and thrives on mesic loamy soils. In contrast, northern pin oak (*Q. ellipsoidalis*) has a narrower geographic

distribution in the Midwest of the U.S.A. and prefers more xeric, sandy sites. These related, and frequently hybridizing, species provide a model for adaptation to drier environments. Samples of *Q. ellipsoidalis* were collected from a single tree for library construction and sequencing. The whole genome *Q. ellipsoidalis* has been sequenced with PacBio long reads, Illumina short reads and Hi-C sequencing. Twelve different types of tissues were used for RNA sequencing. The BUSCO genome completeness is 98.0% with N50 of 61,697,690 bp. In this study, we compared the genome structure of *Q. ellipsoidalis* with *Q. rubra*. Synteny analysis revealed the preserved co-localization of the chromosomes between these species. Sequencing of *Q. ellipsoidalis* genome has made it possible to analyze structural variants (SVs) on a massive scale, which further gives the required knowledge to investigate SV development mechanisms and to investigate their functional impact. The genome of *Q. ellipsoidalis* provide strong fundamentals of understanding the adaptation of oaks in the environment. Our study not only introduces new genomics resources for *Q. ellipsoidalis* research but also exemplifies how structural variation drive fundamental functional discoveries in oak adaptation. We further investigated and compared the gene content of gene families related to root formation and drought adaptation.

664T **Improvements of *Xenopus* genome annotations for the Alliance of Genomic Resources and other Amphibian genomes** Taejoon Kwon[1], Malcolm Fisher[2], Christina James-Zorn[2], Andrew Bell[2], Virgilio Ponferrada[2], Ngoc Ly[2], Sergei Agalakov[3], Brad Arshinof[3], Stan Chu[3], Kamran Karimi[3], Vaneet Lotay[3], Troy Pells[3], Dong Zhuo Wang[3], Peter Vize[3], Aaron Zorn[2] [1]Biomedical Engineering, Ulsan National Institute of Science and Technology (UNIST), [2]Cincinnati Children's Hospital Medical Center, [3]University of Calgary

Two representative genomes of *Xenopus* species (*X. laevis* and *X. tropicalis*) have been completely sequenced recently. However, their genome annotations are still challenging, especially due to different versions being able from different sources (NCBI RefSeq, EnsEMBL, and JGI/UCB). Here, we present how we have integrated these widely used annotations, including their historical builds for the older version of genome sequences, to make comprehensive reference annotations for these species. To evaluate the accuracy of gene model predictions in each method and to resolve the conflict when this happens, we have developed a data-driven evaluation method that utilizes the publicly available RNA-seq and other functional genomic resources. Additionally, we compared these results to other reference species participating in the Alliance of Genomic Resources consortium so we could access higher levels of genomic resource analysis, such as phenotypes related to human disease modeling. Our efforts to improve the annotation of these two *Xenopus* reference genomes are also a valuable resource to improve the annotations of other recently sequenced amphibian genomes, not only for the other Pipidae, like *H. boettgeri*, *X. borealis*, and *X. petersii*, but also other amphibian genomes such as salamanders (*A. mexicanum* and *P. waltl*) and caecilians (*G. seraphini* and *M. unicolor*).

665T **Genetic analysis of the yeast DNA damage response with a genome-wide inducible degron library** Eduardo Gameiro[1], Jia Jun Fung[1], Brian Luke[1,2], Anton Khmelinskii[1] [1]Institute of Molecular Biology gGmbH, [2]Johannes Gutenberg University

The yeast knockout library, comprised of strains carrying deletions of individual open reading frames (ORFs), has been a vital tool to study gene function through both classical and high-throughput approaches over the last two decades. However, the knockout library is limited to non-essential genes, and must be complemented with conditional or hypomorphic alleles of essential genes for complete genome-wide studies. Furthermore, errors in strain annotation, combined with the continuous generation of spontaneous suppressor mutations, can lead to mistakes in functional annotations. To circumvent these problems, here we describe genome-wide libraries of degron alleles for inducible protein depletion.

We constructed two libraries with over 5600 essential and non-essential genes tagged with an auxin-inducible degron (AID*), and an optional fluorescent protein (FP), at the C-terminus of each ORF. The FP tag allows assessing the degradation efficiency in high throughput but substantially increases the overall tag size, with a greater chance to affect protein function. Using fluorescence measurements, we found that approximately 80% of the strains exhibited complete or partial degradation of the tagged protein in the presence of auxin. Partial degradation was more frequent for highly expressed proteins, suggesting saturation of the AID machinery. Furthermore, the efficiency of protein degradation varied between cellular compartments, and was lowest for mitochondrial, vacuolar, Golgi and ER proteins, likely due to tag accessibility. Using the non-fluorescent library, we show that over 60% of tagged essential protein alleles display a fitness defect upon induction of protein degradation. Using these libraries, we screened for DNA damage response factors. Viability screens with hydroxyurea, camptothecin and methyl methanosulfonate (HU, CPT and MMS respectively) identified essential protein alleles that are sensitive to these DNA damage drugs, opening the possibility to discover new gene functions that could not be tested with previously established libraries. Taken together, our work shows that the inducible degron yeast collection is a valuable tool to study gene function, providing mutants with a conditional and fast protein depletion, which can facilitate systematic characterization of the yeast genome.

666T **Characterization of Type II-A Anti-CRISPR Genes** Dinie Zheng, Meru J Sadhu National Human Genome Research

Institute, NIH

CRISPR-Cas systems are found naturally in bacteria as defense systems against bacteriophages. Phages have in turn evolved to have anti-CRISPRs, which are small proteins that inhibit CRISPR-Cas systems. Currently, there have been about 100 anti-CRISPRs that have been discovered, 32 of which specifically target type II-A CRISPR-Cas systems. Many anti-CRISPRs still remain to be discovered and elucidated for their mechanisms. We will seek to characterize over a thousand type II-A anti-CRISPR genes by utilizing large scale oligonucleotide synthesis to synthesize these genes to test for their ability to inhibit type II-A CRISPR-Cas systems in yeast. This research will contribute towards the understanding of anti-CRISPR function and expand upon the arsenal of existing anti-CRISPR genes.

667T **Unveiling the spectrum of potential hosts for SAR-CoV-2 using a high-throughput yeast display screen.** Mudabir Abdullah, Michael Chambers, Sophie Scobell, Meru Sadhu NHGRI, National Institute of Health

The global impact of SAR-CoV-2 extends beyond humans, raising concerns about potential reservoirs and broader implications for disease transmission in various animal species. Understanding the virus's behavior necessitates a comprehensive assessment of its potential host range. Central to this inquiry is the angiotensin converting enzyme 2 (ACE2), the primary attachment site for SARS-CoV-2 spike protein, which exhibits substantial variability among species. The ability of the spike protein to interact with ACE2 receptors in potential animal hosts emerges as a pivotal determinant for host compatibility. In this study we use a high-throughput assessment of ACE2 compatibility with coronavirus spike proteins across hundreds of diverse animal species. The interface of ACE2 with the spike protein exhibits high amino acid diversity between species, influencing the potential binding of spike orthologs. Previously it was shown that the main spike interacting region on the surface of ACE2 involve amino acids from 24-83 and 329-363. To elucidate these interactions, we constructed a library of chimeric ACE2 receptors representing various species orthologs in the ACE2 region crucial for interfacing with SAR-CoV-2 spike protein. We printed an oligo array of DNA molecules containing these segment ACE2 orthologs representing 821 species and clone them into a backbone of the human ACE2 gene. The chimeric ACE2s libraries are transformed into yeast expressing the ACE2 protein on its surface.

These chimeric ACE2 receptors are expressed via yeast surface display and subsequently incubated with fluorescently labeled SAR-CoV-2 spike proteins. The spike-binding ACE2 chimeras are enriched through fluorescence-activated cell sorting (FACS) and identified through high-throughput Illumina sequencing. This approach enables the exploration of whether SARS-CoV-2 variants have altered host range, offering insights into the future dynamics of SAR-CoV-2 host compatibility. This investigation is pivotal in discerning whether the host range will remain consistent or evolve into a subset of the original potential hosts.

668T **Chromatin Structure in the *Ogataea polymorpha* Species Complex** Tiffany Lundberg[1], Daniel Turevski[2], Andrew Klocko[1], Sara J Hanson[2] [1]University of Colorado-Colorado Springs, [2]Colorado College

Three-dimensional chromosome organization and chromatin structure are critical to the regulation of eukaryotic genome function. In budding yeasts, the mechanism for heterochromatin formation underwent a transition in which the Clr4-mediated histone H3 lysine 9 methylation mechanism found in multicellular eukaryotes and the fission yeast *Schizosaccharomyces pombe* was lost and the expanded Sir2 histone deacetylation mechanism observed in *Saccharomyces cerevisiae* was gained. However, the mechanism for heterochromatin formation in yeast species that diverged after the loss of Clr4 heterochromatin formation but prior to the expansion of the Sir2 pathway are less understood. One such species is the methylotrophic yeast, *Ogataea polymorpha*. To gain insights into chromatin structure of constitutively heterochromatic and euchromatic regions of the genomes of two members of the *O. polymorpha* species complex, we used chromatin immunoprecipitation-sequencing (ChIP-seq) to examine histone post-translational modifications and chromosome conformation capture coupled with high-throughput sequencing (Hi-C) to assess three-dimensional genome organization in two members of the *O. polymorpha* species complex.

669T **Educational Resources Hosted at the *Saccharomyces* Genome Database** Rob Nash[1], Suzi Aleksander[1], Marek S. Skrzypek[1], Jodi Lew-Smith[1], Rahi Navelkar[2], Edith D. Wong[1], Stacia R. Engel[1], J. Michael Cherry[1], The SGD Project[1] [1]Genetics, Stanford University, [2]Department of Biomedical Informatics, Harvard University

The *Saccharomyces* Genome Database (SGD; http://www.yeastgenome.org) is the leading community resource for the budding yeast *S. cerevisiae*. SGD provides high-quality, manually curated information on the yeast genome and offers a wide variety of tools and features that make it an indispensable resource for researchers. SGD engages in a variety of online training and educational outreach efforts to inform our user community about new developments, to improve familiarity with SGD features and tools, and to increase public awareness of the importance of yeast not only for biological and biomedical research but also for instructional purposes.

The SGD community wiki (https://wiki.yeastgenome.org) provides users with a venue for accessing and sharing information in areas that include educational resources. This includes information about associations and societies, general and yeast specific classroom materials (teaching modules and project-based courses), and some fun sites of general interest to the aspiring biologist.

To inform the community about new features and tools, SGD creates and posts short videos to YouTube (https://www.youtube.com/SaccharomycesGenomeDatabase) as a means to both educate our users and address their questions. This includes videos on how to use tools like: YeastMine, Variant Viewer, GO Term Finder, GO Slim Mapper and JBrowse, as well as videos to support users interested in navigating phenotypes, interactions, expression data, literature, homologs, human-disease connections and functional complementation.

SGD is also working with micropublications.org to promote the publication of brief, novel, technically sound research results and data that don't fit into full-length articles. This includes single high-quality research results as well as negative results that will accelerate scientific discovery and advance the scientific endeavor. This mechanism for publication is particularly attractive for students interested in rapidly publishing findings of general interest to the greater scientific community. Micropublications are indexed at PubMed, PubMed Central and Europe PMC for greater visibility.

We will continue to develop these services to provide access to educational resources and outreach for students, teachers, and scientists to facilitate greater use and understanding of the resources made available by SGD. This work is supported by a grant from the NHGRI (U41 HG001315).

670T **Transcription associated mutations in haploid and diploid yeast** Rutuja M Gupte, Nathaniel Sharp Genetics, University of Wisconsin-Madison

The highly transcribed regions of the genome are thought to be more susceptible to mutations. Such mutations are called transcription associated mutations (TAM) which can occur through multiple mechanisms. Strand separation due to helicase action during transcription exposes the non-transcribed strand and introduces the possibility of the formation of a 3 stranded R loop in the non-transcribed strand which is highly vulnerable to damage or formation of secondary structures. Processes such as supercoiling promote R loop formation. Transcription associated recombination is also a possibility when there is a head-on or co-transcriptional collision between DNA and RNA polymerase. Head-on collisions, which are more detrimental, occur on the lagging strand.

TAM results in rapid changes in the genome. A positive correlation has been observed between transcription and mutagenesis in introns. These mutations are associated with DNA damage, action of topoisomerase 1, RNA-DNA hybrids, T to U base conversions, stress etc. While these processes persist in bacteria as well as higher eukaryotes, the present study focuses on TAM in yeast.

We are studying the mutation and replication data from ancestor and mutation accumulation lines from a mutation accumulation experiment in haploid and diploid *Saccharomyces cerevisiae*. We are combining mutation, replication and transcription data and also making comparisons between haploid and diploid lines. This study will utilize the available Nascent Elongating Transcript Sequencing (NET Seq) data of the strains used that captures differential transcription rates for rapidly degrading transcription products. This sequencing method uses the stability of the DNA-RNA-RNAP ternary complex and involves sequencing of transcripts from the 3' end. Preliminary analysis of this data indicates that in haploids, which have a higher SNM rate, SNMs are associated with a higher transcription rate which is not true for diploids. Indels are associated with higher transcription rates in both cell types.

This study will provide insights into the repair mechanisms and their effectiveness in the highly transcribed regions, present a comparative analysis of transcription and mutations in coding as well as non-coding regions of the genome and can shed light on the variation in mutation detection across the genome.

671F **Genetic Interactions Between the Gut Microbiota and *C. elegans* Intestinal Cells** Jessica Hill[1], Andrew Moore[2], Justin Ellis[3], Sabrina Zhi[4], Izabella Mastroianni[5], Erin Nishimura[3] [1]BMB, Colorado State University, [2]BMB, Colorado Sate University, [3]BMB, Colorado state university, [4]University of Guam, [5]NIAID

The human gastrointestinal tract is home to trillions of microorganisms which dynamically comprise our gut microbiome. Alteration to our gut microbial community leads to disease. At the forefront of host-microbe interactions are intestinal cells, which establish and maintain beneficial symbiotic relationships with our gut microbiota. *However, how intestinal cells differentiate between symbionts and non-symbionts is unknown. Furthermore, which intestinal cell responses promote symbiont selection in the gut is unclear.* To understand how the intestine responds to distinct bacteria and bacterial

communities, we first generated transcriptional profiles of the whole intestine for *Caenorhabditis elegans* exposed to *E. coli* OP50 (standard lab diet), *Pseudomonas aeruginosa* PA14 (pathogen), and the CeMbio community (simplified, curated microbiome). We found that nearly 5,300 genes differentiate L4 worms exposed to the CeMbio community versus OP50 (2365 up and 2966 down regulated). Notably, pathways involved in muscle regulation and cytoskeletal processes were upregulated in worms exposed to CeMbio compared with OP50 exposed worms, while energy production and biomolecule synthesis pathways were downregulated. Interestingly, worms exposed to CeMbio prior to challenge with the pathogen PA14 displayed less dynamic changes in total gene expression (3.2% increase and 5.4% decrease) compared with worms exposed to OP50 prior to PA14 challenge (6.7% increase and 9% decrease). This is suggestive of a protective effect by the CeMbio community. Next, to characterize the baseline patterns of intestinal colonization for OP50 and the CeMbio community, we made fluorescent reporter strains of each. We found that live bacteria could be observed throughout the intestine, but that both OP50 and the CeMbio community shared a preference for the mid to posterior regions of the intestine. Suggesting that these regions offer a more hospitable yet non-selective environment for hosting bacteria. Future work will investigate the gene regulatory networks that either encourage or discourage colonization of bacteria in specific intestinal regions. Overall, these data begin to explain how intestinal cells interact with and respond to gut bacteria. Reciprocally, they also shed light on how different bacteria and bacterial communities respond to intestinal outputs.

672F **Elucidating the population genetics of structural variants with 79 chromosome-level long-read genomes of Drosophila melanogaster** James Hemker[1], Bernard Kim[2], Paul Schmidt[3], Dmitri Petrov[2] [1]Developmental Biology, Stanford University, [2]Biology, Stanford University, [3]Biology, University of Pennsylvania

With recent advancements in long-read sequencing, it is now possible to sequence and assemble extremely high-quality, long-read Drosophila genomes at an affordable price and with limited work, such that one lab can generate many assemblies. We used Oxford Nanopore Technology and Illumina sequencing to generate chromosome-level, hybrid assemblies of 79, highly-inbred *Drosophila melanogaster* strains from Pennsylvania. We leveraged our de novo assemblies to find large (>35bp), novel structural variants (SV's) that are otherwise missed due to reference-mapping biases. SV's have been largely overlooked and poorly studied, especially in non-human population genetics, and existing studies have primarily relied on reference-based SV mapping. We present population genetic analyses on insertions, deletions, inversions, duplications, and TE events, as well as experimentally-validated case studies on adaptive SV's with large effects on fitness and phenotype.

673F **Effects of Nickel on the Gut Microbiome of *Drosophila melanogaster* in multiple genetic backgrounds** Jesse D Petahtegoose, Allie Hutchings, Thomas Merritt Natural Sciences, Laurentian University

The gut microbiome, GMB, community, the suite of microbes inhabiting a digestive system, reflects the host diet and physiology and in many ways can be considered a host phenotype. Interactions are, however, bidirectional with metabolites and metabolic byproducts shared with and between the microbiome and the host. The host genotype and sex impacts physiology and metabolism, defining the environment the GMB finds its collective self in, and may, therefore, also affect the GMB community structure. Results from other labs are, however, split with some studies finding an impact of host genotype and sex on community structure and others concluding that community structure is determined solely by environmental factors. This study is directly testing the impact of sex and genetic background on GMB community variation driven by nickel toxicity using the Drosophila melanogaster system.

A previous study in our lab showed that exposure to a nickel contaminated diet impacted the D. melanogaster GMB community. Interestingly, results indicated an interaction effect between sex Ni concentration on the community structure, suggesting that the impact of sex is likely to be complex. This early study only included a single line of flies, so the potential impact of genetic background was not tested. A current experiment is testing the impact of nickel across multiple genetic backgrounds and both sexes.

How substantial is the relationship between the host and its GMB, i.e. how much of an effect does one have over the other? In addition to a better understanding of the complexity of GMB changes in response to nickel stress, we will further examine the relationship between GMB and host physiology and metabolism. In part, we will explore this relationship by reconstructing the Ni GMB composition in flies that have not been exposed to nickel and assaying for fly physiological responses. Across a range of phenotypic tests do flies with a Ni microbiome mimic the phenotypes of true nickel exposed flies? Through these experiments, we are not suggesting that the microbiome changes are the main drivers of the phenotype changes from nickel exposure, but we are attempting to find the relationship between host and microbiome.

674F **Epigenetic Control of DNA Replication During Early Drosophila Development** Karla I Troncoso, Aaron T Crain, Robert J Duronio Biology, University of North Carolina at Chapel Hill

To duplicate large genomes during the short cell cycles characteristic of early animal development, cells initiate replication

at thousands of origins throughout the genome. Although the machinery and regulatory mechanisms that govern DNA replication are conserved across eukaryotes, metazoan genomes are distinguished by not using DNA sequence to specify origins of replication. Rather, origin specification and replication initiation is thought to be controlled by the local chromatin environment, which is largely modulated by post-translational modifications (PTMs) on histone N-terminal tails and the interplay between the proteins that establish and bind to these modifications. The 20th lysine in histone 4 (H4K20) can be mono-, di-, or tri- methylated. H4K20 monomethylation (me) has been implicated in DNA replication by analyzing mutations of the enzyme responsible for establishing this mark, SET8. A limitation to this approach is that SET8 has non-catalytic functions and non-histone substrates. Consequently, phenotypes observed from the perturbation of SET8 cannot be solely attributed to the loss of the histone PTM. To delineate the individual contributions of SET8 and the H4K20me mark we engineered a single arginine-to-proline substitution mutation within the highly conserved catalytic domain of SET8 that is predicted to render the enzyme catalytically inactive. Drosophila homozygous for this mutation ($SET8^{RP}$) exhibit full viability, unlike a null allele which causes lethality during larval development. While $SET8^{RP}$ females are able to lay eggs, the embryos never hatch. This phenomenon is called maternal effect lethality and indicates a defect in the first phase of embryogenesis, which is governed exclusively by maternally deposited mRNA and protein and characterized by rapid and synchronous cycles of DNA replication and mitosis that occur in a syncytium and exert substantial demands on the process of replication. We found that embryos from $SET8^{RP}$ mothers exhibit severe morphological defects, developmental delays, and defects in DNA replication. Surprisingly, this essential role for SET8's catalytic activity in S-phase progression appears to be independent of the establishment of the H4K20me mark.

675F **What Role Does Brain Tumor Gene, brat, in Drosophila melanogaster Play In Hybrid Dysgenesis from P-element Transposition** An T Bui, Erin Kelleher University of Houston

Transposable elements (TEs) are parasitic-acting DNA that move, causing DNA damage and mutations that lead to genome instability and cell death. *P*-elements in *Drosophila melanogaster* are widely studied, and in an uncontrolled state, DNA damage resulting from *P*-element mobilization causes a sterility syndrome called hybrid dysgenesis. Hybrid dysgenesis occurs when a naive female mates with a male carrying *P*-elements, resulting in sterile offspring. The degree of dysgenic germline loss depends on the activity of *P*-elements, which in turn is determined by host cofactors required for the transcription and translation of *P*-element transposase. However, these host cofactors are rarely known for *P*-elements or other TEs. Previously in the lab, QTL mapping of natural variation in dysgenic sterility identified a QTL peak that includes *brat*. Brat is an RNA binding protein that determines the differentiation of cystoblasts in the female germline via translational repression of Mad and Myc. Since *P*-elements transpose predominantly in the premeiotic germline, including cystoblasts, Brat could regulate transposition directly or could determine the response of germline cells to the harmful effects of transposition. To differentiate between these alternatives we tested dysgenic sterility in multiple *brat* alleles, compared the transposition rate of *P*-elements via a singed weak assay, and quantify the splicing of *P*-elements and its isoforms with Reverse-Transcriptase Quantitative PCR(RT-qPCR). In a dysgenic cross, heterozygotes for multiple *brat* alleles exhibit higher levels of sterility compared to their wild-type siblings, indicating that *brat* function may be a repressor of *P*-elements or dysgenic sterility. In contrast, from the excision assays, *brat* shows no significant effect on *P*-element transposition. However, results from RT-qPCR data may shed some light on the contrasting results between the dysgenic data and the excision assays. Collectively, these findings will deepen our understanding on how host cofactors interact and regulate its parasitic TE invasions.

676F **Histone 4 Lysine 20 mutation Increases Mitotic Recombination in Drosophila** Priscila Santa Rosa[1], Jeff Sekelsky[2], Bob Duronio[2] [1]Genetics and Molecular Biology, University of North Carolina at Chapel Hill, [2]University of North Carolina at Chapel Hill

Mitotic recombination (MR) is an important DNA repair mechanism; however, in some instances, it can lead to loss of heterozygosity (LOH) or chromosomal rearrangements. LOH is believed to be one of the first genetic events to initiate cancer, and it has been linked to cancer progression and aggressiveness. Although LOH via MR is a hallmark of many types of cancer, the biological mechanisms responsible for MR are not completely understood. MR occurs in a context of chromatinized DNA which is regulated by post translational modifications (PTMs) of histone proteins. These histone PTMs are very dynamic and play important roles in genomic processes, however, it is unknown whether the chromatin state dictated by these histone PTMs affects MR frequency. One such histone PTM is the methylation of histone 4 lysine 20 (H4K20) which is involved in several biological processes, such as DNA replication, gene expression/repression, DNA repair, and chromatin compaction. H4K20 is mono-methylated by PR-Set7/Set8 in humans and flies and can be further modified by SUV4-20H1 (di-methylated), and SUV4-20H2 (tri-methylated) in humans; however, in flies Hmt4-20 performs both di and tri-methylation. In Drosophila, mutation of the H4K20 residue to prevent its PTM or the knockout of its mono-methyltransferase, Set8, increases DNA damage in late-replicating regions of the genome leading to cell cycle arrest. Additionally, in human cells the di-methylated form of H4K20 is essential for DNA repair and DNA repair pathway selection. Using *Drosophila melanogaster* and modern molecular

techniques, this project will test how changes in chromatin structure resulting from loss of H4K20 PTM affect MR events. Preliminary data show that flies heterozygous for H4K20R or H4K20A mutation had a significant increase in MR events when compared to wild-type flies (WT). Because MR events in H4K20 mutants occurred in pericentric regions, I am now performing DNA sequencing to test the hypothesis that these events occurred within heterochromatin. This project will provide insights into how chromatin state plays a role in MR events leading to LOH and potentially advance cancer treatment research.

677F **High-quality annotation of model organism genomes from NCBI's RefSeq project** Shashikant Pujar, Tamara Goldfarb, Alex Astashyn, Olga Ermolaeva, Diana Haddad, John Jackson, Vinita Joardar, Vamsi Kodali, Kelly McGarvey, Mike Murphy, Anjana Raina, Craig Wallin, David Webb, Francoise Thibaud-Nissen, Terence Murphy National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health

National Center for Biotechnology Information's (NCBI) RefSeq project aims to provide a comprehensive, high-quality, non-redundant set of annotations, including transcripts, proteins and genomic DNA. RefSeq provides annotation of model organisms included in the Alliance of Genome Resources (AGR), including annotations for mouse, rat, zebrafish, and Xenopus generated through a combination of curation and NCBI RefSeq's Eukaryotic Genome Annotation Pipeline (EGAP). Expert curation includes review and refinement of structural annotation of known RefSeqs (NM_, NP_, NR_ accessions) as well as descriptors for transcripts, proteins and genes. Much of the curated content is based on user-provided data archived in NCBI's databases, data from external databases and from peer-reviewed publications. Curators in the RefSeq group are also involved in targeted annotation of specific genes and gene-families in collaboration with subject experts. Additionally, we provide specialized sequence products to facilitate basic and applied research. The Consensus coding sequence (CCDS) collaboration provides a core set of high-confidence coding regions for human and mouse. RefSeq Select is a dataset containing a representative transcript for all genes in human, mouse and rat, which is useful in applications that require only one transcript per gene. Overall, curation results in high quality annotation and metadata, which in turn informs future automated annotations as well as better ortholog calls. This presentation will provide data on the high-quality automated annotations of Alliance genomes and provide examples of how curation improves whole genome annotation. This work is funded by the National Center for Biotechnology Information of the National Library of Medicine, National Institutes of Health.

678F **Drosophila as a model for precision toxicology** Shannon Smoot[1], Tank Eisman[1], Sophie Fleck[1], Thomas Kaufman[1], John Colbourne[2], Joe Shaw[1], Brian Oliver[3], Jason Tennessen[1] [1]Indiana University, [2]University of Birmingham, [3]NIDDK, NIH

Global industries are rapidly producing and releasing tens of thousands of chemicals, yet the effects of these molecules on environmental and human health are inadequately understood. This lack of knowledge, coupled with current mammalian testing methods that are both expensive and time-consuming, leaves a dangerous knowledge gap that must be addressed using inexpensive and high-throughput models. The fruit fly *Drosophila melanogaster* has emerged as an ideal system for studying the mechanisms by which individual chemicals alter animal behavior, physiology, metabolism, and gene expression. In this regard, *Drosophila* studies are uniquely situated to quickly identify the molecular targets of individual toxicants via the use high-throughput multi-omics and an unparalleled genetic toolkit. Here we demonstrate the power of this approach by analyzing adult male and female flies fed acute doses of sodium arsenite. By using a combination of transcriptomic and metabolomic methods, we identified a series of dose-dependent effects on metabolic pathways and gene expression networks. Our analysis revealed that sodium arsenite exposure not only activates metabolic and stress-related pathways that are known to protect flies against the toxic effects of this metal, but we also uncovered previously undescribed sex-specific responses. Notably, we observed significant changes in the expression of genes involved in oogenesis and seminal fluid protein expression, indicating that sodium arsenite significantly affects gamete formation and function. Consistent with this observation, we demonstrate that both males and females fed sodium arsenite exhibit decreased fecundity and morphological changes in both the ovary and male reproductive system morphology. Overall, our findings demonstrate how *Drosophila* can serve as a powerful model to identify the sex-specific genetic and metabolic response to toxicant exposure when applying a multi-omics approach.

679F **Functional analysis of candidate Drosophila genes involved in aged host responses to Flock House virus infection** Madelyn Buhl[1], Lakbira Sheffield[2], Stanislava Chtarbanova[3] [1]Biological Sciences, The University of Alabama, [2]University of Alabama Birmingham, [3]University of Alabama

Compared to young adults , aged individuals exhibit greater susceptibility and higher mortality rates to infections caused by viruses, as highlighted by the recent COVID-19 global pandemic. With a growing aging population worldwide, there is an urgent need to better understand the interactions between viruses and their aged hosts in order to improve survival outcomes. *Drosophila melanogaster* is a valuable model for the studies of both innate immunity and aging, and can be used to model aged host-virus interactions. Previously we have shown that FHV infection results in significantly higher mortality in aged flies compared to young flies regardless of sex, and likely because of impaired disease tolerance to infection. We also

demonstrated that older flies mount qualitatively distinct transcriptional responses to FHV than younger flies. Here, using 150 lines from the *Drosophila* Genetic Reference Panel (DGRP) we show that the age-dependent response to FHV infection has a genetic basis, leading us to hypothesize that variations in the genome associate with age-dependent survival of FHV. A genome-wide association study (GWAS) using these lines identified 36 *loci* respectively with a discovery p-value <1E-05, variations of which associate with age-dependent survival of FHV. Among these, 16 *loci* correspond to genes with human orthologs. Here, we are testing whether a causative relationship exists between candidate genes' expression levels and the response to virus infection with aging. Using the GAL-4/UAS system and RNAi, we are ubiquitously knocking down (KD) these candidates and comparing survival of FHV between young and aged flies and controls of both sexes. For one gene, *CG33143*, our preliminary results show that the aged KD females outlive both young KD females and controls following infection with FHV. These results were not seen in the male KD flies pointing to sex-specific effects. Currently we are measuring viral loads in experimental and control flies, with the goal to determine whether expression levels of *CG33143* impact survival outcomes via modulation of disease resistance or tolerance to FHV infection.

680F **Annotation and Phylogenetic Analysis of STUB1 and Sdr Across *Drosophila* Species** Reese Saho, Jennifer Cifranic, Annie Richters, Jamie Siders School of Science, Technology, and Mathematics, Ohio Northern University

The insulin signaling pathway is a highly conserved regulatory pathway across animal species due to its involvement in metabolism and cellular growth and development. There are over 70 different genes known to be involved in the insulin signaling pathway (ISP), notably the insulin receptor protein. However, dysfunction in any of these genes can lead to the development of diabetes, which occurs when the body fails to produce enough insulin (Type I) or insulin receptors do not properly respond to the insulin that is produced (Type II). This results in an inability to regulate blood sugar levels in the body, which can contribute to weight gain and the development of diabetic ketoacidosis. Diabetes decreases the quality of one's life at any age, making it critical to investigate all facets of how the ISP functions and how it has evolved into such a critical and robust network in animals. The Genomics Education Partnership (GEP) is specifically interested in investigating how the location of a gene within the complex architecture of the ISP influences its rate of evolution. Using a comparative genomics approach, the GEP is systematically annotating all of the genes in the insulin signaling pathway across 28 *Drosophila* species. It is hypothesized by the GEP that genes that serve as hubs, which interact with several other genes in the pathway, evolve less quickly than spokes, which interact with relatively few genes. The current work annotated 2 genes, *Sdr* and *STUB1*, across 16 species each in the *Drosophila* genus. Annotation of *Sdr* and *STUB1* using the UCSC genome and subsequent phylogenetic analysis using MUSCLE alignment suggests that Sdr may be more variable than *Sdr*, despite the fact that *Sdr* is suspected to interact with more products in the ISP than *STUB1*.

681F **Integrating multi-omics datasets across diverse species to characterize the effects of genetic variation** Heidi S Fisher[1], Gaurab Mukherjee[1], Jason A Bubier[1], Alexander Berger[1], Robyn L. Ball[1], Erich J. Baker[2], Elissa J. Chesler[1] [1]The Jackson Laboratory, [2]Belmont University

The accumulation of genomic, genetic, and epigenetic data from diverse experimental systems and model species presents significant challenges and opportunities for integrating these complex datasets. Collectively these data provide a powerful resource for researchers to both identify genomic features that are associated with phenotypic variation and to functionalize the role of genetic variants within molecular pathways and disease related networks. Here we show the integrated capabilities of two open-access web-based tools to explore, compare and contrast heterogenous genetic and genomic datasets across species. GeneWeaver is both a curated data repository and a platform to analyze and harmonize gene sets from various sources and divergent experimental systems. Recent upgrades include a transition to a cloud-based infrastructure to increase efficiency, improvements to the data model to allow batch uploads from multiple sources, including public data archives, and expanded features to reflect multiple data scores and potential sources of bias. VariantGraph is a new graph database that efficiently connects genetic variants and regulatory features to orthologous target genes across humans and model systems to enable the identification of variants in potentially non-conserved sequence that have conserved, context specific gene regulatory effects. Using streaming technology and database batch import, VariantGraph extracts large-scale relationships among datasets by parsing the data sources and building relational databases. We present the utility of these tools by exploring the genetic basis of a complex behavioral phenotype, opioid use disorder, by integrating genomic data from human populations with extensive genetic and transcriptomic data from model organisms. Together, GeneWeaver and VariantGraph allow users to efficiently connect and traverse complex genetic datasets from multiple sources, ingest new data, and interact with existing datasets for a variety of multi-omics approaches.

682F **GenomeMUSter: A uniformly dense comprehensive mouse variation analytical resource for genomic analyses** Robyn L Ball, Hongping Liang, Molly A Bogue, Vivek M Philip, Elissa J Chesler The Jackson Laboratory

In recent years, a subset of diverse mouse strains including the Collaborative Cross, BXDs, and the classical inbred strains have undergone whole genome sequencing providing dense variant sets that can be used in genomic analyses to identify genes and genetic variants underlying complex traits and diseases. Many other strains, including some wild-derived strains have been genotyped at varying densities. However, due to the sparsity of genotyped datasets and the disparate coverage across the genome, these data are not easily combined or readily accessible for use in analytical pipelines, such as GWAS meta-analysis. We created GenomeMUSter (https://muster.jax.org), a web- and programmatically-accessible data service that includes observed and imputed allelic states for 657 strains across 106.8M segregating sites. Sixteen variant datasets were merged and harmonized. Missing allelic states were imputed using a data-driven approach that incorporates *local* phylogenetic distance. The median strain-specific imputation accuracy on a 'held-out' test set was 0.944, interquartile range [0.923, 0.991]. As a uniformly dense analytical resource, GenomeMUSter provides the genomic foundation for genetic and genomic analyses, such as identifying genes and variants related to complex disease through cross-trait cross-population GWAS meta-analyses and prioritizing mouse backgrounds for pre-clinical studies. Funding provided by NIH DA037927, DA028420 and by The Jackson Laboratory, The Cube Initiative Program Fund.

683F **Affordable short-read genome assembly allows diverse downstream genetic analyses on non-model fishes** Eric Garcia[1,2], Roy Roberts[3], Brendan Reid[4], Rene Clark[4], Jem Baldisimo[2], John Whalen[2], Abner Bucol[5], Ivan Lopez[2], Malin Pinsky[3], Kent Carpenter[2], Chris Bird[1] [1]Texas A&M University-Corpus Christi, [2]Old Dominion University, [3]University of California Santa Cruz, [4]Rutgers University, [5]Silliman University

Many genetic analyses require or are improved by utilizing a reference genome for the focal organism. However, given that producing the long-read data that is traditionally used in the assembling process remains expensive, we still lack genomic information for the great majority of non-model species. Here, we test the performance of four commonly used tools (ABySS, HipMer, SOAPdenovo, and SPAdes) in generating short-read *de novo* assemblies from eight marine fish species with contemporary and historical samples (collected over 100 ya) available. We demonstrate that assemblies with high values for N50 and BUSCO Complete and Single Copy are possible using only short-read data, and highlight a case study where this type of assemblies can later be used in combination with capture and lcWGS to investigate the loss of genetic diversity in marine fish populations from the Philippines as a result of anthropogenic impacts (overfishing and habitat degradation). Overall, successful genome assembly from short reads allows for a large suite of downstream genetic analyses from contemporary or museum specimens, and represents a new paradigm for studying non-model organisms, especially for large-scale projects, programs monitoring genetic diversity, or studies with limiting resources.

684F **Modified Mechanisms of Chromosome inheritance in the Trioecious Nematode *Auanema rhodensis*** Liesl G Strand[1], Pablo M Gonzalez de la Rosa[2], Sally Adams[3], Mark L Blaxter[2], Andre Pires da Silva[3], Anne M Villeneuve[4] [1]Developmental Biology, Stanford University, [2]Tree of Life, Wellcome Sanger Institute, [3]School of Life Sciences, University of Warwick, [4]Departments of Developmental Biology and Genetics, Stanford University

Auanema rhodensis is an unusual three-sexed nematode species in which XX females, XX hermaphrodites, and XO males co-exist in natural populations. *A. rhodensis* also exhibits unusual patterns of sex chromosome inheritance, driven in part by alterations of the oogenic meiotic program that result in the production of haplo-X oocytes in females, but nullo-X oocytes in hermaphrodites. We set out to explore the mechanisms underlying this meiotic variation by examining the cytological distribution of histone modifications associated with active and repressive chromatin, which revealed that *A. rhodensis* displays distinct patterns of germline and chromosome organization during meiotic prophase that diverge from those found in the well-studied Caenorhabditis genus. Notably, sex chromosome organization in both hermaphrodites and females appears distinct from the autosomes, with the X chromosomes being highly enriched for the repressive chromatin mark H3K9me3. Despite enrichment for this repressive mark, however, the X chromosomes appear much larger than the autosomes during diakinesis, when chromosomes condense in preparation for the meiotic divisions. This finding was unexpected based on the previously-published *A. rhodensis* short-read genome assembly, which had indicated an X chromosome half the size of autosomes. The basis of this discrepancy became clear following a new genome assembly derived from accurate long-read sequencing and Hi-C data, which revealed that roughly half of the genome is composed of extensive multimegabase blocks of repetitive DNA that are eliminated from the somatic genome during development. Using FISH probes targeted to germline-specific and somatic-retained repeat sequences, we have established that programmed DNA elimination (PDE) in somatic cells occurs subsequent to the 8-cell stage, with germline-specific repeats becoming largely restricted to apparent germline founders by the 16-cell stage and clearance of micronuclei containing eliminated DNA by the 64-cell stage. We have also used FISH to confirm the unusual patterns of meiotic sex chromosome inheritance inferred from the genetic data and to demonstrate lack of chiasmata between X chromosomes in hermaphrodite oocytes. We are intrigued by the possibility that the large repetitive chromosomal regions maintained in the germline may play structural or functional roles that contribute to the atypical segregation patterns observed during spermatocyte and oocyte meiosis.

685F **Optimal thresholds for variant impact prediction in human genes appear to depend on selection** Brynja Matthiasardottir[1,2], Stephen Mount[1], Daniel Kastner[2] [1]CBBG, University of Maryland, [2]Inflammatory Disease Section, NIH, NHGRI

Immunological disorders caused by dysregulation of the immune system include allergy, asthma, autoimmune diseases, autoinflammatory syndromes and immunological deficiency syndromes. The identification of over 450 genes underlying human immunological diseases has revolutionized our understanding of innate and adaptive immunity and provided the basis for life-saving therapies. However, the diagnostic yield of patients suffering from these disorders remains low, and many variants of uncertain significance (VUS) occur in known immune genes.

We find that validated pathogenic variants in these genes often score below standard thresholds for several tools that predict variant impact, which suggests a high false negative rate. Most methods for variant impact prediction apply the same model to all genes and assume that conservation positively correlates with functional importance. These methods have been trained using known variants in ClinVar. Variants associated with immune diseases are underrepresented in ClinVar, so it might be that existing mutation pathogenicity prediction tools are not well-suited to these genes. We find that the optimal accuracy thresholds for binary classification of variants associated with autoinflammation, found in the Infevers database, are lower than those for validated variants in ClinVar (0.324 vs. 0.65 for REVEL and 17.24 vs. 20.0 for CADD; this same trend is seen for ten other predictors).

We speculate that this difference is due to the nature of selection on these genes, with episodes of strong selection for increased inflammation due to pathogen exposure balanced by selection for reduced inflammation otherwise. In support of the hypothesis that strong but variable selection is responsible for the difference in thresholds, we verified that many genes with either extreme iHS or Fst scores are involved in immunity. Furthermore, variants in the top iHS and Fst decile of genes that are in ClinVar also show significantly lower thresholds for optimal accuracy.

Our study provides evidence that optimal variant curation guidelines may depend on the history of selection for each gene. We are exploring the relationship between measures of selection and optimal accuracy thresholds further and developing a new method of variant effect prediction that accounts for this.

686F **Pharmacogenomic Profiling of the Mu Opioid Receptor Reveals Mechanisms of Opioid Resistance in Human Patients** Ping Guo[1], Alexander Sebastian Hauser[2], Tao Che[3], Justin English[1] [1]Biochemistry, University of Utah, [2]University of Copenhagen, [3]Washington University in St. Louis

The mu opioid receptor (OPRM1) is the molecular target of opioid analgesics, first line therapies for the treatment of pain. While their therapeutic potential remains unmatched, opioids are also fueling a substance use disorder epidemic in the United States and across the world, with estimates of opiate misuse approaching 60 million individuals in 2021. However, the experience of individuals consuming opiates varies widely, from euphoria and nausea to individuals that experience no analgesia whatsoever. We hypothesized that this variability in patient response may be encoded directly in the many unstudied missense variants of OPRM1. We therefore characterized how the ten most common, but understudied, missense variants of OPRM1 (>1/10,000 individuals) altered the molecular pharmacology of these important drug targets. This study revealed multiple variants that significantly disrupt normal receptor function, including a mechanism for how one variant acts as a dominant negative receptor in heterozygote individuals, inhibiting all opioid activity in human patients. In addition, our work establishes a model for identifying and characterizing missense mutations that augment the pharmacology G-protein coupled receptors, the most commonly targeted gene family for FDA approved drugs.

687F **Evolutionary Origins and Mechanisms of Fish Antifreeze Protein in Unrelated Taxa: Insights into New Gene Birth** Nathan Rives, Vinita Lamba, Xuan Zhuang University of Arkansas

Understanding the origin and evolution of new genes with novel functions and the genetic mechanisms behind the emergence of new traits is challenging but crucial for unraveling nature's repertoire of evolutionary innovations. Fish antifreeze proteins, displaying remarkable examples of convergent evolution, offer valuable opportunities to investigate the genetic origins and evolutionary pathways of new genes. Intriguingly, nearly identical type I antifreeze proteins (AFPI) have been discovered in four distantly related fish taxa. This study tested the hypothesis of the potential sequence convergence beyond functional convergence of this new gene, and investigate different paths through which the same gene originate from different genomic resources. we investigate the genomic origin and evolutionary process of AFPI genes in three distinct fish lineages. We sequenced the complete genome of two AFPI-containing (AFPI+), each belonging to separate lineages. We also incorporated data from other AFPI+ species available in public databases and included AFPI-lacking (AFPI-) outgroup species for comparison. We isolated the genomic loci containing *AFPI* or homologous regions and annotated the *AFPI* to illustrate their gene structure.

By comparing the new gene and their homologous sequences in these genomes, we found that the *AFPI* in the three lineages exhibit dissimilar gene structure and their neighboring genomic regions do not share microsynteny, suggesting that AFPI independently evolved in each lineage. The *AFPI* in each AFPI+ lineage was linked to homologous regions in outgroup species that contain the ancestral sequence. Interestingly, the near-identical *AFPIs* originated from different precursor genes in each lineage. They arose from functionally unrelated precursor gene, and de novo evolved coding regions with novel antifreeze functions. This study provides an illustrative example of how novel functions arise and advance our understanding of the process of new gene formation.

688F **Identification of Genetic Biomarkers for Response to Proton Radiation Therapy in PCa Patients** Ayse B Cemek[1], Johnny Velasquez[2], Luisel Ricks-Santi[2] [1]New College of Florida, [2]University of Florida

Prostate cancer (PCa) is the most common cancer in men worldwide. In 2020, according to the National Cancer Institute, 3,343,976 men have PCa in the United States, with an estimated death rate of 34,700 and an estimated new case rate of 288,300 in 2023. Currently, the prostate-specific antigen (PSA) test is the cornerstone of PCa screening. In order to measure PSA, which is a protein that is generated by both healthy and cancerous cells of the prostate gland, blood samples are taken to test PSA levels. Even though the PSA test is the main measurement for PCa diagnostics, PSA is not PCa -specific but instead prostate gland-specific which results in many inaccurate diagnoses of PCa. Additionally, depending on the age of the individual, PSA levels can be elevated without the risk of PCa resulting in high false-positive rates. A positive PSA test is usually followed by a tissue biopsy to confirm the diagnosis of PCa. Given the heterogeneity of PCa, biopsy can be imprecise and may result in complications. These biopsies are used to stratify patients into PCa risk groups based on Gleason grade, stage, and prostate-specific antigen (PSA) levels and guides PCa treatment based on the risk for recurrence and metastases. In the era of precision medicine, there is a compelling need for more precise, minimally invasive methods, such as liquid biopsies, to improve the prediction of who may be at risk for recurrence or progression at diagnosis, during and following treatment. Liquid biopsies, which can detect nucleic acids in plasma or serum, hold great promise for determining the risk for recurrence and metastatic spread in cancer patients. For many cancers, it has been shown that increasing circulating cell free (ccf) DNA is associated with adverse outcomes. Therefore, the objective of this study was to determine whether ccfDNA quantity was associated with the PCa risk group. Our methods include isolating ccfDNA from serum, determining the quantity in each sample over time, and performing statistical analysis to determine its association with the risk group. Specifically, PCa patients who are eligible for the study volunteered to have their blood to be taken for Pre-Radiation Therapy, 2 weeks, 4 weeks, 8 weeks, and 12 weeks after the Radiation Therapy. Our result indicated increasing DNA quantity was not associated with PCa risk group.

689F **A fresh look at germline mutation rates at repetitive loci with AVITI sequencing and multi-generational CEPH pedigrees** Hannah C Happ[1], Tom Sasani[2], Taeho Kim[2], Deborah Neklason[2], Aaron Quinlan[2] [1]Human Genetics, University of Utah, [2]University of Utah

By sequencing the genomes of thousands of human and primate families, the genetics community understands the factors influencing the number of new mutations passed to offspring through sperm and egg. Human genome evolution is male biased, with 80% of new mutations in a typical child originating from sperm. Moreover, the primary factor influencing the rate of germline mutation accumulation in all primates is parental age: in humans, an average of 1.5 and 0.4 additional mutations arise per year of parental age in sperm and egg, respectively. While sperm progenitor cells divide throughout male adulthood, eggs are created while the future mother develops in utero; therefore the effect of paternal age was expected under a continued replication model of germline mutation, but the maternal effect was surprising. These findings led our group and others to detail the underappreciated role of DNA damage in the accumulation of germline mutation with parental age.

In 2019, we published the first large study of inter-family paternal age effects on germline mutation accumulation by sequencing the genomes of 603 individuals from 33 large, three-generational CEPH/Utah families. We found striking variability in the accumulation of paternal germline mutations in offspring over time. In 2021, we studied *de novo* structural variants (SVs) in the CEPH/Utah pedigrees, finding at least 0.160 new SV per genome.

Taken together, we now have a detailed picture of the factors that influence point and structural mutation. Ironically, however, nearly all studies have ignored the most mutable loci in the human genome: short tandem repeats and homopolymers. The reason for this is largely technological, as short-read sequencing technologies have an elevated error rate near repetitive sequence that overwhelms the signal of true mutations and precludes studies of short-tandem repeat and homopolymer mutation.

In 2023, Element Biosciences released the AVITI sequencing platform, which achieves a substantially lower error rate within and near homopolymers. Using this technology, we are sequencing the genomes of the same CEPH/Utah pedigrees to measure germline mutation rates at repetitive loci. We will present our ongoing analysis of mutation rates as a function of polymer

composition, length, and parental age and sex. Such foundational knowledge is critical for exploring the causes of genome mutation and applying this new technology to studies of repeat-associated human disease.

690F **Genome assembly of an expanding forest pest: Dendroctonus frontalis (southern pine beetle)** Megan Copeland[1], Adekola Owoyemi[1], Michelle Jonika[1], Shelby Landa[1], Jamie Alfieri[2], Terrence Sylvester[3], Zachary Hoover[1], Claudio Casola[1], Heath Blackmon[1] [1]Texas A&M University, [2]University of Texas, [3]University of Memphis

The southern pine beetle (Dendroctonus frontalis) is a type of wood-boring pest found in the United States. Since D. frontalis depends on host trees throughout its life cycle, this species is responsible for extensive ecological damage and economic loss in the timber industry. Although it has considerable damage potential, limited information is available regarding the genomics and genetics of this beetle. We produced a high-quality, chromosome-level genome assembly using long-read and Hi-C sequencing data. Our final assembly has a size of 174MB, 707 scaffolds, and a scaffold N50 of 24.829 MB. Our assembly confirms the conservation of the core stevens elements that have been identified in other polyphagan beetles. By delving deeper into the genetic makeup of D. frontalis, this assembly provides ciritical resources for research in functional and comparative genomics.

691F **A Chromosome-Scale Reference Genome to Study the Unusual Chromosome Biology and Gene Amplification in the Dark-Winged Fungus Gnat, Bradysia (Sciara) coprophila** John M. Urban[1], Susan A. Gerbi[2], Allan C Spradling[3] [1]HHMI Research Laboratories, [2]MCB, Brown University, [3]Carnegie Institution for Science, Dept of Embryology, HHMI Research Laboratories

The dark-winged fungus gnat, Bradysia (Sciara) coprophila, is a “lower Dipteran” fly with rich opportunities for studying chromosomal phenomena and genome theatrics. For example, there are “L” chromosomes limited to the germline, and across B. coprophila’s lifecycle there is a “chromosome cycle” featuring chromosome elimination and non-disjunction events. Chromosome imprinting, the ability of a cell to differentiate between maternal and paternal copies, was first discovered in this fly several decades ago. In the various chromosome elimination events across the chromosome cycle, it is the paternal copies that are targeted. In addition to the gains and losses of specific chromosomes, Bradysia coprophila larval salivary gland cell chromosomes polytenize to over 8000 copies in each nucleus, which becomes the template for further locus-specific gene amplification to produce hundreds of thousands of copies of targeted genes, presumably needed for a pre-pupal or pupal process. Whereas these gene products may well be part of the pupal case or cocoon, we are interested in determining if a subset of secreted products of gene amplification also play a role in the collective migratory Sciarid snake behavior observed in the wild.

To pursue such studies, we produced the first reference genome for Bradysia coprophila (Bcop_v1), a highly contiguous optical-map-scaffolded long-read assembly of the male somatic genome that contains four chromosomes (Urban et al, 2017 (https://repository.library.brown.edu/studio/item/bdr:733543/); Urban et al 2020 (https://doi.org/10.1101/2020.02.24.963009); Urban et al 2021 (https://doi.org/10.1186/s12864-021-07926-2)). Although this first reference assembly proved useful, the majority of contigs were not assigned to chromosomes nor were they in chromosome-scale scaffolds. Therefore, we updated it to resolve these weaknesses, producing Bcop_v2, which contained the first sequence models of each somatic chromosome (Urban et al, 2022 (https://doi.org/10.1101/2022.11.03.515061)). The chromosome-scale reference has enhanced our study of larval gene amplification. Although deep sequencing of salivary gland genomic DNA allowed us to identify amplified loci on more fragmented assemblies, the chromosome-scale scaffolds more readily allow us to infer to which previously known chromosomal locus each amplicon corresponds.

692F **PERCEPTIVE: a (Pipeline for the pRediCtion of EPigenetic modulaTors in noVel spEcies)** Eric M Small, Christina R Steadman Earth and Environmental Sciences, Los Alamos National Laboratory

ABSTRACT: Epigenetic marks, including histone post-translational modifications (PTMs) and the methylation of nucleic acids, have been shown to play key roles in regulating gene expression, genome stability, and chromatin architecture in model organisms. As novel species are identified and characterized, the role epigenetics may play in regulating their genomes and behaviors remains unexplored. However, given the extraordinary conservation of epigenetic mechanisms from budding yeast to humans, in many cases, it is possible to infer how gene expression, genome integrity, and chromatin are regulated in novel species by simply identifying epigenetic modulators or those proteins responsible for regulating epigenetic marks. Despite this, the cumbersome nature and species-dependent attributes (e.g., antibody specificity) of most wet-lab methodologies to study epigenetics preclude the rapid identification of epigenetic marks and epigenetic modulators in novel species. To address this problem, we have developed a one-click graphical software package: PERCEPTIVE (Pipeline for pRediCtion of EPigenetic modulaTors in noVel spEcies) that solely uses a species genomic sequence (plus transcriptome data if available) and preexisting information from model species to predict the epigenetic modulators and associated epigenetic marks a novel species may possess and presumably utilize. This package consists of a pipeline for genome annotation, which relies on existing software

packages and hidden Markov models to identify and annotate genes in a species of interest. These genome annotations are written out for downstream user-defined genomic experimentation and then automatically fed into a graphical application that extracts evidence for epigenetic modulators and histones. This interface provides a literature-based interpretation of results, enabling users to quickly understand potential epigenetic mechanisms in their species of interest and plan follow-up experiments. Moreover, in tandem, this pipeline extracts histone sequence information for comparison against model species, which provides invaluable information about potential histone PTMs and guides the design of sequence-specific wet lab experiments (e.g., antibody selection). Overall, this one-click software package does not require a priori knowledge of epigenetics, extensive literature review, or familiarity with command-line bioinformatics tools, making it accessible to all users who are familiar with a standard graphical computational environment.

693F **Xenbase: Improvements in *Xenopus* gene nomenclature annotations** Andrew J Bell[1], Christina James-Zorn[1], Taejoon Kwon[2], Malcolm Fisher[1], Konrad Thorner[1], Virgilio Ponferrada[1], Ngoc Ly[1], Stanley Chu[3], Sergei Agalakov[3], Bradley Arshinoff[3], Kamran Karimi[3], Troy Pells[3], Vaneet Lotay[3], Elspeth Bruford[4], Tsviya Olender[5], Peter Vize[3], Aaron Zorn[1] [1]Division of Developmental Biology, Cincinnati Children's Hospital Medical Center, [2]Department of Biomedical Engineering, Ulsan National Institute of Science and Technology (UNIST), [3]Department of Biological Sciences, University of Calgary, [4]HUGO Gene Nomenclature Committee (HGNC), University of Cambridge, [5]Department of Molecular Genetics, Weizmann Institute of Science

Xenbase, the *Xenopus* Model Organism Knowledgebase, is the official centralized resource for gene, genome and biological research data supporting the international *Xenopus* frog research community. Xenbase continues to play a foundational role in supporting basic biomedical science, developmental, cell and cancer biology, among other disciplines, as key questions are often first explored in the *Xenopus laevis* and *Xenopus tropicalis* model organisms. Xenbase sources genome build data from the UCB *Xenopus* genome group, the NCBI and ENSEMBL, to produce curated gene page entities and integrated Xenbase general feature format (GFF) genome annotation files across successive versions. The most recent genome builds for *X. laevis* and *X. tropicalis* had thousands of instances where previously well characterized genes lost key identifying metadata such as gene symbols and gene names. This presents a major opportunity to improve the utility and potential impact of the latest *X. laevis* and *X. tropicalis* genome annotations, by addressing the underlying gene nomenclature metadata of individual genes and large gene families that lost this key information, in addition to those that have never had proper annotations. In this poster, we outline the various approaches and strategies we have undertaken at Xenbase and in collaboration with domain experts around the world to address gene symbol and gene name assignments for specific groups of genes and for large gene families. In an effort to first carry over annotations from v9 to v10 genome builds, we were able to recover annotations for hundreds of genes based on sequence similarity and by assigning gene synteny scores. We also addressed specific gene families, naming over one thousand genes belonging to the Olfactory Receptors (OR), the interleukin immune genes, Heat Shock Protein Beta (HSPB) genes and the FC receptor gene families. Meanwhile, we are in process of integrating data sharing pipelines with the Alliance of Genome Resources group in a manner that will facilitate future integration with the gold standard DIOPT pipeline for making automated gene annotations by identification of cross-species gene orthologs from protein sequences. We further collaborate directly with individuals in the *Xenopus* research community who contact us to resolve gene nomenclature issues for key genes of import to their research. Xenbase is funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD/NIH).

694F **Potential Role in Cell Wall Integrity of a Gene of Unknown Function in *Saccharomyces cerevisiae*** Claire E. Magill, Jill B. Keeney Biology, Juniata College

Despite the yeast *Saccharomyces cerevisiae* being an intensely studied model organism, there remain hundreds of genes of unknown function. The Yeast ORFan Gene Project is an undergraduate and faculty research project to attempt to determine the molecular functions of these genes. I am studying *FYV8* (*YGR196C*), a protein of unknown function required for survival upon exposure to K1 killer toxin. The molecular function and biological process of *FYV8* are unknown; cellular component localizes to the cytoplasm in a large-scale study. K1 killer toxin is a protein secreted by *Saccharomyces cerevisiae* that kills sensitive yeast strains. Killer yeast cells require self-immunity mechanisms against their own toxin. Past experiments confirmed the killer toxin sensitive phenotype. Bioinformatics investigations reveal *FYV8* may be involved in chitin cell wall biosynthesis. Experiments have revealed that *fyv8Δ* is sensitive to Calcofluor White, a dye that impacts cell wall stability and acts as a chitin antagonist. A related gene of interest, *ECM13* (*YBL043W*), also displays sensitivity to Calcofluor White. *ECM13* is a protein of unknown function induced by treatment with 8-methoxypsoralen and UVA irradiation and is thought to be involved in cell wall biosynthesis. Molecular function, biological process, and cellular component are unknown. Current experiments include testing the *fyv8Δ* and *ecm13Δ* on antifungal medications because these drugs impact cell wall architecture. Preliminary results suggest that *fyv8Δ* confers sensitivity to and *ecm13Δ* confers resistance to undecylenic acid and zinc undecylenate, an antifungal that is thought to interact with cell membrane components of yeast to inhibit biofilm formation or morphogenesis. Current experiments include testing *fyv8Δ* on isolated undecylenic acid to determine if there are different phenotypes

between the antifungal cream and undecylenic acid liquid with plans to test *ecm13Δ* as well. Future experiments include addressing the solubility issues of undecylenic acid by combining it with L-arginine to make it soluble in water to better perform assays. Other future experiments include testing the deletion strain for other toxic phenotypes.

695F **Specific high effect mutations in clinical and experimentally evolved *Saccharomyces 'boulardii'* isolates show that genes involved in chemical response might have a role during the adaptation to the human host** Alexandra Imre[1], Renátó Kovács[2], Ibrahim Al' Abri[1], Nathan Crook[1], Walter P. Pfliegler[3] [1]Department of Chemical and Biomolecular Engineering, North Carolina State University, [2]Department of Medical Microbiology, University of Debrecen, [3]Department of Molecular Biotechnology and Microbiology, University of Debrecen

Among dietary supplements, *Saccharomyces 'boulardii'* probiotics stand out not only with their outstanding health promoting effects, but also their ability to survive hostile niches in the human body, like the acidic environment of the stomach or the 37 °C body temperature. However, in the case of immunocompromised or severely ill hospitalized patients there is a high risk of developing fungemia. Despite several such cases are reported every year, the genetic causes of virulence are under-researched. Hence, we applied experimental evolution combined with a comparative genomics approach to identify specific mutations in 38 clinical *S. 'boulardii'* isolates and 18 isolates subjected to in vivo or in vitro experimental evolution. During the in vivo experiments the CNCM I-745 commercial isolate was injected into the bloodstream of immunosuppressed BALB/c mice, then yeast colonies were re-isolated from the kidneys followed by Illumina whole genome sequencing. The same commercial isolate was cultured in liquid Synthetic Defined (SD) media in the presence of NaCl or fluconazole, to serve as a model for stress environments yeast cells were potentially exposed to in the kidneys and in the human body, respectively. Additionally, germ-free mice were gavaged with commercial isolates from various sources. These were able to colonize the GI tract, thus isolates from fecal material were collected after 5 weeks and sequenced.
The annotation of de novo mutations showed that the clinical and evolutionarily evolved isolates have specific variants that affect protein function. These high-effect mutations resulted in numerous loss-of-heterozygosity (LOH) and gain-of-heterozygosity (GOH) events. In total 84 genes were affected by these mutations. Published large scale studies revealed that some of these genes have a role in competitive fitness, resistance to chemicals and heat sensitivity. Genes with high effect mutations were annotated to 53 GO Terms in total, among which the GO Term "response to chemical" contained the most genes after Go Term Mapping. These data indicate that the human host might exert selective pressure on the probiotic yeast isolates resulting in specific mutations that potentially have a substantial role during the adaptation of the probiotic yeast to the human host.

696F **A minimal *Saccharomyces cerevisiae* chromosome** Zachary Krieger, Cara Hull, Alessandro Coradini, Ian Ehrenreich Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California

Identifying minimal sets of genes that produce viable eukaryotic cells will reveal the core cellular components required for this domain of life. Minimization, the systematic removal of as many genes as possible from a chromosome or genome, can empirically define such minimal gene sets. However, methods for deleting large numbers of non-adjacent genes and producing chromosomes with minimal gene content are needed to make minimization possible in eukaryotes. To enable chromosome minimization in a eukaryote, we developed a method called MoSAIC (Minimal or Streamlined Architectures of Individual Chromosomes) in the budding yeast *Saccharomyces cerevisiae*. MoSAIC leverages the extensive genomics data available for this key model organism to experimentally generate and test libraries of reduced versions of an *S. cerevisiae* chromosome, some of which may have minimal gene content. To generate libraries of chromosomes that have substantially reduced gene content and give rise to viable cells, MoSAIC utilizes *in vivo* recombination between a native chromosome and synthetic DNA fragments containing known essential genes from that chromosome. Using MoSAIC, we have generated versions of *S. cerevisiae* Chromosome I from which >50% of the genes have been deleted and expect to have achieved much greater chromosome reduction by the conference. I will discuss our current work and our plans to utilize MoSAIC to generate a minimal eukaryotic genome.

697F **Effect of host genotype on the genetics of fungal persistence in mice** Yunsun Eoh, Brandon Bernardo, Matthew Dean, Ian Ehrenreich Department of Biological Sciences, USC

Fungal pathogenesis is a major source of morbidity and mortality, especially in immunocompromised individuals, infecting billions and killing millions of people every year. Previous literature has established that different mice strains have varying susceptibility to fungal infection. Identifying genetic polymorphisms that enable fungi to persist in distinct mammalian host strains can reveal mechanisms underlying host-microbe and host-pathogen interactions. Previously, we used 822 DNA-barcoded, genotyped, haploid segregants from a cross between a clinical isolate (3S) and the lab reference strain (BY) of *Saccharomyces cerevisiae* to perform linkage mapping of fungal persistence in mice. This work detected 17 loci that enable yeast to persist in different organs in C57BL/6 mice. Here, we are repeating our previous work in all eight founder strains of

the mouse Diversity Outbred (DO) population. This experiment should reveal the extent to which the same or different loci influence the organ-specific persistence of yeast in other mouse genotypes.

698F **Characterizing mechanisms of yeast persistence in mice using fine-scale genetic mapping and high resolution microscopy** Brandon Bernardo[1], Yunsun Eoh[2], Chris Ne Ville[1], Jason Junge[1], Le Trinh[1], Scott Fraser[1], Matthew Dean[1], Ian Ehrenreich[1] [1]Biological Sciences, University of Southern California, [2]University of Southern California

Identifying genetic and molecular mechanisms that enable fungal infections could enable the development of better antifungal therapies. The budding yeast Saccharomyces cerevisiae is an opportunistic pathogen. This model organism can be used to better understand fungal persistence in mammalian hosts. We previously identified 17 loci that explained most heritable variation in yeast persistence across mouse host organs using a cross of the S. cerevisiae lab reference strain (BY) and 322134S clinical isolate (3S). Half of these loci showed consistent effects across organs while the other half showed antagonistically pleiotropic effects on persistence between brain and non-brain organs. We are now trying to more deeply understand how genetic polymorphisms in yeast shape the ability of strains to persist in different parts of the mammalian body. Part of this ongoing work involves resolving the previously identified loci to causal genes using a synthetic biology strategy based on CReATiNG (Cloning, Reprogramming, and Assembling Tiled Natural Genomic DNA), a method our group recently developed for cloning and assembling segments of natural chromosomes. In addition, we employ high resolution imaging of yeast strains tagged with different fluorescent proteins inside of mouse hosts. Jointly, this ongoing work will determine molecular mechanisms and spatial patterns of yeast persistence in the mammalian body.

699S **Investigating the role of H3K9 tri-methylation in regulating heat-induced transposon excision** Hannah R Wilson, Nicole Kurhanewicz, Diana E Libuda Biology, University of Oregon

The proper development of haploid gametes, such as sperm and eggs, is critical for sexually reproducing organisms to faithfully pass their genome onto the next generation. Environmental stressors, such as heat stress can negatively impact genomic integrity during gamete development, leading to genetic defects, infertility, and cancer. Chromatin modifications, including H3K9 tri-methylation (me3), protect the genome from transposon-associated damage by regulating the accessibility of heterochromatin thereby repressing the expression of transposons. In *Caenorhabditis elegans,* acute heat stress causes spermatocyte-specific heat-induced transposon mobilization and increased male infertility. Recent work indicates that heat stress perturbs H3K9me3 in a sexually dimorphic manner. My research is investigating how the chromatin modification, H3K9me3, regulates sexually dimorphic heat-induced transposon activity. To determine whether H3K9me3 is associated with heat-induced transposon excision, I am comprehensively defining the heat-induced transposon landscape across the *C. elegans* genome and comparing this dataset to the sex-specific H3K9me3 landscape. Furthermore, I am using germline histone methyltransferase mutants to determine whether H3K9Me3 differentially regulates heat-induced transposon activity in developing sperm and eggs. Lastly, I am determining whether the complete loss of histone H3K9Me3 impacts heat-induced male infertility. Overall, these studies will illuminate sexually dimorphic mechanisms that regulate transposon activity in developing gametes to maintain genomic integrity for fertility.

700S **Investigating the impact of seasonality on the gut microbiome in *Drosophila melanogaster*** Harjit Khaira, Nichole Broderick Johns Hopkins University

The interaction between the gut microbiome and its host has been studied in many species. Particularly, in the context of human health, a wide variety of host conditions and diseases has been linked to the microbiome. The gut microbiome is impacted by environmental factors such as diet, antibiotic intake, and air pollution. Diurnal changes of the environment are sensed by the master circadian clock in the superchiasmatic nucleus (SCN) region of the brain. Which controls behaviors like feeding time, and the sleep wake cycle. The gut microbiome and the host also undergo diurnal changes in composition and function that are regulated by daily feeding rhythms. This suggests that diurnal change in light conditions can impact the gut microbiome. It is known that humans experience a seasonal shift in diet which in turn can alter the microbiome composition of the gut. Seasonal changes mean changes in day-length (photoperiod) and temperature. Abrupt changes in photoperiodic conditions can have detrimental effects on human health, such as development of certain mood disorders and reproductive consequences. However, the effects of seasonal changes on the gut microbiome remains poorly understood. To address this knowledge gap, we use *Drosophila melanogaster*, which has proven to be a powerful model to study the gut microbiome due to its simple composition (5 to 20 microbial species) and ease of manipulation in the lab. Here, we report that shifts in photoperiod and temperature alter microbiome composition in *D. melanogaster*. In addition, cold temperature increases overall microbiome abundance. Shifts in photoperiod and temperature also impact host physiology, including impacts on metabolism, reproduction, and immunity. We will discuss the relative contribution of microbiome to these host phenotypes. Altogether, our study will determine how the microbiome is impacted by seasonal changes and identify its subsequent impacts on host physiology.

701S **Pinpointing the impact of a commonly used *nanos-Gal4* driver on *I-R* hybrid dysgenesis** Mia J Willingham[1], Justin Blumenstiel[1], Kelly Van Vaerenberghe[2] [1]Ecology and Evolutionary Biology, University of Kansas, [2]University of Kansas

Hybrid dysgenesis is a phenomenon of hybrid sterility that arises when paternally transmitted transposable elements absent in the mother become activated in the germline. Because transposable elements are broadly distributed through the genome, genetic analysis of hybrid dysgenesis with commonly used genetic tools is challenging. This is because moving these tools into the background of the strains of the dysgenic syndrome is likely to alter the transposable element profile, confounding clean genetic analysis. In the course of our investigations of *I-R* hybrid dysgenesis, we found that even after ten generations of backcrossing, a commonly used *nanos-Gal4* transgene altered the rate of sterility. We attributed this to two possible causes. First, the transgene might have disrupted the gene *CG6325,* thus modulating the sterility phenotype. Alternatively, the transgene might be on a haplotype that differs from the original inducer strain with respect to nearby *I* element insertions. To investigate these possibilities, we first performed strain specific CRISPR knockout of *CG6325* with non-homologous end joining. Preliminary data suggests that the impact of the *nanos-Gal4* insertion on *CG6325* function is unlikely to be the cause of altered rates of sterility. We are now performing whole-genome Oxford Nanopore sequencing of the different strains to determine if differences in sterility among crosses with different strains are more likely explained by differences in the *I* element profile of the strain carrying the *nanos-Gal4* insertion. By combining the tools of strain specific CRISPR and Oxford Nanopore sequencing, we thus illuminate a path forward for clean genetic analysis of syndromes of hybrid dysgenesis.

702S **Annotation of Thor in Drosophila albomicans: Detangling the Insulin Signaling Pathway of *Drosophila*** Laury A. Valentin Rodriguez[1], Chinmay P. Rele[2], Alondra M Diaz-Lameiro[3] [1]Biology, University of Puerto Rico-Mayaguez, [2]The University of Alabama, [3]Biology, University of Puerto Rico at Mayaguez

The insulin signaling pathway is well-conserved across animals, including humans, due to its critical role in growth and metabolic homeostasis. An evolutionary analysis of these genes in *Drosophila* can provide insight into how complex diseases related to this pathway, such as diabetes, develop in humans. As part of the Pathways Project of the Genomics Education Partnership (GEP), the *Thor* gene of the insulin signaling pathway, which contributes to translation regulation, response to environmental stress, and cell growth regulation, was annotated in *D. albomicans* based on conservation of local synteny and parsimony with *D. melanogaster*. After identifying the genomic location of the putative ortholog through a protein alignment of *Thor* in *D. melanogaster* against a scaffold of *D. albomicans* using NCBI BLAST, the genomic neighborhood of this ortholog was examined using synteny to the *Thor* neighborhood in *D. melanogaster*. Based on local synteny analysis, *Thor*'s gene structure in *D. melanogaster* and the alignment to *D. melanogaster* proteins, gene prediction models, RNA-Seq data, and splice junction sites in the UCSC Genome Browser, the two coding exons of the putative ortholog were localized and annotated. Although the genomic neighborhood of the putative ortholog did not share synteny with *Thor*'s neighborhood in *D. melanogaster*, a comparative analysis of *Thor*'s genomic neighborhood across different *Drosophila* species between *D. melanogaster* and *D. albomicans* revealed that this neighborhood has gone through recombination during the speciation of the genus. This analysis and the annotation supported a putative ortholog of *Thor* in *D. albomicans* and revealed a *Thor* gene duplicate, which has been observed in other basal *Drosophila*. This duplicate shares the same gene structure and coding exon as the ortholog and only diverges from it by a few amino acid changes. *Thor's* conservation, regardless of changes in local synteny, suggests an essential role in the insulin signaling pathway. Future gene annotations of this pathway across different *Drosophila* species through GEP could provide a better understanding of its evolution and function and the role of genes such as *Thor* in diseases such as diabetes.

703S **Adaptive TE insertions in a long non-coding RNA: a novel class of transcriptional repressors?** Erin K Kelleher[1], Savana Hadjipanteli[2], Natalie Copeland[1] [1]Biology and Biochemistry, University of Houston, [2]Cell and Molecular Biology, University of Pennsylvania School of Medicine

Transposable elements are genetic parasites whose mobilization throughout the genome is a major source of deleterious mutations. However, some TE insertions are beneficial and are positively selected because they improve host fitness. Adaptive TE insertions have been shown to alter the function of adjacent genes by positively and negatively impacting their expression. Alternatively, individual TE insertions can also be adaptive because they establish repression of transposition through piRNA production or other mechanisms. In a recent laboratory evolution experiment, we discovered that *lncRNA43651* is an adaptive insertion hot spot for *P*-element DNA transposons in *Drosophila melanogaster*. However, the functional effects of these insertions on adjacent gene expression or *P*-element repression remain unknown. To this end, we examined the effects of *lncRNA43651* insertions on viability, *P*-element transcriptional regulation and piRNA biogenesis. We determined that although *lncRNA43651* insertions exhibit recessive viability effects, these fitness costs may be offset by dominant beneficial effects on *P*-element regulation. *P*-element insertions in *lncRNA43651* exhibit stronger transcriptional repression of P-element promoters than known repressive insertions in traditional piRNA clusters. Furthermore, the presence of *lncRNA43651* insertions enhances P-element piRNA production initiated from cluster insertions. However,

the *lncRNA43651* insertions themselves are not a significant source of ovarian *P*-element derived piRNAs. Our findings point to a new class of repressive TE insertions, that establish and enhance piRNA-mediated silencing through an unknown mechanism.

704S **New biological insights of the 3D nuclear architecture using WaveTAD, a probabilistic, resolution-free, and hierarchical TAD caller** Ryan Pellow[1], Josep Comeron[2,3] [1]University of Iowa, [2]Department of Biology, University of Iowa, [3]Interdisciplinary Program in Genetics, University of Iowa

Eukaryotic genomes fold their chromosomes within nuclei in three-dimensional space, with systematic and coordinated multiscale structures including loops, topologically associating domains (TADs) and higher-order chromosome territories. This 3D organization plays essential roles in gene regulation and development, responses to physiological stress and disease. Our understanding of the 3D organization of genomes has benefited from the current ease to obtain sequencing data that identifies genomic contacts in 3D space. These genomic datasets are, however, highly sparse and noisy and current methodologies to infer 3D structures show limitations and biases, including i) different outcomes depending on the resolution of the analysis and sequencing depth, ii) results that are only qualitative and prevent statistical comparisons, iii) no insight into the frequency of the structures that can exist in a sample with multiple genomes, and iv) no direct prediction of hierarchical structures. These caveats hinder rigorous and objective comparisons of 3D properties across genomes and between experimental conditions or species.

To address all these challenges, we developed a wavelet transform-based method (WaveTAD) that describes the 3D nuclear organization in a resolution-free, probabilistic, and hierarchical manner. Besides being the only resolution-independent method, WaveTAD shows increased accuracy and sensitivity than current approaches, predicts multi-layered structures and generates probabilities associated with each structure that capture variable frequency within samples. We applied WaveTAD to multiple datasets from *Drosophila*, mouse, and humans to illustrate new biological insights that our new method provides, including extensive embryonic 3D organization before zygotic genome activation, the quantitative effect of multiple CTCF units on the stability of loops and TADs, the association between histone marks and transcription factors with TAD structures and strengths, or the analysis of COVID patients unveiling 3D genomic changes not previously identified.

705S **The role of *Lactiplantibacillus plantarum* in the gut microbiota-brain axis - implications for aging** Melanie Reinoso, Caroline Casiano, Charles Pfeiffer, Josue Rodriguez-Cordero, Alfredo Ghezzi, Jose Agosto, Imilce Rodriguez-Fernandez University of Puerto Rico Rio Piedras

The gut microbiota-brain axis is a bidirectional communication between the resident microbes, the gut, and the brain; it plays a pivotal role in aging and age-related diseases, particularly neurodegenerative conditions. Probiotics have emerged as a promising avenue for interventions targeting age-related diseases by modulating this axis. In this study, we explore the effects of the commensal bacteria and probiotic *Lactiplantibacillus plantarum* (formerly *Lactobacillus plantarum*) on the gut-brain axis in the fruit fly *Drosophila melanogaster* by using an untargeted metabolomics approach.

Flies are a genetically amenable model, display age-related phenotypes, and have a simpler microbiota than mammals that is easy to manipulate. These traits allow discoveries made in flies translatable to mammals. To understand how *L. plantarum* can provide a benefit to the health of animals we supplemented young and old flies with or without *L. plantarum*. These flies were flash-frozen and separated by heads (brain) and bodies (intestine and other organs) and collected separately. This approach allowed us to identify changes in metabolites that are age-, tissue- and treatment-specific. Our results show a total of 855 biochemicals: 798 known biochemicals and 57 unknown biochemicals. Our findings revealed substantial metabolomic disparities linked to age and body section, emphasizing the dynamic nature of the gut-brain axis in the context of aging. Notably, the influence of *L. plantarum* supplementation on the metabolome appeared relatively modest. However, there were significant differences in neurotransmitters of interest, specifically acetylcholine which is increased in the bodies of old flies treated with *L. plantarum*. Preliminary data from our lab shows that *L. plantarum* can alter sleep latency and locomotion. Our ongoing work aims to characterize the link between *L. plantarum*-mediated changes in neurotransmitters and distinct behaviors. Data obtained from this project will help us characterize the molecular mechanisms used by *L. plantarum* to influence the gut-brain axis.

706S **The impact of Piwi overexpression on *I-R* hybrid dysgenesis** Sean A Nash[1], Kelley Van Vaerenberghe[2], Justin P Blumenstiel[1] [1]Ecology and Evolutionary Biology, University of Kansas, [2]University of Montana

Drosophila Piwi is the founding member of the PIWI clade of Argonaute proteins and plays a critical role in transposon silencing in the germline nucleus via small RNAs known as PIWI-interacting RNAs (piRNAs). These piRNAs derive from fragmented transposons residing in genomic compartments known as piRNA clusters. Piwi has diverged from an ancestral gene owing to a duplication of a Piwi/Aubergine ancestor. In contrast to the nuclear function of Piwi, Aubergine is expressed

in the cytoplasm. The role that Piwi has in the establishment of piRNA biogenesis from germline dual-strand clusters is not well understood, but studies indicate that maternally provisioned piRNAs, loaded into Piwi protein in the early embryo, play a critical role in licensing their establishment. Interestingly, later in development, Piwi becomes dispensable, when the Rhino-Deadlock-Cutoff complex maintains cluster identity independent of Piwi. To investigate the role that ongoing Piwi expression has on piRNA function, we performed an analysis of Piwi overexpression in the *I-R* syndrome of hybrid dysgenesis. In the *I-R* syndrome of hybrid dysgenesis, young dysgenic females that have inherited active *I-elements* solely from their father experience a loss of fertility when their eggs fail to hatch. This is caused by lack of maternally transmitted *I-element* piRNAs and activation of the *I-element* during oogenesis. Interestingly, as they age, females become fertile again and eggs begin to hatch. This is presumably due to the slow accumulation of piRNAs that eventually restore *I-element* silencing. Our study seeks to determine the influence that Piwi overexpression has on this process and evaluate the history of Piwi gene duplication in this context.

707S **Starting to Remember: Initiation of Polycomb target gene regulation in the Early Drosophila Embryo** Sean Johnsen, Dan McKay Genetics, University of North Carolina at Chapel Hill

The Polycomb Group proteins serve in one of the most highly conserved epigenetic regulatory systems across eukaryotic life, enabling the maintenance of cell identity across mitosis through stable repression of target genes. Meiosis, however, enables a total reset of the developmentally-restricting epigenetic information, resulting in a totipotent zygotic chromatin state. From this totipotent state, developmental gene regulatory programs re-impart Polycomb-mediated gene repression in a cell-type specific manner. The onset of Polycomb chromatin domain formation coincides with the transcriptional activation of the zygotic genome. Prior to this stage in embryogenesis, Polycomb gene products are produced during oogenesis and deposited into the zygote by the mother. The requirement of Polycomb proteins during oogenesis has made genetic dissection of their role in early embryogenesis technically challenging. As a result, our understanding of de novo cell-type specific initiation of Polycomb-mediated repression remains incompletely understood. We are using recently developed conditional protein inactivation systems to determine which epigenetic information is required for proper initiation of epigenetic memory by the Polycomb regulatory system.

708S **The Relationship Between Thiamine and Drosophila Melanogaster Preference for Dietary Yeast** Dean Peterson Life Sciences, Brigham Young University

This study will focus on the microbiota's effects on *Drosophila Melanogaster* dietary preference for yeast (DPY). A study completed in our lab suggested that bacterial thiamine biosynthesis/metabolism might influence fly DPY which shifted from yeast restricted diet to yeast rich (Call 2022). I previously confirmed the prediction that thiamine influences fly DPY by showing that flies reared on thiamine supplemented diets do not display reduced DPY. I will now perform follow-up tests to determine the specificity of thiamine as the molecule causing shifts in DPY. I will test flies given other vitamin B supplemented diets. If thiamine is the only B vitamin that influences fly DPY, then these tests show that the effect is relatively specific to thiamine when compared to other B vitamins. I will also perform a parallel experiment to confirm the role of bacterial thiamine on DPY. I will rear flies colonized with bacterial thiamine biosynthesis/metabolism mutants on thiamine supplemented diets then measure DPY. If flies raised with increased thiamine in their diet prefer yeast restricted diet, then thiamine is the molecule involved in yeast preference for these mutants. Together, these approaches will reveal that thiamine is the molecule used by the microbiota to influence fly DPY.

709S **Diet reveals tissue-specific gene expression of an uncharacterized gene in *Drosophila melanogaster*** Meri Nehlsen[1], Maria Langegger[1], Julien Ayroles[2,3], David Stern[4], Luisa F. Pallares[1] [1]Friedrich Miescher Laboratory, Max Planck Society, [2]Lewis-Sigler Institute for Integrative Genomics, Princeton University, [3]Ecology and Evolutionary Biology Department, Princeton University, [4]Janelia Research Campus of the Howard Hughes Medical Institute

Understanding how organisms respond to changing environmental conditions is a key goal in evolutionary biology. One of the potential mechanisms underlying such responses are Genotype-by-Environment (GxE) interactions, which describe that a genotype can produce different phenotypes depending on the environmental context. In a study of diet-dependent differential gene expression in *Drosophila melanogaster*, among many modest changes under a High-Sugar (HS) diet, we previously identified a gene with striking tissue-specific upregulation: while only moderately upregulated in the body, expression in fly heads increased 16-fold on HS diet, resulting in the strongest response to a diet high on sugar. Interestingly, this gene and its function have not been previously characterized. Here we explore the cryptic gene expression unveiled by HS diet and potential diet-dependent function of this gene.

First, to determine the protein localization, we created a fly line using CRISPR-Cas9 in which the candidate gene is tagged with hemagglutinin (HA). Using anti-HA antibodies, we detected protein expression in the gut as well as in several brain

compartments, likely glia cells, tracheas, and the mushroom body, and confirmed that the expression of the candidate gene is indeed stronger under HS diet.

Using a whole-genome gene expression dataset, we estimated the correlation between the candidate gene and every other gene in the genome for head and body, in both conditions, control and HS diet. GO enrichment analysis of the top correlated genes suggested involvement of the gene in digestive functions in the body regardless of the diet. This result aligns with the predicted chymotrypsin-like serine protease activity of this gene. In the head, under control diet the gene had no strong correlation with any gene, whereas under HS diet strong correlations with genes involved in lipid catabolism were unveiled. This correlation suggests that the candidate gene becomes part of well-known regulatory networks in a diet-dependent and tissue-specific manner.

In conclusion, locating the expression of the gene to specific structures in the fly head, as well as determining the putative function of the gene based on co-expression with other genes provides the first step towards characterizing the molecular function of the candidate gene as well as its potential role in regulating the response to HS diets.

710S **The role of Polycomb group proteins in animal activity** rachel e ferris[1], Nicole C Riddle[2] [1]biology, university of alabama at brimingham, [2]Biology, university of alabama at brimingham

The Polycomb Group (PcG) proteins were defined initially based on their regulation of the Hox gene cluster and the homeotic mutations that result in their absence. Molecular characterization of the PcG proteins show that they modify histones and repress developmentally regulated genes, including the Hox genes, through the action of two complexes, PRC 1 and PRC 2. Our previous work has linked components of PRC1 and PRC2 to the control of physical activity, when PcG genes were identified as candidate genes in a genome-wide association study for animal activity. Here, we follow up on this initial finding and systematically remove individual components of PRC1 and PRC2 in the central nervous system to identify which PcG protein are involved in the control of animal activity levels. To achieve tissue-specific knockdown, we used the UAS/GAL4 system. While we do not see many changes in activity early in life, we find that late in life, activity levels are significantly increased in the knockdown compared to the control genotypes. Our findings further support the potential role of the PRC complexes in the control of animal activity. Identifying the major players involved in the control of physical activity will aid in the development of personalized healthcare interventions.

711S **Cas9 electroporation and AAV templates efficiently generate knock-in and conditional alleles in mice** Lauri G Lintott[1], Valerie Laurin[1], Linda Chan[1], Qing Fan-Lan[1], Marina Gertsenstein[2], Lauryl MJ Nutter[2,3] [1]The Hospital for Sick Children, [2]The Centre for Phenogenomics, [3]Genetics & Genome Biology, The Hospital for Sick Children

Introduction: Genome editing with Cas9 has simplified generation of genetically modified mice. However, targeted insertion of large fragments and one-step generation of loxP-flanked conditional alleles remain challenging. Co-incubation of recombinant adeno-associated virus (rAAV) with rodent embryos was used to deliver repair templates for Cas9-mediated genome editing to produce knock-in alleles.

Aim: Our aim was to adapt these protocols to establish a workflow to efficiently generate knock-in and conditional alleles.

Strategy: We used rAAV to deliver repair templates for conditional and knock-in alleles and Cas9 RNP to introduce DNA double-strand breaks at the target sites.

Results: We successfully generated founders with either knock-in or loxP-flanked conditional alleles. Using template-specific PCR and template copy number assessment we found that multicopy rAAV integration occurred. We also developed a founder screening pipeline to eliminate the most mice at early steps, minimizing the number of animals screened. Using founders that passed our founder quality control for germline transmission test breeding we established mouse lines with the desired allele in each case tested.

Conclusions: Template delivery by rAAV co-incubation and Cas9 RNP electroporation is a robust protocol to generate knock-in and conditional alleles.

712S **Adding the missing tiles to the puzzle: reconstruction of KRAB-ZFP gene clusters sequence and evolution in mice** Melania Bruno, Apratim Mitra, Sharaf Maisha, Ryan Dale, Todd Macfarlan The Eunice Kennedy Shriver National Institute of Child Health and Human Development, The National Institutes of Health

KRAB-zinc finger protein (KZFP) genes are an abundant and fast evolving family of transcription factors, numbering in the hundreds in most mammalian genomes.

KZFPs are characterized by the presence of a KRAB domain, often recruiting heterochromatin forming factors, and of an array of tandem C2H2 zinc fingers, conferring DNA binding specificity. Although some conserved KZFPs play a role in fundamental developmental processes, many evolutionary young and clade- or species-specific KZFPs repress the expression of endogenous retroviruses (ERVs) and, intriguingly, share a similar evolutionary age with the elements they repress. This suggests that new KZFP genes "emerge" in response to waves of ERV invasion into the host genome.

However, it is currently unknown how new KZFP genes emerge and evolve.

The mouse germ line has been recently colonized by numerous distinct retroviruses that have established ERV families unique to mice. The KZFP gene family has also recently expanded in the mouse lineage, with parallel evolution in different inbred mouse strains. This makes the mouse an ideal model to study the evolution of KZFP genes.

KZFP genes are organized in highly repetitive and dynamic genomic clusters. In the mouse, several KZFP gene clusters display evidence of recent segmental duplications, but sequence gaps in the available genome assemblies have prevented a thorough reconstruction of their evolution. We have generated de novo assemblies and filled the gaps in all KZFP gene clusters in the reference C57BL/6J and the 129S1/SvImJ mouse strains, by combining PacBio HiFi and Nanopore long read sequencing. We found that some KZFP gene clusters are much larger and repetitive than previously thought, harboring many more KZFP genes. Complete reconstruction and analysis of clusters that emerged in the Muridae clade revealed that new KZFP genes emerge by duplication of large regions harboring multiple KZFP genes. We found that one region in particular expanded from ~1Mb in rat to ~5Mb in C57BL/6J and ~7Mb in 129S1/SvImJ mice. Furthermore, comparison between C57BL/6J and 129S1/SvImJ KZFP gene clusters, revealed different modes of cluster expansion: C57BL/6J clusters display a higher degree of intra-cluster homology while 129S1/SvImJ clusters present more fragmented duplications with less overall intra-cluster homology. This suggests likely differences in the pathways that regulate the maintenance and evolution of these repetitive loci in different mouse strains.

713S **Time-series transcriptomic analysis reveals selfish B chromosome, PSR, may regulate wasp development through testis-biased gene expression** Xinmi Zhang[1], Ying Zhang[2], Xu Wang[2], Patrick Ferree[3] [1]W.M. Keck Science Center, [2]Auburn University, [3]W. M. Keck Science Center

Paternal Sex Ratio (PSR) is a selfish B chromosome found in the parasitoid wasp *Nasonia vitripennis*. PSR is transmitted through sperm to progeny and can cause Paternal Genome Elimination (PGE) in fertilized diploid embryos, leading to the conversion of diploid female wasps into haploid males. This action leads to super-Mendelian transmission of PSR. Understanding how PSR causes PGE is important for comprehending how B chromosomes can induce genome conflict, how B chromosomes evolve, and their potential applications in insect pest control. A recent study has revealed that the PSR-expressed *haplodizer* gene is responsible for the PGE event, but it remains unclear when and mechanistically how *haplodizer* functions in this process.

To address this knowledge gap, we are performing transcriptome profiling across different developmental stages of both wildtype (WT) and PSR-carrying male wasps, from early embryos to adults. Tissue-specific and stage-specific gene expression patterns were analyzed to investigate the expression level changes of *haplodizer* and other PSR-expressed genes. Differential gene expression analysis was also conducted between WT and PSR-carrying wasps at different stages to uncover transcriptional changes caused by PSR.

Preliminary analyses of the mid pupal stage showed that out of 28 PSR expressed genes, 18 genes had low to very low expression levels (RPKM < 2). Of the higher expressed genes, 2 were testis-specific, and 7 others, including *haplodizer*, were testis-biased. Furthermore, among ca. 12,000 normal genes in the wasp's genome, 69 showed significant up-regulation in the testis and 9 genes were up-regulated in the carcass of PSR-carrying males compared to WT males. No genes were down-regulated in the testis, while 44 genes exhibited down-regulation in the carcass of PSR-carrying males compared to WT males. These preliminary findings suggested that there is a testis-specific bias for PSR-expressed genes, which may be relevant to the ability of PSR to induce PGE and favor its vertical transmission. This study represents one of the most comprehensive transcriptome-level gene expression studies for a B chromosome across development.

714S **Differential adenine methylation analysis reveals 6mA variability after experimental evolution.** Carl Stone, Megan Behringer Vanderbilt University

Methylated DNA adenines (6mA) are a critical epigenetic modification in bacteria that affect cell processes like replication, stress response, and pathogenesis. While much work has been done characterizing the influence of 6mA on specific loci, very few studies have examined the dynamics of 6mA over evolutionary time. We used third-generation sequencing technology and a newly developed differential methylation analysis pipeline to examine 6mA methylation across the Escherichia coli K-12 substr. MG1655 genome. 6mA levels were consistently high across GATC sites; however, we detected regions of decreased

6mA in the WT genome and in experimentally evolved populations from WT and methyl-directed mismatch repair-deficient (MMR-) lineages. We show that characterization of 6mA in bacterial populations is complementary to genetic sequencing and informative for molecular evolution.

715S **Genome assembly of three rhabditid species** Juan Pablo Aguilar Cabezas, Janna Fierst Biological Sciences, Florida International University

The evolution and phylogeny of nematodes has conflicts, but with the revolution in DNA sequencing sequencing, the future is very promising, potentially not only resolving taxonomic uncertainties but also shedding light on the diversity of this group. The suborder Rhabditina includes the most famous species, *Caenorhabditis elegans*, a model organisms for genetic studies. The goal of this study was to shed light into the evolution and natural history of this order by reconstructing the genome of three species at the root of the tree: Pelodera teres, Poikilolaimus oxycercus, and Bunonema sp. These data will serve to not only build a robust phylogeny of rhabditids and outgroups, but also to better estimate genome evolution such as gene gain/loss, transposable elements, and potentially new epigenetic marks.

716S **Achieving epigenetic precision: The complete human diploid reference genome of RPE-1 identifies the phased epigenetic landscapes from multi-omics data** Emilia Volpe, Luca Corda, Simona Giunta Dpt. Biology & Biotechnology Charles Darwin, University of Rome Sapienza

Comparative analysis of recent human genome assemblies highlights profound sequence divergence that peaks within polymorphic loci such as centromeres. This raises the question about the adequacy of relying on human reference genomes to accurately analyze sequencing data derived from experimental cell lines. Here we propose a novel approach, referred to as 'isogenomic reference', that leverages a matched reference genome to perform multi-omics analyses. We have generated a new diploid genome assembly for the human retinal epithelial cells (RPE-1), a widely used non-cancer laboratory cell line with a stable diploid karyotype, that presents phased haplotypes and chromosome-level scaffolds completely spanning centromeres. Using this assembly, we have characterized haplotype-resolved genomic variation unique to RPE-1, including a stable marker chromosome X with a 73.18 Mb segmental duplication of chromosome 10 translocated onto the microdeleted telomere t(X*q*;10*q*), specific to this cell line. Comparative analyses revealed sequence polymorphism within centromeric regions, including unexpected genetic and epigenetic diversity among haplotypes for all chromosomes. Using our assembly as reference, we re-analyzed both our own and publicly available sequencing, methylation and epigenetic data generated in RPE-1 which had previously been analyzed with non-matched and non-diploid reference genomes. Our results show that the isogenomic reference improves alignments with an increased mapping quality up to 85% while halving mismatches, resulting in significant changes in peaks calling related to centromeres. Notably, we were able to call the precise kinetochore site for each chromosome and show how differences between the two haplotypes, with implications in chromosome segregation dynamics. Our work represents a proof-of-concept, showcasing the use of matched reference genomes for multiomics analyses and, at scale, serves as the foundation for a call to comprehensively assemble experimentally relevant cell lines for a widespread application of isogenomic reference genomes.

717S **Next-generation map of constrained coding regions from hundreds of thousands of humans** Suchita Lulla, Aaron Quinlan, Peter McHale University of Utah

A longstanding interest in human genetics has been to identify the subset of the human genome that is critical to normal human development. In pursuit of this question, we previously created a map of constrained coding regions (CCRs) [1], or regions where the absence of genetic variation implies negative selection due to critical function during development, and in which variation is expected to cause disease. We defined a region as the coding distance (in coding space) between consecutive protein-changing variants, and we weighted region lengths by sequencing coverage. We then quantified the degree of constraint of each region in proportion to its length, where regions with the greatest distance between protein-changing variants have the highest predicted constraint. This map provided a more fine-scale metric of intraspecies constraint than other previously established gene-wide measures and nominated new protein-coding regions that are essential to human development.

We will present progress on a more rigorous approach to modeling constraint in coding space that calculates a ratio of observed to expected constraint in small sliding windows across protein-coding exons. This approach allows us to relax the original requirement of the complete absence of protein-changing variants in a CCR to capture cases where genetic variation in a region is present, but extremely sparse, which will occur more often as cohort sizes increase. The gnomAD v4 dataset provides unprecedented deep sampling of human coding variation, coupled with our more complete model of constraint, allowing us to construct a higher-resolution and more accurate map of constraint and assess which CCRs from the previous dataset survive given the expanded dataset. We anticipate that our efforts will yield a much higher resolution map of

constrained coding regions in the human genome, providing a valuable resource for rare disease interpretation and identifying coding sequence that is essential to human development.

718S **Establishing baseline transcriptome profiling of ATCC's human and mouse cell lines** Ajeet P Singh, Rula Khairi, Amy L Reese, Jade Kirkland, Corina Tabron, Noah Wax, James Duncan, Robert Marlow, Steve King, Ana Fernandes, John Bagnoli, Briana Benton, Jonathan L Jacobs ATCC

Cell lines are essential tools in biomedical research, serving as primary resources for numerous laboratory experiments. However, cell line contamination and inaccuracies in public datasets can adversely affect research. To address the need for authenticated cell lines with comprehensive data provenance, ATCC® collaborates with QIAGEN® to establish the ATCC® Cell Line Land. This continually growing database contains baseline whole transcriptome (RNAseq) data traceable to the highly utilized human and mouse cell lines in ATCC®'s repository. By providing this data, we aim to refine cell line selection, shifting from traditional methods to decisions informed by genotype-phenotype correlations. Such informed decisions can foster reproducible research, which can reduce the timelines in the development of impactful therapeutics. Currently, we are creating over 1,000 new RNAseq data sets annually and, ultimately, sequence all the cell lines held within ATCC's collection. To date, we've sequenced over 300 cell lines from kidney, blood, and lung tissues (Over 1,500 datasets), encompassing primary, engineered, cancerous, and healthy cells. Our overarching objective is to establish research standards by offering traceable, standardized, and authenticated transcriptomic data.

In this study, we conducted a comparative analysis of the naive HEK-293 (ATCC® CRL-1573™) cell line and its derivatives, which are extensively used in virology and biomanufacturing production, and in research and development. Through transcriptome analysis, we identified molecules exhibiting both general and specific profiles across these cell lines. Our pilot study on differential gene expression specifically highlighted distinct genes and pathways in the HEK-293.2sus (ATCC® CRL-1573.3™) cells cultivated in suspension as compared to the adherent parental HEK-293 cells (ATCC® CRL-1573™). Further analysis using Ingenuity Pathway Analysis(r) unveiled dysregulated pathways and pivotal upstream regulators that influence cellular phenotypes and gene expression shifts. Recognizing the significance of HEK-293 cells in these applications, our study leverages RNAseq to shed light on unique gene expression patterns and pathways within this cell line panel, particularly under suspension conditions, offering valuable insights to optimize their use and improve therapeutic outcomes. The meticulously curated RNAseq data housed in the ATCC Cell Land empowers researchers with the ultimate decision-making tool for selecting the right cell line model for their own use cases.

719S **Diversity of cow transposable elements and developmental expression in early embryos** Guangsheng Li, Jingyue (Ellie) Duan Animal Science, Cornell University

Transposable elements (TEs) are genetic elements that replicate and mobilize within host genomes, influencing gene regulation and genome stability. However, their role in cattle genome remains poorly understood. This study aims to investigate TE diversities in cattle genome and determine their transcription during early embryo development. First, we identified that TEs constitute 46.29% of the bovine genome, with DNA transposons accounting for 2.15% and retroelements at 44.1%. To estimate TE age, we constructed phylogenetic trees for all TE families with at least 10 copies, using defragmented insertions of at least 100 bp in length (n=677), revealing a moderate correlation between TE age and TE copy numbers. Interestingly, TE length and age showed no correlation. For the genomic distribution of TEs, we observed that TEs were more enriched in intergenic and intronic regions than gene bodies, including exons, and promoters. Moreover, different TE classes exhibited correlations on their distribution, with DNA and SINEs negatively correlated with LINEs and LTRs, but positively correlated with gene distribution. Next, we analyzed 163 samples representing diverse developmental stages and embryo types, including in vivo, *in vitro,* and somatic cell nuclear transfer (SCNT) embryos at each pre-implantation stage. At the transcriptome level, TE expression clusters showed distinct changes between 4-cell and 8-cell stages in *in vivo* embryos, while similar patterns were observed between 8-cell and 16-cell stages in both in vitro and SCNT embryos. These results suggest different embryo productions impact the timing of zygotic genome activation. Overall, this study provides comprehensive profiles of TEs in the bovine genome and novel insights into the complex molecular mechanisms of early embryogenesis. These findings open avenues for further research into the functional roles of TEs in embryonic development and their implications in reproductive technology and embryo quality.

720S **The first two chromosome-scale genome assemblies of American hazelnut enable comparative genomic analysis of the genus *Corylus*** Scott Brainard[1], Tomas Bruna[2], Julie C Dawson[1], Dean Sanders[3] [1]Plant and Agroecosystem Sciences,

University of Wisconsin-Madison, [2]U.S. Department of Energy Joint Genome Institute, Lawrence Berkeley National Lab, [3]Bioinformatics Resource Center, University of Wisconsin-Madison

The native shrub *Corylus americana* is currently utilized in breeding programs developing commercially viable hazelnut varieties for the Upper Midwestern U.S. Modern breeding methods (e.g, marker-assisted selection and genomic prediction) are greatly aided by a high-quality reference genome assembly, however this is currently lacking for *C. americana*. We have therefore developed the first chromosome-scale reference assemblies for *C. americana*, using the accessions 'Rush' and 'Winkler'.

Genomes were assembled using HiFi PacBio reads and Arima Hi-C data, and Oxford Nanopore reads and a high-density genetic map were used to perform error correction. N50 scores are 31.9 Mb and 35.3 Mb, with 90.2% and 97.1% of the total genome assembled into the 11 pseudomolecules, for 'Rush' and 'Winkler', respectively. Gene prediction was performed using custom RNAseq libraries and protein homology data. 'Rush' has a BUSCO score of 99.0 for its assembly and 99.0 for its annotation, while 'Winkler' had corresponding scores of 96.9 and 96.5, indicating high-quality assemblies. These two independent assemblies enable unbiased assessment of structural variation within *C. americana*, as well as patterns of syntenic relationships across the *Corylus* genus. Furthermore, we identified high-density SNP marker sets from genotyping-by-sequencing data using 1,343 *C. americana*, *C. avellana*, and *C. americana* x *C. avellana* hybrids, in order to assess population structure in natural and breeding populations. Finally, the transcriptomes of these assemblies, as well as several other recently published *Corylus* genomes, were utilized to perform phylogenetic analysis of sporophytic self-incompatibility (SSI) in hazelnut, providing evidence of unique molecular pathways governing self-incompatibility in *Corylus*.

These assemblies are an important first step in providing a resource for using next-generation sequencing data in the improvement of *C. americana*, while also enabling comparisons of structural variation across *Corylus* species. We hope these assemblies will aide in the application of modern breeding methods to the development of commercially viable hazelnut varieties for the Upper Midwest.

721S **Qploidy: ploidy and aneuploid determination for polyploid species** Cristiane H Taniguti[1], Jeekin Lau[2], David Byrne[2], Oscar Riera-Lizarazu[2] [1]Horticultural Sciences, Texas A&M University, [2]Horticulture Sciences, Texas A&M University

In the field of plant genetics, ploidy detection has traditionally relied on methods such as microscopy, flow cytometry, or their correlation with pollen diameter. However, these methods come with a set of limitations including low precision and unreliability for many samples. In human cancer genetics studies, single nucleotide polymorphism (SNP) array technologies have been successfully used to determine ploidy and identify aneuploidy. The application of these technologies for ploidy and aneuploidy estimations in the field of polyploid plant genetics remains relatively uncommon despite the substantial volume of array data generated for other research goals in plants. The challenge in this context is the normalization of allele intensities in polyploid plant array data due to the quality and stability differences between plant and human arrays. Furthermore, the fact that available normalization methods consider predominately diploid genotype calls, a common occurrence in humans but not in polyploid plants. Thus, our study aims to develop methods that use genotypic data for these ends. First, we developed a standardization method for array data intensities to account for higher ploidy genotype calls, specifically tailored to the needs of polyploid plants. We implemented the method in an R package and Shiny app called Qploidy. To evaluate the effectiveness of this approach, we conducted experiments using a total of 1,536 rose samples from collections and mapping populations. The method successfully differentiated 176 diploid, 76 triploid, and 420 tetraploid plants, as well as seven tetraploid mapping populations (N=769). It also detected an average of 2.8% of aneuploid individuals among the tetraploids in the collections and a substantially greater proportion within mapping populations, averaging 17.4%. We explored the consequences of those aneuploids when constructing linkage maps for mapping populations. The presence of aneuploidy led to a higher number of erroneously estimated recombination breaks for the affected chromosomes since data for these did not align with the linkage map-building software's assumptions. By quantifying the number of estimated recombination breaks, we could also discern which parent of the mapping population was the source of an aneuploid gamete. The male parent was shown to be a less frequent source than the female parent (84%), revealing a stronger negative effect of aneuploidy on male gametophytes. Among tetraploids, we also observed a higher number of aneuploids with an extra chromosome (pentasomy) than with a reduced one (trisomy). In summary, the Qploidy approach allowed us to characterize many samples in terms of ploidy, aneuploidy, and, in some cases, the parental origin of aneuploid gametes in mapping populations.

722S **Fine-scale genetic mapping using synthetically recombined chromosomes** Christopher J Ne Ville, Alessandro Venega Coradini, Ian Ehrenreich Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California

Since Mendel, geneticists have used crosses to characterize genotype-phenotype relationships. While crosses remain an

incredibly powerful tool in genetics research, they require mating, meiosis, and living parents, and often provide poor mapping resolution due to limited recombination during gametogenesis.

To enable the production of highly recombined chromosomes without crossing, we extendedCReATiNG (Cloning, Reprogramming, and Assembling Tiled Natural Genomic DNA), a technique that we previously developed for cloning segments of natural chromosomes and building synthetic chromosomes from them. In its prior iteration, CReATiNG exclusively involved in vivo DNA assembly of large chromosomal segments, limiting the amount of synthetic recombination that could be generated between two or more donor chromosomes. Here, we introduce an intermediate in vitro assembly step into CReATiNG, after cloning and before chromosome assembly. This step enables the efficient synthesis of chromosomes with substantially more recombination breakpoints and makes it scalable to generate synthetically recombined chromosomes with many, if not all, possible combinations of donor segments. To illustrate these points, we report our efforts to generate 512 recombinant versions of Chromosome I, a ~200-kilobase chromosome, between the budding yeasts Saccharomyces cerevisiae and S. paradoxus in an otherwise isogenic genetic background. This library of synthetically recombined chromosomes should allow us to map the genetic basis of interspecies trait differences at the resolution of 10-20 kilobases.

723S **Determining Gene Function of *YBR220C* in *Saccharomyces cerevisiae*** Hailey H Hendricks, Jill B Keeney Biology, Juniata College

The model yeast *Saccharomyces cerevisiae* is widely studied, yet the function of nearly 10% of genes is unknown; my research focuses on one of these genes of unknown function. I study *YBR220C*, a non-essential protein of unknown function with gene ontology terms of molecular function, biological process, and cellular component annotated as unknown. A series of bioinformatic modules revealed that *YBR220C* may be involved Acetyl-CoA transport and may be localized to the endoplasmic reticulum. In an attempt to determine the function of Y*BR220C*, I deleted the *YBR220C* ORF to study phenotypic differences from wild type in specific growth conditions. Deletion does not impact growth rate. Wild-type and *YBR220C* deletion strains were treated with a variety of carbon sources including 2-deoxy-D-glucose, glucose, acetate, ethanol, and glycerol. Results showed that these medias had no effect on the growth of a *YBR220C* deletion strain compared to wild-type. I›m currently investigating the cellular component of *YBR220C* through fluorescent tagging.

724S **Characterizing and cataloging *Saccharomyces cerevisiae* isolates from ancient metagenome samples** Megan Brown[1], Bryce Taylor[2] [1]Loras College, [2]Biology, Loras College

Saccharomyces cerevisiae, better known as brewer's yeast, has been a companion to humans for thousands of years. During this time, yeast have undergone a domestication process that has yielded strains specialized for baking bread, brewing beer, and making wine. We can see results of this domestication when we look at their genomes. A large body of research has identified genetic variation that likely contributed to the domestication process by providing yeast isolates with useful traits. However, we don't have a good understanding of the evolutionary history of S. cerevisiae, or how our modern strains came to be. One way that we can fill in this timeline is by investigating the genomes of yeast found in ancient samples like coprolites (fossilized feces) or fossilized dental calculus. I am cataloging and characterizing yeast from ancient metagenome studies to gain new insight into the domestication process.

My first aim characterizes a yeast that was identified in Iron Age coprolites from miners in Hallstatt, Austria by a group led by Frank Maixner. I aligned sequencing reads to a reference genome and called SNPs from this strain. I then compared these to a list of known S. cerevisiae SNPs from the 1,002 Genome Project. This left me with 525 candidate novel SNPs. At least three of these ancient SNPs are in genes associated with phenotypes that could be useful for food and beverage production (CPA2, HXK1, and SSA4). I will be using CRISPR/Cas9 to edit these SNPs into a modern yeast to see if they change the phenotype of the modern yeast. This will give us a better understanding of the properties of the Hallstatt yeast, filling in a new point on the evolutionary timeline.

My second aim is to curate a list of other ancient metagenome datasets that include Saccharomyces cerevisiae sequence reads. This information will allow scientists and archaeologists with an interest in fermentation to easily determine where yeast DNA was found in ancient samples. It will additionally enable researchers to investigate how yeast strains were shared among and migrated with ancient peoples.

725S **Examination of the genome of the species *Saccharomyces cerevisiae*** Fred S Dietrich Molecular Genetics and Microbiology, Duke University

Whole genome sequencing of strains of the species *S. cerevisiae* makes it possible to identify the core gene set, and the variable features found in the genome of this species. Using a definition of a gene being conserved at the same location and

orientation in 95% of genome sequences, this species has 5873 core protein coding and RNA coding genes. Analysis suggests more that 200 genes currently annotated in strain S288c should be relabeled as dubious, and there are less that 400 protein coding genes of unknown function. Careful analysis of the genomes identifies an unusual transposable element (Ty7), found in many strains but not in S288c. There are also gene remnants, pseudo genes, and non-core genes, those found in less than 95% of strains at the same location and orientation. Gene remnants are areas where in most or all strains examined homology could be detected to genes found in other organisms, though multiple frame shifts and stop codons suggest the gene is lost in this species. Comparison of the genomes reveals a very clear pattern of the central portions of the genome being comprised primarily of core genes, and a distinct location where the sub-telomere begins and many of the strain-specific genes and pseudogenes are found. Careful analysis of these genomes uncovers multiple interesting features.

Example 1: The COX5B gene contains an intron where the 5' splice site is GC. The other 277 nuclear encoded introns have GT at the 5' splice site, usually GTATGT. Several other introns are currently annotated in S288c as having GC at the 5' splice sites, but they all appear to be dubious introns. 94 out of 94 of the *S. cerevisiae* strains examined in this work, as well as the COX5B gene in *S. paradoxus* have GC at the splice site.

Example 2: Genes encoding tRNA's are generally quite conserved, though there is one example of a change in the anti-codon. While all strains contain multiple copies of a gene encoding identical alanine tRNA (AGC), four strains contain an unusual tRNA, possibly acquired from *Torulospora* sp. by introgression that appears to be an Alanine tRNA (AGC), but the tRNA sequence is similar to Threonine tRNA's. In *Torulospora*, there are two types of (AGC) tRNA genes, one type 100% identical to the Alanine to tRNA genes found in all strains, and the other very similar to the novel tRNA.

More details about this work can be found in bioRxiv 2023.09.07.545205 726S

Investigating the effects of yeast deletion mutations under a resource partitioning model of the cell Michael S. Overton, Sergey Kryazhimskiy Biological Sciences, University of California, San Diego

An important way that microbes adapt to new environments is by acquiring mutations that increase growth rate. However, mutations do not affect proliferation directly, but are transmitted through the molecular architecture of the cell, e.g. a nucleotide substitution changing an amino acid in a catalytic site, which goes on to alter the flux through a hierarchy of pathways to finally affect growth. While this architecture has proven difficult to parse, certain features of biological growth may reduce its complexity, such as its intimate reliance on nutrient metabolism and protein synthesis through translation. A recently developed proteome resource partitioning model (PRPM) exploits these features to accurately predict bacterial growth rates under varying environments using only a few parameters. These include the relative sizes and catalytic efficiencies of proteome sectors devoted to nutrient metabolism and ribosome biosynthesis and the proteome fraction devoted to other processes. To test whether this model is also applicable to the effects of mutations, we reanalyzed yeast transcriptomic and growth rate data of 650 deletion mutants from a pair of recent studies. We found that mutations perturbed the transcriptome in strikingly similar patterns to those expected under the PRPM. Specifically, expression profiles clustered transcripts into three groups, each enriched for GO terms associated with one of the three PRPM sectors. Expression levels of the putative nutrient and ribosome sectors had a strongly negative, linear association, while the third, putative housekeeping sector remained relatively unperturbed. In addition, the growth rate effects of mutations were positively associated with ribosome sector size. These results are all consistent with the PRPM, and suggest that mutations can shift resource allocation between the ribosome and nutrient sectors, which may, in part, explain their growth rate consequences. However, mutations also tended to affect the catalytic efficiencies of the nutrient and translation sectors jointly, rather than independently, as would be expected from the physiological modularity assumed under the PRPM. This suggests that cellular physiology responds to mutations in a manner distinct from that of environmental perturbations. These contrasting results beg for further characterization of yeast physiology under the PRPM, as it could provide a simple and generic mechanism whereby mutations produce growth rate changes.

727S **High-throughput Screening for Aflatoxin B1 Resistance Genes in Budding Yeast and VERO-E6 Cells Identifies Genes That Confer Resistance to Replication Stress** Michael Fasullo[1], Chris Vulpe[2], Abderrahmane Tagmount[2], Miral Dizdaroglu[3], Bharti Bharti[4] [1]Nanoscale Science and Engineering, University at Albany, [2]University of Florida, [3]National Institute of Standards and Technology, [4]University at Albany

Introduction: Aflatoxin B1 (AFB1) is a class I carcinogen and a potent known hepatocarcinogen. The bioactivated epoxide derivative generates mutagenic DNA adducts. Previously, we used a "humanized" yeast deletion library that expresses CYP1A2 to profile the yeast genome and identified 86 resistance genes, which included 15 DNA repair genes. These DNA repair genes included those that participate in nucleotide excision repair (NER) and homologous recombination. We hypothesize that mammalian genes, orthologous to these yeast genes, also confer AFB1 resistance. **Methods:** Our strategy to identify mammalian AFB1 resistance genes utilizes a CRISPR KO approach to knockdown ~19,053 genes in green monkey kidney

epithelial (VERO-E6) cells. Four sgRNAs for each of the ~19,053 genes were cloned into the LentiCRISPRv2 Puro vector to generate the CRISPR KO library. The resulting transfectants were exposed to 200 nM AFB1 for seven and fourteen days. AFB1-associated DNA adducts were detected after exposure to 200 nM AFB1. Resistance and sensitive genes were identified using the negative binomial approach implemented in edgeR and CRISPR analysis software (MAGeCK). Data sets were obtained at t0, and at t7 and t14 for toxicant exposed and control cells. **Results:** From comparing toxicant exposed (t7, t14) and the initial cell library (t0), we identified 55 common sensitivity genes, including genes involved in AFB1 bioactivation (POR, CYP3A4) and senescence (SMARCD1, BACH1, CDKN1). We identified twelve common resistance genes, including those that function in DNA replication stress (RFC3, MCM3) and in non-homologous end joining (APLF). In comparing toxicant (t7) to control (t7), we identified NER genes (ERCC4, UVSA). XRCC3, a Rad51 paralog, was identified in comparing t14 to t0 data sets. **Discussion**: We obtained initial results that genes conferring AFB1 sensitivity in VERO include those that bioactivate AFB1, and genes conferring resistance include NER NHEJ, and genes that participate in homologous recombinaiton. These data suggest that a subset of DNA repair pathways that confer AFB1 resistance are shared among both lower and higher eukaryotes.

728V **NCBI's RefSeq Select dataset for mouse genome** Anjana R Vatsan, Alexander Astashyn, Olga Ermolaeva, Tamara Goldfarb, Diana Haddad, John Jackson, Vinita Joardar, Vamsi Kodali, Kelly McGarvey, Michael Murphy, Craig Wallin, David Webb, Terence D Murphy, Shashikant Pujar National Center for Biotechnology Information of the National Library of Medicine, National Institutes of Health

The reference sequence (RefSeq) project at the National Center for Biotechnology Information (NCBI) aims to provide high quality, complete and accurate annotation of human and mouse genomes along with other organisms across the tree of life. Genes often are annotated with multiple RefSeq transcripts and proteins due to alternative splicing. While some alternatively spliced transcripts have been shown to play important functions in several tissues including disease related state, others may not be of great significance. Several transcripts per gene can also become problematic in certain studies like comparative genomics and evolutionary analysis. NCBI's RefSeq Select dataset provides a representative transcript for every protein coding gene. RefSeq Select transcripts are well supported by experimental data, biologically relevant and conserved. The dataset is produced using computational processes and manual curation by a group of expert curators. The RefSeq Select dataset was originally available for human but now includes mouse (GRCm39) and rat (mRatBN7.2) genomes, as well as a subset of prokaryote proteins. We aim to expand it to other high value organisms. The RefSeq Select transcripts can be accessed from multiple NCBI resources such as Gene, RefSeq, Genome Data Viewer and annotation files, and are available for bulk download from NCBI's FTP sites. BLAST now offers RefSeq Select databases for faster searches and better results. This work is funded by the National Center for Biotechnology Information of the National Library of Medicine, National Institutes of Health.

729V **Genotype vs environment effect on housefly *(Musca domestica)* microbiome** Sohana Al Sanjee, Kiran Adhikari, Richard P. Meisel Biology and Biochemistry, University of Houston

Host-associated microbiomes affect physiology, behavior, health, and other phenotypes. Microbiomes can be highly variable among individuals, which can be caused by genetic differences between hosts, variation across environments, or the interactions between genotype and environment. Temperature may be an especially important environmental factor on host-associated microbiomes because it affects both host physiology and myriad bacterial characteristics. In particular, increased temperature can disrupt the microbiomes of ectotherms, but it is not clear if that disruption is caused by higher temperatures *per se* or merely by deviating from the thermal optimum. Addressing that question requires shifting a warm adapted host to a cooler temperature and measuring the change in the associated microbial community. House fly (*Musca domestica*) is a well-suited model organism to those ends because it is warm-adapted animal with segregating genetic variation that modulates temperature-dependent phenotypes. We performed two studies of house fly associated bacterial communities across genotypes and environments. First, we used 16S rRNA sequencing to profile the microbiomes of two-house fly genotypes with temperature-dependent phenotypic effects raised at two different temperatures (18°C and 29°C). We sampled 26 male flies from each of the genotype-by-temperature combinations. Second, we sequenced 16S rRNA from 86 house fly males from two collection sites in Texas. The bacterial communities associated with the house flies differed between the environments in both studies (either developmental temperature or collection site), but we did not detect significant differences between genotypes. Specifically, the house flies raised at 29°C had microbiomes that were more similar to each other (i.e., lower between-fly beta diversity) than the 18°C flies. Similarly**,** there were differences in the between-fly bacterial diversity between the two collection sites within Texas. Our results therefore provide consistent evidence of an environmental effect on the house fly microbiome and no evidence of an effect of the host genotype. Our results also provide evidence that colder temperatures increase the heterogeneity of the house fly microbiomes. More generally, our results suggest that deviation from the thermal optimum (in this case shifting from warm to cooler temperatures) disrupts the host associated microbiome, regardless of whether the disruption is toward hotter or colder temperatures.

730V **Sequence Analysis of Heat Resistant Gene in Naked Neck Nigerian Indigenous Chicken** Hannah E Etta Animal and

Environmental Biology, University of Cross River State

The sequence characteristics of heat resistant genes (HRG) in naked neck Nigerian Indigenous chicken (NIC) was investigated. The HRGs are IL6, HSPB2, HSP2B, HSFP, and HSP90. Relevant DNA and amino acid sequences for the heat resistant genes hoisted by the National Centre for Biotechnology Information (NCBI) database were sourced for and retrieved from the genebank using the FASTA format and basic local alignment search tool (BLAST). The were analyzed using Chromas 7.0 software. The results revealed a total of 10 conserved regions which were visible at the exons sites of the multiple aligned nucleotide sequences of the heat resistant genes. Results obtained for Protein sequence characterization showed high variability in the characteristics of heat resistant genes. The polymorphic characteristics scores were also obtained. From these results, it can be deduced that the HSG in the naked neck NIC should be preserved as it shows low mutation rate and can also be used to modify the genes of other organisms that are very susceptible to high temperature especially here in the tropics. This investigation presents valuable insights into the functional roles of the HRG in thermal adaptation, stress response, and overall health Status of the naked neck NIC. It provides bench mark information that could be useful in the strategic planning for the conservation and management of the breed.

731V **Three-dimensional genome organization in the mosquito central nervous system** Christopher Catalano[1], Xiao Li[2], Michael Levine[2] [1]Molecular Biology, Princeton University, [2]Lewis-Sigler Institute, Princeton University

Mosquito-borne diseases are responsible for nearly one million deaths per year, killing more humans than any other predator by far. There have been intensive efforts to understand and modify the genomes of disease-bearing mosquito species, and here we add to the understanding of the chromosome-level organization of the mosquito genome. Recently described meta-loops in *Drosophila* coordinate the expression of distant genes, spanning 2-20 megabases, primarily in post-mitotic neurons of the central nervous system. We have produced a comprehensive Micro-C chromosome conformation map for the adult brain of the malaria vector, *Anopheles coluzzii*. This high-resolution, three-dimensional map reveals long-range meta-loops in the adult *Anopheles* brain. These meta-loops are often associated with genes influencing neuronal function, including cell surface adhesion molecules involved in axon guidance and connectivity. Further, we have identified specific DNA segments that act as robust loop anchors, facilitating spatial interactions between distant genomic loci. This work has the potential to identify regulatory loops as promising targets for disruption, adding to the arsenal of technologies aimed at controlling mosquito behaviors in natural populations.

732V **5-Nitroimidazole-resistance in *Mycoplasma genitalium* strains is associated with mutations in an NAD(P)H-dependent FMN reductase gene.** Abhi Kancherla[1], Alessandro Rizzi[2], Cameron Weller[2], Derek Wood[3], Gwendolyn Wood[4] [1]Seattle Pacific University, [2]Department of Chemistry and Biochemistry, Seattle Pacific University, [3]Department of Biology, Seattle Pacific University, [4]Department of Medicine, University of Washington

Mycoplasma genitalium (MG) is a sexually transmitted pathogenic bacteria that causes urethritis in men and pelvic inflammatory disease (PID) in women. MG has developed resistance to first-line antibiotics like azithromycin, doxycycline, and moxifloxacin—making it one of three microorganisms added to the CDCs Watch List for Antibiotic Resistant Threats in the US. 5-Nitroimidazoles (5-Ni) are being evaluated as alternative treatment options based on two recent studies. A 2020 study by Weisenfield found that adding metronidazole to a standard multidrug treatment with ceftriaxone and doxycycline reduced MG presence in patients with PID and we recently showed that MG was susceptible to 5-Nis. These drugs may provide alternative treatment options following clinical studies, however, MG can develop resistance to them. In this study, we isolated and sequenced the genomes of nine 5-Ni-resistant G37S mutants with the MinION Mk1B genome sequencer. We identified mutations in the MG_342 and MG_179 genes, which encode for a putative NAD(P)H-dependent FMN reductase and energy-coupling factor (ECF) transporter ATPase, respectively. Mutations in the FMN reductase may cause reduced expression or loss of function of the enzyme leading to resistance.

733V **Investigating the Role of Transposable Element-Derived Promoters in Tissue-Specific Gene Expression and Phenotype in Zebrafish Testis** Irene Wang, Yujie Chen, Hyung Joo Lee, Ju Heon Maeng, Yiran Hou, Ting Wang Washington University School of Medicine in St. Louis

Transposable elements (TEs) are repetitive sequences found in various eukaryotic genomes, constituting a substantial portion of vertebrate genomes, including zebrafish. Emerging studies suggest that TEs can act as cis-regulatory elements, offering alternative promoters for gene regulation. Previous work from our lab demonstrated that 37% of TEs are associated with active regulatory states in adult zebrafish tissues, particularly in the testis. Additionally, we confirmed that novel TE-derived promoters have the capacity to initiate testis-specific transcription of alternate gene isoforms. However, it remains unclear whether these TE-derived promoters play a crucial role in testis development.

In this study, we have selected two promising candidates, *srl* and *rasgrp4*, from a pool of 413 novel TE-derived promoters identified using nanoCAGE and RNA-seq analyses. Employing CRISPR-Cas9 technology, we performed targeted deletion of both the canonical promoter and the TE-derived promoter for each candidate. Our goal is to generate homozygous mutant zebrafish lines to delve into the functional significance of TE-derived promoters in terms of their impact on testis-specific gene expression and overall testis development. This investigation will shed light on the essentiality of TE-derived promoters in zebrafish development and tissue-specific gene regulation.

734V **Health assessment of Resident Killer Whale populations via whole genome analysis** Lance Barrett-Lennard[1], Adam Warner[1], Stephane Flibotte[2], Thomas Doniol-Valcroze[3], Sheila Thornton[3] [1]Raincoast Conservation Foundation, [2]LSI Bioinformatics Facility, University of British Columbia, [3]Fisheries and Oceans Canada

Southern Resident Killer Whales (SRKW) and Northern Resident Killer Whales (NRKW) are listed as endangered and threatened, respectively, under Canada's Species at Risk Act, and recovery of these populations face a number of obstacles. Noise impacts on Resident Killer Whale (RKW) individuals and populations include degradation of the acoustic environment, stress responses, and a decrease in foraging efficiency. In addition, displacement of RKW from key foraging areas is likely to result in changes in the stock composition of their salmonid prey and may lead to nutritional deficiencies. Hormone analyses from individuals (fecal and blow) provide insights into the impacts of both noise and nutritional stress, and identification of prey from fecal samples informs our knowledge of prey selection and foraging success. Health-related hormone data can be linked to a specific individual by genotyping the RKW DNA found within fecal samples and matching to archived skin biopsy samples from RKWs.

While anthropogenic impacts are of primary concern, of equal importance is the need to identify intrinsic factors that may be limiting SRKW recovery. This includes the extent of inbreeding and its impacts on the population. Comparisons of SRKW inbreeding to that observed in the threatened NRKW population is an important aspect of this analysis, as this small ecologically- similar population continues to increase in numbers. Whole genome sequences obtained from 141 NRKW biopsies collected over the last 25 years have been used to assess the level of inbreeding within the population, and comparisons with the SRKW data reveal the level of genetic diversity within each of the populations. Characterizing the impact of intrinsic factors such as inbreeding is necessary to obtain a more complete understanding of the magnitude of anthropogenic threats. This knowledge supports the development of efficient and effective mitigation measures targeted at anthropogenic threats.

In addition, unique genetic fingerprints have been produced for each of the 141 NRKW in this study using a 68 loci SNP panel to provide as a reference for matching RKW fecal samples collected for health-related hormone analysis to specific individuals. We have developed a Nanopore-based SNP amplicon sequencing protocol to rapidly genotype RKW fecal samples using the same 68 loci SNP panel, allowing for in-house DNA sequencing and matching of fecal samples using commercially available flow cells. Matching of RKW fecal samples to individuals allows for health-based assessments to be linked to individuals, and a broader understanding of overall population health.

735T **Extreme allelic diversity likely underlies adaptation to environmental heterogeneity** Erik Andersen Biology, Johns Hopkins University

Starting in the 1950s, Stebbins and others argued that selfing is an evolutionary dead end because these species cannot adapt to changing environments. However, countless selfing species have persisted over long evolutionary time scales, so they must have adapted to environmental heterogeneity. Recently, numerous examples of punctuated genomic regions harboring high levels of diversity have been discovered across selfing lineages of plants and nematodes. In the *Caenorhabditis* genus, selfing has evolved three times independently, and these hyper-divergent regions are found in all three species. Specifically in *C. elegans*, these regions were found to contain unique sets of genes enriched for environmental response functions, including pathogen resistance, stress responses, and food sensing. These discoveries led to the hypothesis that hyper-divergent regions could give these selfing species a means to adapt to changing environments. We used short- and long-read technologies to create new reference genomes and gene models for *C. briggsae* and *C. tropicalis*, the two less well studied species as compared to *C. elegans*. Additionally, we sequenced the genomes of all known wild strains from each of these three species to identify hyper-divergent regions and their gene contents. We have found hundreds of previously unknown and uncharacterized *Caenorhabditis* genes, and these genes are enriched for environmental responses. These wild strains paired with ecological sampling data led to hypotheses about adaptation to specific environmental stress (*e.g.*, pathogens). I will present our progress validating how the genes in these regions promote adaptation to different stresses in the natural niche. The evolutionary origins of these regions are unknown but could be ancestral genetic diversity maintained by long-term balancing selection from an outcrossing ancestor or recent adaptive introgression from a closely related outcrossing species. Because *C. elegans* lacks a closely related outcrossing species, we turned to *C. briggsae* and its closely related outcrossing

sister species, *C. nigoni*, where we can investigate signatures of balancing selection or evidence of recent introgression events. We sought to identify shared genetic variation and haplotypes between these two species to test hypotheses about the origins of hyper-divergent regions. The results from these studies provide insights into how selfing shapes the patterns of diversity in selfing species and how selfing species are able to adapt to environmental heterogeneity.

737T **Rapid evolutionary diversification of the *flamenco* locus across simulans clade *Drosophila* species** Sarah Signor[1], Jeffrey Vedanayagam[2], Bernard Kim[3], Filip Wierzbicki[4], Robert Kofler[4], Eric C. Lai[5] [1]North Dakota State University, [2]University of Texas, San Antonio, [3]Stanford University, [4]Vetmeduni Vienna, [5]Sloan-Kettering Institute

Suppression of transposable elements (TEs) is paramount to maintain genomic integrity and organismal fitness. In *D. melanogaster*, the *flamenco* locus is a master suppressor of TEs, preventing the mobilization of certain endogenous retrovirus-like TEs from somatic ovarian support cells to the germline. It is transcribed by Pol II as a long (100s of kb), single-stranded, primary transcript, and metabolized into ~24-32 nt Piwi-interacting RNAs (piRNAs) that target active TEs via antisense complementarity. *flamenco* is thought to operate as a trap, owing to its high content of recent horizontally transferred TEs that are enriched in antisense orientation. Using newly-generated long read genome data, which is critical for accurate assembly of repetitive sequences, we find that *flamenco* has undergone radical transformations in sequence content and even copy number across *simulans* clade Drosophilid species. *Drosophila simulans flamenco* has duplicated and diverged, and neither copy exhibits synteny with *D. melanogaster* beyond the core promoter. Moreover, *flamenco* organization is highly variable across *D. simulans* individuals. Next, we find that *D. simulans* and *D. mauritiana flamenco* display signatures of a dual-stranded cluster, with ping-pong signals in the testis and/or embryo. This is accompanied by increased copy numbers of germline TEs, consistent with these regions operating as functional dual-stranded clusters. Overall, the physical and functional diversity of *flamenco* orthologs is testament to the extremely dynamic consequences of TE arms races on genome organization, not only amongst highly related species, but even amongst individuals.

738T **An Evolutionary Puzzle: Examining the High Insertion Bias of P-Elements into X-TAS** Shashank Pritam[1], Robert Kofler[2], Almorò Scarpa[3], Sarah Signor[1] [1]Biological Sciences, North Dakota State University, [2]Institut für Populationsgenetik, [3]Vienna Graduate School of Population Genetics

Transposable elements, also known as transposons or “jumping genes,” are DNA sequences that can move and replicate within the genome. Transposons significantly impact genome stability, and understanding their dynamics is crucial for evolutionary biology and medical research. The formation and function of piRNA clusters still need to be fully understood. Previous research based on the prevalent population genetics model called the “Trap Model” has demonstrated that invading transposable elements (TEs) are stopped in their proliferation when a TE copy gets inserted into a piRNA cluster. This insertion triggers the production of piRNAs that silence transposons in the germline. The P-element, a well-known piRNA cluster, has been observed to show a strong insertion bias into piRNA clusters. This is peculiar behavior since piRNA clusters are known to silence transposable elements (TEs) according to the Trap Model. To understand the dynamics of transposon insertion and its influence on genome stability, we investigated transposon dynamics accounting for piRNA-mediated silencing of TEs. Our preliminary result suggests that organisms can compensate for smaller piRNA cluster sizes through increased transposon insertion bias into the clusters. Population fitness rises with greater cluster size and higher average insertion bias. However, negative bias leads to population extinction despite the large cluster size. Further research quantifying transposon impacts and insertion biases across species will enable more accurate modeling of this arms race between transposons and host genomes. Our model provides a framework for understanding transposon invasion and the role of piRNAs in maintaining fertility and genome stability.

739T **Evolutionary rate covariation is pervasive between unrelated glycosylation pathways and points to potential disease modifiers** Holly Thorpe[1], Nathan Clark[2], Clement Chow[3] [1]Human Genetics, University of Utah, [2]University of Pittsburgh, [3]University of Utah

Glycosylation, a common post-translational modification, is necessary for protein localization, folding, and stability. Defects in glycosylation pathways, such as N-linked glycosylation, O-linked glycosylation, and GPI anchor synthesis, lead to rare diseases classified as Congenital Disorders of Glycosylation (CDG). CDGs typically present with seizures, hypotonia, and developmental delay, but display large clinical variability with symptoms affecting every system in the body. This variability suggests modifier genes affect the phenotypes. I am employing evolutionary approaches to identify modifier genes of CDGs.

Evolutionary Rate Covariation (ERC) relies on the premise that proteins that interact physically or genetically or are functionally related evolve at similar rates. ERC values are calculated using the correlation coefficient of evolutionary rates of protein pairs in a species tree. I used ERC to identify genome-wide covariation with proteins involved in GPI anchor synthesis. There was enriched, strong ERC among GPI anchor synthesis proteins. Unexpectedly, there was also enriched ERC between GPI anchor

synthesis proteins and proteins in other glycosylation pathways, suggesting underappreciated overlap between the different pathways. Gene Ontology analysis of top proteins showing high ERC with GPI anchor synthesis proteins revealed enrichment in RNA modification and DNA damage repair, suggesting interactions between these processes and GPI anchor synthesis. Protein pairs with the highest ERC scores included HTT and PIGG and ATG7 and PIGG. HTT and ATG7 are associated with neurodegenerative disorders, possibly indicating overlap in pathophysiology between the disorders.

To functionally validate these exciting signals, I tested for genetic interactions using the *Drosophila* eye as a model. Many GPI anchor synthesis genes are necessary for *Drosophila* eye development and knockdown of these genes leads to small, disorganized, rough eyes. Using double knockdowns of GPI anchor synthesis genes and coevolving genes in the *Drosophila* eye, I identified genetic interactions between genes previously thought to be unrelated. Many of the strongest evolutionary signals validate as interactors in this *in vivo* analysis. Evolution and covariation are underutilized tools for identifying disease-relevant, novel genetic interactions. These connections could lead to better understanding of glycosylation pathways and potential treatments for CDGs.

740T **Population genomics of *Drosophila pseudoobscura*** Camryn Kritzell, Zhao Zheng, Christopher Gonzales, Richard Meisel University of Houston

Drosophila pseudoobscura is a model organism for population genetics, speciation genetics, and sex chromosome evolution. For example, natural populations of *D. pseudoobscura* harbor a rich inversion polymorphism on their third chromosome, which has been a model system for studying clinal variation and genome evolution for decades. In addition, *D. pseudoobscura* has a neo-X chromosome, which formed when an autosome fused to the ancestral *Drosophila* X chromosome. This neo-X chromosome represents a natural evolutionary experiment that is informative of the selection pressures acting on X-linked genes. Despite the tremendous utility of *D. pseudoobscura* as a model organism, genome-wide genetic variation has yet to be comprehensively explored in this species beyond the third chromosome inversion polymorphism. To address that shortcoming, we sequenced the genomes of >60 isolates (inbred lines) of *D. pseudoobscura* from across the species' range in North America. We used these data to identify single nucleotide polymorphisms and small insertion/deletion polymorphisms, as well as fixed substitutions with a closely related species (*Drosophila miranda*). Tajima's *D* was negative across most of the genome, consistent with a recent population expansion. However, the magnitude of Tajima's *D* varied across chromosomes, suggesting unique intra-specific evolutionary trajectories across chromosomes. We found no evidence for population structure across most of the *D. pseudoobscura* genome, consistent with previous analyses of individual loci that suggested high migration rates across the species' range effectively create a single, panmictic population. In contrast, there was substantial evidence for population structure on the third chromosome, which we attribute to inbred lines carrying different arrangements of the third chromosome. We used this population structure, along with geographic information, to probabilistically infer the arrangements carried by each line. Lastly, we failed to detect evidence for a higher adaptive substitution rate on the ancestral- or neo-X chromosomes, suggesting that there is not a faster-X effect.

741T **Accelerated evolution in the protein components of the genomic dark matter, heterochromatin** Leila Lin[1], Yuheng Huang[1], Jennifer McIntryre[1], Ching-Ho Chang[2], Serafin Colmenares[3], Yuh Chwen G Lee[1] [1]Ecology & Evolution, UC Irvine, [2]Fred Hutchinson Cancer Research Center, [3]Cell and Molecular Biology, UC Berkeley

Heterochromatin plays an important role in maintaining the stability of the genome despite being the transcriptionally silent, gene-poor, and repeat-rich compartment of the genome. Without the silencing effects of heterochromatin, deleterious selfish genetic elements, such as transposable elements, are free to jump around the genome and disrupt functional elements. Accordingly, genes that encode the regulatory elements that modulate heterochromatin are theorized to be highly conserved due to their essential functions. However, previous studies have found a few heterochromatin-regulating genes fast evolve through rapid accumulation of amino acid substitutions or exhibit differences in gene copy number between species. Here, we aim to investigate if previously observed fast evolution of genes modulating heterochromatin is a common trend among all genes known to influence heterochromatin function amongst 16 *Drosophila* species, spanning 40 MYR. Our candidate genes include (1) PEV modifiers known to modulate the spreading of repressive epigenetic marks from heterochromatin, (2) histone-modifying enzymes that influence enrichment levels of repressive epigenetic marks, H3K9me2/3, and (3) genes whose protein products localize to heterochromatin, suggesting their potential functional roles in heterochromatin. For the control, we used polycomb genes as they also interact with repressive epigenetic marks, H3K27me3, but play no role in heterochromatic function. We found that, compared to control polycomb genes, candidate genes that enhance heterochromatin silencing show more prevalent adaptive evolution in terms of changes in amino acid sequences and copy number variation at both short and long evolutionary time scales. Many of the signatures of accelerated evolution fall within domains with known functions, such as nucleic acid binding and histone modification. Interestingly, evidence of adaptive evolution was also found in intrinsically disordered regions (IDRs) that are suggested to play important roles in the phase properties of heterochromatin. In fact, we found that fast-evolving candidate genes show greater variability in the total IDR content than other genes. We further

identified that the evolutionary rates of our candidate genes are significantly associated with the abundance of repetitive sequences across species. These findings suggest that the rapid evolution of genes involved in heterochromatin regulation may be tightly intertwined with the rapidly changing repeatome through not only their well-structured protein domains but also their phase properties.

742T **Breaking mating barriers between *Drosophila melanogaster* and *D. simulans*** Tianzhu Xiong, Daniel Barbash Molecular Biology and Genetics, Cornell University

Interspecific hybrids between *Drosophila melanogaster* and *D. simulans* have been incredibly useful to study repetitive DNA regulation and hybrid incompatibilities. However, creating hybrids is difficult, especially between *D. melanogaster* males and *D. simulans* females. Here we report the progress to improve the mating rates in this cross direction. Between 15% to 43% of females can be successfully inseminated by the other species using our methods, with variation attributed to different female strains. The improvement in mating rates enables us to screen for polymorphic maternal factors of *D. simulans* causing variable levels of hybrid lethality.

743T **Drosophila tripunctata: Is sympatric speciation occurring due to host preference and toxin tolerance ?** Grace Kropelin, Clare Scott Chialvo Biology, Appalachian State University

An evolutionary arms race between insects and hosts is no new concept. For millions of years, they have been in this evolutionary race that results in the evolution of host defense mechanisms and adaptations in the insets to mitigate the risks of the host defenses. One example of a defensive product includes producing highly, toxic compounds. These compounds deter most insects, typically those classified as generalist feeders. Generalist feeders have not developed the strategies to combat these toxic compounds. Despite this, some mushroom-feeding *Drosophila* species, considered to be generalists, have been shown to be tolerant of deadly cyclopeptide mushroom toxins. Specifically, species within the *immigrans-tripunctata* radiation including our species of interest, *Drosophila tripunctata*. Previous studies have shown that *D. tripunctata* tolerates the deathcap mushroom cyclopeptide toxins. Furthermore, *D. tripunctata* uses both mushrooms and tomatoes as hosts and possesses significant genetic variation for toxin tolerance. Due to their host choice and toxin tolerance to the deathcap mushroom, we hypothesize that *D. tripunctata* is potentially undergoing sympatric speciating. To assess this, we are examining host preference and toxin tolerance in a population of 101 genetically unique inbred lines of *D. tripunctata*. In addition, we sequenced the genome of each line to identify single nucleotide polymorphisms associated with both host preferences and mushroom toxin tolerance. Our results will increase our understanding of how traits associate with a novel adaptation typically found in specialist feeders impacts a generalist species.

744T **Integrating genomes and legacy marker data to estimate the Drosophilidae Tree of Life** Bernard Y. Kim[1], Hannah R. Gellert[1], Samuel H. Church[2], Ben Hopkins[3], Richard Xu[4], James A. Hemker[1], Sofia G. Beskid[1], Patrick O'Grady[5], Masanori J. Toda[6], Artyom Kopp[3], Thomas Werner[7], Dmitri A. Petrov[1], Anton Suvorov[4] [1]Stanford University, [2]Yale University, [3]University of California Davis, [4]Virginia Tech, [5]Cornell University, [6]Hokkaido University, [7]Michigan Technological University

The family Drosophilidae is a premier model system for studies in biology, including genomics, ecology, and evolution. Resolving the phylogenetic relationships of the >4,400 described species in the family is of fundamental importance for interpreting these studies through the lens of evolutionary processes. Despite this, many of the phylogenetic relationships in this model family remain unresolved. So far, the majority of genomic data acquisition efforts were concentrated around the model genus *Drosophila*, which includes species that have played a fundamental role in life science research. This taxonomic bias, where genomic data for the remaining taxa outside *Drosophila* are unavailable or highly fragmented, hindered progress in building the Tree of Life for the whole family Drosophilidae. With the recent advances of long-read sequencing technologies it became possible to affordably and efficiently generate high quality genome assemblies necessary for robust phylogenomic inference. Here, we gather, consolidate and combine large amounts of heterogeneous sequencing data, namely molecular markers and multi-locus datasets derived from newly assembled genomes to estimate phylogenetic relationships within the Drosophilidae family. This practical approach has a twofold advantage: (i) to drastically broaden taxon coverage across the entire family and (ii) to increase reliability of an estimated tree topology.

Using this procedure we inferred a highly resolved and stable phylogeny of the Drosophilidae family that includes >1,500 species across 38 genera. Additionally, we performed nodal-based divergence time estimation using several fossil calibration points. Such a dated phylogenetic tree represents an important resource for the communities of evolutionary biology. First, it serves as a prime structure to approach questions in micro- and macro-evolutionary research. Second, it exhibits an immense technical importance for multiple sequence alignment estimation, ancestral reconstruction and many other tasks.

745T **The co-evolutionary network of 155 species of *Drosophila*** Andrius Jonas Dagilis[1], Daniel Matute[2] [1]University of Connecticut, [2]University of North Carolina at Chapel Hill

Using 2470 genes among 155 species of *Drosophila*, we describe genes that evolve at more similar rates than expected by chance alone. This co-evolutionary network provides a resource to test a variety of long-standing evolutionary hypotheses, including the enrichment of co-evolution in co-localized genes. The co-evolutionary network of *Drosophila* is enriched for interactions among genes that are located on the same Muller elements, except for a notable decrease in the number of interactions among genes located on the *Drosophila melanogaster* X chromosome. We further investigate how these interactions relate both to protein interactions and known incompatibilities in *Drosophila*, and demonstrate how co-evolving genes may be more likely to co-introgress. Finally we compare the co-evolutionary networks of major clades of *Drosophila* to examine the stability of long-term evolutionary interactions.

746T **Clade-scale genomic data reveal heterogeneity in natural selection across the drosophilid protein-coding genome** Bernard Y Kim[1], Hannah R Gellert[2], Sofia G Beskid[2], Donald K Price[3], Thomas Werner[4], Darren J Obbard[5], Dmitri A Petrov[2] [1]Biology, Stanford University, [2]Department of Biology, Stanford University, [3]Life Sciences, University of Nevada, Las Vegas, [4]Biological Sciences, Michigan Technological University, [5]Institute of Ecology and Evolution, University of Edinburgh

The genome is heterogeneous in functional constraint down to the base pair level. The functional constraint evolves between species and these evolutionary shifts are indicative of the functional differences between species. Population genetic data – containing younger, mostly ephemeral variants that are less likely to be driven by positive selection affecting divergence between species – are the most useful kind of genomic variation data for quantifying constraint in a species and for understanding these shifts. Unfortunately, polymorphism is sparsely distributed throughout the genome, even in large datasets of high diversity species like *Drosophila melanogaster*. This leads to our inability to define constraint reliably even at the resolution of single genes, not to say anything at the resolution of specific codons within genes or specific short regulatory regions. To address this, we present an approach that quantifies constraint at very high resolution by integrating population genomic data across multiple closely related species. Specifically, we employed Oxford Nanopore long-read sequencing to rapidly generate over 300 inexpensive but high quality reference genomes for the model family Drosophilidae, along with population genomic resequencing datasets for ~150 of these species (~50 from a single wild individual), with the goal of generating genomes and population genomic datasets at the same scale. Then, we used whole-genome alignments to perform comparative population genomic analysis of variation at orthologous protein-coding positions across these 150 drosophilid species. This reveals extensive heterogeneity in the distribution of fitness effects and the impact of natural selection on genetic variation not only at the level of single genes, but even at resolutions of just a few amino acids. Remarkably, some proteins are evolving in a manner consistent with the strict neutral theory of molecular evolution, some evolve in accordance with the nearly neutral theory, and some show extremely high rates of adaptation. Furthermore, this heterogeneity is clearly related to the function and structure of the protein. The fine-mapping of natural selection we present here holds great promise for understanding the relationship between biological function and molecular evolutionary change and for connecting micro- and macro- patterns of molecular evolution.

747T **Fitness consequences of sex chromosome non-disjunction in *Drosophila melanogaster*** Nathaniel Sharp[1], Elizabeth Makovec[2], Caitlin Kestell[3], Kayla Janke[1], Ethan Carter[4], Aaron Ragsdale[1] [1]Genetics, University of Wisconsin-Madison, [2]University of Toronto, [3]North Carolina State University, [4]Xavier University

Non-disjunction of the sex chromosomes in *Drosophila melanogaster* provided foundational evidence for the chromosome theory of heredity over a century ago. Many subsequent studies using this system have detailed how chromosomes segregate, but the phenotypic and evolutionary consequences of such spontaneous mis-segregation events have not been well characterized. Non-disjunction can result in flies with an aneuploid XXY karyotype, which are females. While the Y chromosome has few protein-coding genes, its size and repetitive nature are known to contribute to genome-wide gene expression patterns in XXY females. This karyotype can potentially persist in a population, with XXY flies producing both XXY daughters and XYY sons. We address two related questions about this phenomenon. First, what are the phenotypes of XXY and XYY flies in terms of fitness-related traits? Second, how common are such flies in a laboratory population? We used visible markers to track the spontaneous appearance of XXY females and measured several phenotypes. XXY females showed normal viability and attractiveness, but also elevated size and fecundity, particularly when they were of spontaneous origin, as opposed to being derived from other XXY females. We performed a series of assays to rule out a negative maternal effect of XXY, indicating a parent-of-origin effect: females appear to benefit from having a paternally-derived Y chromosome, possibly due to imprinting. The higher fecundity of XXY females is offset by a slightly slower development time, and the production of smaller eggs. In contrast, while XYY males showed normal reproductive success, they also had reduced viability. We examined the standing frequency of XXY females in a large outbred laboratory population using both PCR and test crosses, finding a frequency of 1.3%. Given the apparently good fitness of XXY females, we used analytical models and simulations to understand why the standing frequency of XXY is not higher. We conclude that the XXY karyotype does not spread because of viability selection on XYY males, and that the XXY karyotype itself is neutral or beneficial. Our results shed light on the consequences of aneuploidy in an important model organism and have implications for genome evolution. Evidence has emerged that a natural

population of *D. melanogaster* recently evolved an XXY karyotype, indicating that our observations can help us understand chromosomal variation in both natural and laboratory populations.

748T **Origination and function of a newly identified female sexual behavior in *Drosophila santomea*** Shengxi Chen[1], Minhao Li[1], Ian P Junker[1], Fabianna Szorenyi[1], Guan Hao Chen[1], Arnold J Berger[1], Aaron A Comeault[2,3], Daniel R Matute[3], Yun Ding[1] [1]Department of Biology, University of Pennsylvania, [2]School of Natural Sciences, Bangor University, [3]Biology Department, University of North Carolina at Chapel Hill

Pre-copulatory sexual behaviors form an integral part of social interaction. In *Drosophila*, males often perform complex courtship behaviors that undergo rapid diversification, but female sexual behaviors and their evolution remain underexplored. How do female sexual behaviors evolve, and how do new behaviors integrate into existing social interactions? Here, we report a newly identified and recently originated female sexual behavior in the *melanogaster* subgroup species *D. santomea*, where females spread their wings in response to male courtship songs. This behavior is observed in multiple strains of *D. santomea* but not in other *melanogaster* subgroup species, thus placing its origination at 0.4 MYA. Wing spreading (WS) is strongly correlated with a female's receptivity state, and WS probability increases before copulation. By abolishing WS in *D. santomea* and closely related species, we show that WS acts as a species-specific signal during courtship to enhance copulation success. This effect is mediated by WS promoting longer male courtship songs, and pairs that engage in this social feedback loop are more likely to copulate. Vaginal plate opening (VPO) is another female receptive behavior and manifests as abdomen extension. We show that WS co-occurs and quantitatively scales with more intense expressions of VPO, suggesting that they share social contexts but convey non-identical information. Lastly, informed by previous reports of WS as a copulation acceptance signal in the *Drosophila* subgenus, we sampled species beyond the *melanogaster* subgroup to understand WS's evolutionary history. WS has evolved multiple times along the *Drosophila* lineage and always co-occurs with VPO and responds to male cues. In summary, we report a newly originated female sexual behavior and describe how it was integrated into the dynamic social interaction during courtship. WS lends itself as a tractable neural comparative model, and parallel efforts in the lab have begun to uncover the underlying neural circuit mechanism. We highlight the value of understanding species-specific female behaviors in developing a comprehensive framework of social behavior evolution, and provide a comparative paradigm for studying the neural mechanism and evolution of newly originated social behaviors.

749T **Adaptive Evolutionary Responses to Heavy Metal Toxicity in Organisms** Geetanjali Sageena Human Resource Development, Indian Council of Medical Research

The widespread dispersion of heavy metals, owing to their extensive application in industrial, residential, agricultural, medical, and technological domains, has prompted inquiries into their potential ramifications on human health and the environment. The deleterious effects of these metallic elements on various organs are well-documented, even at relatively low exposure levels, and they are recognized as systemic toxic substances. The extent of their harmfulness is influenced by the dosage, mode of exposure, chemical composition, as well as the age, gender, genetic makeup, and nutritional status of the affected individuals.

Under such environmental stressors, there can be a notable decline in the overall fitness of populations, exerting a pivotal influence on the evolution and adaptive processes of living organisms. Biological systems have developed diverse compensatory mechanisms to counteract stress, necessitating energy for all cellular functions. Exposure to such conditions can induce significant selective pressure, potentially resulting in phenotypic or genotypic variations. These adaptations play a critical role in comprehending the mechanisms of evolution. Consequently, a solitary environmental stressor can manifest differently across different life stages, with its associated adaptations exhibiting specificity.

In reaction to these challenging conditions, a variety of organism taxa, ranging from insects to invertebrates, have evolved physiological mechanisms to enhance the efficient utilization of energy. To address this fundamental question, I conducted studies on the tolerance of oxidative stress, employing two distinct populations of Drosophila melanogaster. One population exhibited diminished internal energy reserves, yet displayed increased longevity without compromising on reproductive capacity. The response to chemical stimuli at different life stages was evaluated in both populations of D. melanogaster. The primary objective was to unravel the interrelations and trade-offs among life history traits, whether they are rigid or transitory in nature.

750T **Duplicative transposition of the male fertility gene *kl-2* to the Y chromosome triggers gene subfunctionalization in *Drosophila*** Eduardo Dupim[1], Antonio Bernardo de Carvalho[2], Rodrigo Cogni[3], Maria D Vibranovski[1] [1]Departamento de Genética e Biologia Evolutiva, Universidade de São Paulo, [2]Departamento de Genética, Universidade Federal do Rio de Janeiro, [3]Departamento de Ecologia, Universidade de São Paulo

Unique to males, Y chromosomes are considered a potential source for the emergence and specialization of new sex-specific genes. Although there are reports of duplicative transposition of genes from the autosome to the Y chromosome in the well-studied *Drosophila* fruit flies, little is known about the underlying evolutionary mechanisms maintaining both copies. Here, we explore the origin and duplication of the *kl-2* gene: a male fertility factor encoding a dynein heavy chain protein (DHC) of ~4450 aa, associated with sperm flagellar motility in *Drosophila*. Originally located on an autosome, as observed in other Diptera, *kl-2* was transposed to the Y chromosome in the common ancestor of the Drosophilinae subfamily, leaving an autosomal copy in its ancestral site, called *CG9068*, conserved in all analyzed species genomes. While the Y-linked *kl-2* copy keeps the same size and structure, *CG9068* experienced size reduction, encoding a truncated protein with ~1200 aa, retaining only the first functional domain of the ancestral DHC. In contrast to *kl-2*, predominantly expressed in testes, our differential gene expression analysis, based on public RNA-Seq libraries for *D. melanogaster*, reveals that *CG9068* exhibits specific expression in the second antennal segment, housing chordotonal neurons. These auditory sensory cells possess ciliary motility, suggesting that the truncated gene may play a similar role to *kl-2* in spermatozoa. Comparative analysis of outgroups, including the mosquito *Aedes aegypti*, the screw-worm fly *Cochliomyia hominivorax*, and the drosophilid *Rhinoleucophenga americana* (subfamily Steganinae), indicates that the autosomal nonduplicated gene is expressed in both tissues. Moreover, the antenna, exhibits alternative splicing, resulting in the coding of only the first protein domain, mirroring *Drosophila*'s *CG9068*. These results strongly suggest that the ancestral gene was originally expressed in both hearing cells and sperm, with each copy subfunctionalized following the duplication to the Y chromosome, specializing in one cell type. Intriguingly, we detected a vestigial — but significant — expression of the Y-linked *kl-2* gene in male *Drosophila*'s antenna, pointing to a potential conflict with *CG9068*, as both genes appear to interact with the same proteins in the axonemal complex. This system is an illustrative example of how sexual chromosomes promote diversification and the rise of new genes.

751T **A cryptic evolutionary arms race with an unsuppressed selfish chromosome in *Drosophila*** Jackson Bladen, Hyuck-jin Nam, Nitin Phadnis University of Utah

Sex Ratio (*SR*) chromosomes are selfish *X*-chromosomes that selectively eliminate *Y*-chromosome-bearing sperm in the male germline. By manipulating gametogenesis, *SR* chromosomes dominate the viable gamete pool, bias the sex ratio of progeny, and gain an evolutionary advantage – often at the organism's expense. Unchecked, these selfish genetic elements are predicted to spread rapidly and drive populations extinct. Alternatively, they provide strong selective pressure for the rapid evolution of suppressors, which is then predicted to form a cryptic drive system. *SR* chromosomes fueling evolutionary arms races between X-linked distorters, Y-linked targets, and autosomal suppressors is a central idea in evolutionary theory. Theory shows that an unsuppressed state of a distorting chromosome is expected to be observed only transiently. Several well-studied Sex Ratio systems show no evidence of suppression despite the ancient origins of their *SR* chromosomes. This violation of prediction from our theoretical and experimental understanding of evolutionary conflict is known as the "ancient gene drive paradox."

The *SR* chromosome of *Drosophila pseudoobscura* originated nearly one million years ago, shows near-perfect drive in the male germline, and imposes substantial fitness effects on its carrier. In North American populations, the *SR* chromosome can be found at high, stable frequencies. Despite decades of comprehensive surveys, there are no known drive-resistant *Y*-chromosomes or autosomal suppressors for this ancient chromosome. The absence of suppressors of the *D. pseudoobscura Sex-Ratio* chromosome exemplifies the "ancient gene drive paradox" and has remained an unresolved contradiction in evolutionary genetics.

Here, we experimentally test the intragenomic arms race hypothesis by surveying for cryptic suppressors of the ancient, unsuppressed *SR* chromosome in *Drosophila pseudoobscura.* We generated recombinant chromosomes that reflect the ancestral state of the *SR* chromosome in North American populations. In segregation assays using these recombinants, we discovered a partially dominant suppression system against the ancestral distorter. In addition, we discover an *X*-linked locus that is a suppressor-of-suppressor, producing near-perfect distortion even in the presence of autosomal suppressors. We deconstruct the *D. pseudoobscura SR* system as the ancestral distorter, suppressor-of-distortion, and suppressor-of-suppressor consistent with the framework of an ancient, ongoing evolutionary arms race. Further, these results indicate that the contemporary absence of *SR* suppression is merely a transient phase in an ongoing evolutionary arms race. This ancestral drive-suppression system suggests a resolution to the "ancient gene drive paradox."

752T **Divergence in thermal sensitivity of meiosis in related cold tolerant and thermotolerant species** Jessica McNeill, Nathan Brandt, Caiti Smukowski Heil North Carolina State University

Meiosis is a well conserved process required for the formation of gametes in all sexually reproducing species. However, meiotic structures are sensitive to a variety of external factors, which can impact chromosome pairing, recombination, and fertility. For example, the optimal temperature for successful meiosis varies between species of plants, animals, and fungi. This suggests that meiosis is temperature sensitive, and that selection may act on variation in meiotic success as organisms

adapt to different environmental conditions. One lens through which we can better understand the link between temperature and the evolution of meiosis is to investigate how temperature alters meiotic phenotypes within and between related species with different thermal niches. The budding yeast Saccharomyces are an ideal system to investigate this question, as optimal growth temperature is a defining characteristic delineating species of the genus. We thus surveyed three metrics of meiosis in the thermotolerant species *Saccharomyces cerevisiae* and its relative cryotolerant *Saccharomyces uvarum*: the proportion of diploid cells that complete meiosis (sporulation efficiency), the proportion of spores that are viable following meiosis (spore viability), and recombination rate at a range of temperatures from 4°C-42°C. Our results indicate that there are genetic background and temperature effects on recombination rate variation and sporulation efficiency within and between *S. uvarum* and *S. cerevisiae*. In particular, we demonstrate meiotic failure of cryotolerant *S. uvarum* at 30°C, whereas some *S. cerevisiae* strains can complete meiosis at 42°C, indicating a divergence in thermal sensitivity of meiotic processes over the 20 my of divergence between these species. We then conducted mating trials between strains of *S. uvarum* at three temperatures, and demonstrate that high temperatures significantly reduce viable matings between strains. Together, these results suggest that meiotic thermal sensitivity evolves between closely related species and may even result in temporal reproductive isolation if populations/species differ in temperature tolerance.

753T **Investigating Murine Y Chromosome Diversity and its Functional Consequences** Alexa C Michaels[1,2], Beth Dumont[2,3] [1]Jackson Lab, [2]Tufts University, [3]The Jackson Lab

More than 40% of cases of male factor infertility are caused by Y chromosome aberrations, leading to problems such as azoospermia or low sperm counts. Despite its central importance for male fertility, the Y chromosome exhibits extreme structural variability between species and within populations. Recent advances in sequencing technologies are refining our understanding of Y chromosome diversity and divergence, but our understanding of the functional consequences of this variation is lacking. To address this knowledge gap, I am developing moderate-throughput genomic pipelines using state-of-the-art long-read sequencing methods to systematically catalog structural and sequence-level diversity across the Y chromosome of diverse house mouse strains. I have used these pipelines to generate quality assemblies of multiple mouse lines in the past with high enough coverage to use in downstream analysis of structural variation. Additionally, I will link Y chromosome genetic variation with quantitative metrics of male fertility in large panels of genetically diverse mice to assess the functional impacts of Y chromosome diversity for male fitness. My work is predicated on the hypothesis that discoveries from investigations in mice will provide translational insights for human Y chromosome evolution, diversity, and function, even despite poor conservation of sequence and gene-level content of the mouse and human Y. Indeed, multiple features of the Y chromosome are conserved between human and mouse genomes, including PARs, ampliconic genes, and single copy genes with divergent-X-linked homologs. Overall, my work is expected to generate new Y chromosome genomic resources for the mouse, catalog Y chromosome diversity in diverse mouse populations, assess the functional consequences of Y chromosome variation on male fertility, and document mutational mechanisms of Y chromosome evolution.

754T **Karyotype Analysis and Quantification of Male Fertility Metrics in a Novel Wild-Derived Inbred Mouse Strain Panel** Hilda Opoku Frempong[1], Beth Dumont[2], Lydia Wooldridge[2] [1]The Jackson Laboratory and University of Maine, [2]The jackson Laboratory

Wild mice harbor much greater genomic diversity than their laboratory counterparts and present an opportunity to bring increased genomic complexity into the fold of biomedical research. To this end, we have been pursuing a course of phenotypic and genomic investigations on a new panel of wild-derived inbred strains developed from wild-caught house mice from North and South America (The Nachman Panel). Our ultimate goal is to develop a novel high diversity mouse multiparent mapping population founded from a subset of strains in the Nachman Panel. To ensure that crosses between strains do not unmask of genetic incompatibilities that lead to breeding challenges, we pursued a series of karyotype analyses and fertility phenotyping. First, we sought to karyotype strains in this panel to assure the absence of large-scale structural rearrangements. Indeed, Robertsonian translocations are common in wild mouse populations and, if present in these wild-derived inbred strains, could lead to reduced breeding performance and infertility in experimental crosses. We used DAPI-banding of metaphase cell spreads prepared from tail-tip fibroblasts and cytological analyses of meiotic chromosome axes in spermatocyte cell spreads to confirm that all tested strains possess karyotypes with the expected 40 acrocentric chromosomes. Second, we quantified a number of male fertility metrics, including testis weight, sperm density, and sperm morphology in inbred strains of the Nachman Panel and a subset of their derivative F1 hybrids. Overall, F1 hybrids exhibit fertility metrics that exceed those quantified in the inbred parental lines, and even exceed values observed in classical inbred strains. Overall, our findings point to a conserved karyotype in wild mice from North and South America and reveal hybrid vigor in male reproductive parameters. We conclude that genomic incompatibilities are unlikely to impede future breeding efforts involving strains from the Nachman Panel.

755T **Effects of the Breeding Sex Ratio on Genomic Patterns of Variation** William J Spurley, Bret A Payseur Laboratory of

Genetics, University of Wisconsin-Madison

Population genetic inference routinely assumes that equal numbers of females and males contribute to the next generation. Evidence for sex differences in reproductive success and other life history variables indicates that natural populations often violate this assumption. When the breeding sex ratio is biased away from 1:1, the effective population size is reduced, but this reduction is not distributed equally throughout the genome. Shifts in effective population size caused by skews in the breeding sex ratio differ between sex chromosomes and autosomes because of sex chromosomal imbalances between females and males. To investigate the consequences of changes in the breeding sex ratio on genomic patterns of sequence diversity, we conducted coalescent simulations across a range of demographic histories. We show that the breeding sex ratio interacts with demography to differentially shape sequence variation on the X Chromosome and the autosomes. In this context, the breeding sex ratio exerts disparate effects on levels of variation, the site frequency spectrum of polymorphisms, and linkage disequilibrium. We discuss the implications of our results for interpreting comparisons between X Chromosomal and autosomal diversity and we pinpoint combinations of summary statistics that are promising targets for inferring the breeding sex ratio from population genomic data.

756T **Gene-by-environment interactions, gene expression, and body size in house mice from the Americas** Katya Mack[1], Nico Landino[2], Tiffany Longo[2], Sebastian Vera[2], Lilia Crew[2], Kristi McDonald[2], Megan Phifer-Rixey[3] [1]University of Kansas, [2]Monmouth University, [3]Drexel University

Body size in house mice (*Mus musculus domesticus*) covaries with latitude, consistent with Bergmann's Rule. There is clear evidence that genetic variation contributes to this pattern in the Americas. However, traits related to body size are complex not only because they are polygenic, but also because they are sensitive to the environment and, in particular, diet. New wild-derived strains from regions of the Americas have been developed which vary consistently in aspects of body size. In this study, mice from the new strains were fed either a typical breeder or a high fat diet. Our goal was to use diet as a tool to determine whether there was genetic variation for plasticity among the strains, to characterize gene regulatory divergence between strains, and to connect regulatory variants to adaptive variation in body size. Not only was there evidence that diet affected body size, but also that strains differed in phenotypic response to the high fat diet. Gene expression divergence was extensive both among strains and across diet treatments. Finally, using crosses between strains and allele specific patterns of gene expression, we found that *cis*-by-diet interactions are common (and associated with genes involved in metabolism), and that *cis*-regulatory changes are associated with signals of selection from latitudinal transects of wild populations. Together, these results add to our understanding of the genetic basis of Bergmann's Rule in house mice.

757T **Parent-of-origin disruption of growth and metabolism in hybrid mice** Emily Moore[1,2], Fernando Rodriguez-Caro[2], Jessica C Powell[2], Zac Cheviron[2], Cole Wolf[2,3], Jeffrey Good[2] [1]University of Denver, [2]Biological Sciences, University of Montana, [3]Biology, University of Wisconsin

Pregnancy in placental mammals requires a delicate balance of growth and nutrient allocation on the part of mother and developing offspring, with the needs of the two seemingly at odds. One way intimate interactions between maternal and fetal genomes are mediated is through the expression of imprinted genes with parent-of-origin-biased expression. In theory, genomic imprinting could evolve to reduce antagonistic interactions (conflict) or promote cooperation (coadaptation) between the maternal parent and developing offspring. Regardless, both scenarios can generate coevolutionary dynamics that lead to rapid divergence between species. Consistent with this, mammalian hybrids often show parent-of-origin deficits in growth and development indicating that imprinted gene networks are sensitive to hybrid mismatch. However, it is unclear if and how often such hybrid incompatibilities lead to altered metabolism and growth, if there is disruption to gene networks associated with nutrient allocation in development, or if disrupted fetal development may contribute to adult metabolic phenotypes. In this study, we identified patterns of developmental asymmetry, placental gene expression, and adult growth and fat deposition at scaled levels of divergence using reciprocal crosses within and between three lineages of mice: *Mus musculus musculus (mus)*, *M. m. domesticus (dom)*, and *M. spretus (spret)*. By examining gene expression in functionally distinct regions of the placenta, we found enriched paternal expression in placental tissue responsible for nutrient acquisition, and enriched maternal expression in the tissue that coordinates materno-fetal physiology. Asymmetry in adult sizes in reciprocal crosses was found both in hybrids between more closely-related mice (*mus* and *dom*) and more distantly-related mice (*mus* and *spret*), and adult overgrowth is decoupled from placental size in *mus* and *dom* hybrids. To determine whether adult overgrowth was associated with changes in adiposity, we quantified body fat with QMR and collected gonadal white and intrascapular brown fat depots. Overgrown hybrid mice were longer and fatter than reciprocal hybrids and parents. With connections between placental size, and fetal birth weight and adult phenotypes, hybrid mice are a promising model with which to investigate epigenetic controls linking early development with metabolic disease, as well as serving as a model for mechanisms underlying overgrowth in mammalian hybrids.

758T **The Influence of *MUTYH* on Germline and Somatic Mutagenesis Across Species** Candice L Young[1], David Mas-Ponte[1], Annabel Beichman[1], David Ashbrook[2], Suheeta Roy[2], Shelby Hemker[3], Jeanne Fredrickson[4], Brendan Kohrn[4], Ming Yu[5], William M Grady[5], Jacob Kitzman[3], Brian Shirts[4], Robert W Williams[2], Rosana Risques[4], Kelley Harris[1] [1]Genome Sciences, University of Washington School of Medicine, [2]Genetics, Genomics & Informatics, University of Tennessee Health Science Center, [3]Human Genetics, University of Michigan Medical School, [4]Laboratory Medicine & Pathology, University of Washington School of Medicine, [5]Translational Science and Therapeutics Division, Fred Hutchinson Cancer Research Center

DNA repair mechanisms safeguard our genome, with breakdowns in these processes increasing cancer susceptibility. The tissue-specific impact of mutations in repair genes and their role in aging and health are not fully understood. In addition, even modest increases in germline mutation rates can influence congenital disease risk and the rate of evolution. The *MUTYH* gene, which is associated with human cancers and is also a germline mutator in mice, plays a crucial role in preventing C>A transversion mutations by correcting DNA mispairings. Our research focuses on how *MUTYH* variants modulate mutation frequencies in the somatic and germline cells of both humans and mice, shedding light on how repair genes can impact mammalian aging and the evolution of mutagenesis.

In the BXD recombinant inbred mouse strains, certain *Mutyh* alleles have been found to increase the germline C>A mutation rate. To probe the effects of the *Mutyh* sequence variation on somatic mutagenesis in the same mice, we have sequenced whole genomes at 50X coverage from the spleens of aged BXD mice fed low fat and high fat diets. Using Strelka for mutation calling, we are measuring the accrual of high-frequency somatic mutations attributable to age-related clonal hematopoiesis, a phenomenon previously observed in mice but little studied beyond the C57BL/6J strain. With this, we aim to analyze the BXD mutation spectra to investigate how the *Mutyh* genotype, other potential mutator QTLs, and diet can alter the rate and patterns of somatic mutagenesis in the murine bloodstream.

In parallel to studying the impact of murine germline mutators on somatic mutagenesis, we have been testing human somatic mutator alleles for germline mutator activity. To achieve this, we quantify *MUTYH*'s impact on *de novo* mutagenesis in a 3-generation human family pedigree. By comparing mutations observed in the children of parents with and without pathogenic *MUTYH* mutations, we highlight an association between pathogenic *MUTYH* variants and increased rates of heritable C>A *de novo* mutations. We identify this rate increase in children of mothers but not fathers harboring biallelic pathogenic *MUTYH* mutations, suggesting that the oxidative stress being repaired by *MUTYH* has a proportionally larger effect on the female germline. This study broadly advances our understanding of the role of *MUTYH* and oxidative stress in cancer susceptibility and genomic evolution, and sex-specific reproductive aging in humans.

759T **Investigating the drivers of interspecific variation in antibody immunity using comparative genomic and phylogenetic approaches** Yana Safonova[1], Matt Pennell[2], Anton Bankevich[1], Corey Watson[3] [1]Penn State University, [2]University of Southern California, [3]University of Louisville

A central challenge faced by all organisms is how to defend themselves against pathogens and parasites, particularly those that evolve rapidly. Across the Tree of Life, evolution has devised many ingenious solutions to this problem. Arguably, the most elegant of these is the adaptive immune system of vertebrates that includes antibody immunity and T-cell immunity and in which evolution stumbled upon the idea of using evolution itself to combat a wide variety of infections. The fundamental principles of adaptive immunity are conserved among vertebrates, suggesting a single evolutionary origin. However, the relatively limited set of studies that have investigated adaptive immunity across species have uncovered remarkable variation in adaptive immune repertoires, as well as in the genetics underlying them. A fundamental question is: what are the evolutionary causes and consequences of this variation? Comparative studies of the adaptive immune systems have been infeasible until now owing to technical limitations that have only recently been overcome.

In this work, we conducted the first phylogenetic comparative study of adaptive immune systems with the focus on antibody immunity. We developed novel computational tools for annotation of germline immunoglobulin (IG) loci and expressed antibody repertoires encoded by them and applied these tools for a wide range of mammalian species. We also used comparative phylogenetic tools to reveal the evolutionary history of IG genes encoding antibodies.

As a result, we revealed numerous species-specific adaptations of adaptive immune systems including non-canonical antibodies with therapeutics potential. We also described rapidly evolving regions of immunoglobulin loci and showed that they are responsible for generation of new IG genes. Finally, we formulated hypotheses linking the genetic diversity of IG loci with the diversity of expressed antibody repertoires.

760T **HIV rapid intra-host evolution allows evasion from VRC01 infusion via positive selection** Frida Belinky[1], Sung Hee Ko[1], Pierce Radecki[1], Vanessa Guerra Canedo[1], Emily Elizabeth Coates[1], Pamela J M Costner[2], Julie E Ledgerwood[1,3], John R Mascola[1,4], Eli A Boritz[1] [1]Vaccine Research Center, National Institute of Allergy and Infectious Diseases, [2]National Institute of

Allergy and Infectious Diseases, [3]CONSORTIUM FOR HIV/AIDS VACCINE DEVELOPMENT, [4]ModeX Therapeutics Inc

One of the factors contributing to HIV's persistence is its rapid evolution. Understanding how the *env* gene evolves under antibody-mediated pressure is particularly important for efforts to use antibodies as therapies for HIV. In a previous clinical trial, infusion of the broadly-neutralizing antibody (bNAb) VRC01 lowered plasma HIV viremia in a subset of participants, but was associated with the emergence of neutralization-resistant *env* variants. Here we sought to develop an analytical approach for identifying *env* mutations that confer escape from antibodies using single-genome sequence data from participants treated with VRC01. We applied single-genome amplification and sequencing (HT-SGS) using unique molecular identifiers (UMIs) and the Pacific Biosciences long-read platform, to measure HIV *env* allele frequency changes over time in longitudinal samples from people with chronic, untreated HIV infection who received one dose of VRC01, which targets the CD4 receptor binding site region of HIV *env*. Eight participants were studied, and a total of 29,433 sequences were analyzed. We used two approaches to identify changes adaptive to VRC01 escape. The first was a codon-based dN/dS approach executed by HYPHY with the FUBAR algorithm to identify positions under positive selection at only the post-infusion timepoint. The second approach is a population genetics approach where positive selective sweeps along the *env* gene are identified with Tajima's D and other measures, and then a score for the Selected Allele Favored in Evolution (SAFE) is calculated for each variation with >0.1 frequency change between pre and post infusion. A panmixia analysis revealed that in six of eight individuals the viral populations post infusion were distinct from the pre infusion populations. Specifically, the VRC01 epitope is changed in these six individuals, as seen by logo plots comparison between pre and post infusion. In two individuals, both FUBAR and SAFE approaches identified the same positions as adaptive. In another four individuals FUBAR and SAFE pointed at different residues as adaptive. Examining manually regions of selective sweeps revealed complex evolutionary scenarios and suggest the existence of several adaptive mutations in each host, with possible epistasis between positions as suggested by the existence of low frequency combinations of the adaptive mutations that do not grow in frequency. In two individuals, subpopulation structure correlating with sequence signatures of cell tropism is associated with different escape mutations. These results suggest diverse virological responses and adaptive pathways to bNAb escape among different individuals. While some mutations are easily identified as adaptive, the existence of multiple escape mutations in a single host, as well as sub populations may result in more obscured signals that are more challenging to interpret.

761T **How mammals lost their vision, according to genetics** Sarah Lucas[1], Charles Feigin[2], Stephen Frankenberg[2], Andrew Pask[2], Nathan Clark[3] [1]Human Genetics, University of Utah, [2]School of BioSciences, University of Melbourne, [3]Biological Sciences, University of Pittsburgh

Vision is a critical sensory system for survival in many mammalian species. It is therefore fascinating that a trait so critical to many mammals has become dispensable and repeatedly lost in several independent lineages including moles, echolocating bats, shrews, armadillos, and several others. While possible, it is unlikely that these species instantaneously became blind. Instead, they likely underwent a process to lose their vision over millions of years. What remains unclear is if they all went through the same process to lose their vision. Most vision-loss research has focused on documenting changes in genes vital for rod and cone photoreceptor function within the retina. While these cell types convert dim and colored light respectively into signals that the brain can detect, they are not the only cell types important for vision. One understudied cell type is the lens fiber cells which ensures a clear image is focused onto the photoreceptors. To understand if there is a universal process whereby mammals undergo vision-loss, we compared the change in constraint of three cell types: lens fiber cells, cone photoreceptors, and rod photoreceptors across poorly sighted species and their sighted sister taxa. We measured the constraint of a given cell type by collectively assessing cell-type specific gene groups and compared the observed codon changes between the orthologs of the poorly sighted species and its sister taxa. Our study revealed that the most frequent cell type to lose constraint in the poorly sighted species was the lens, followed by rod and then cone photoreceptors. We found multiple independent instances of loss in the Eulipotyphla (moles and hedgehogs) and Chiroptera (bats) clades. Within Xenarthra we discovered armadillos only lost constraint of their rods while sloths lost constraint only of their cones. Many species lost constraint in multiple cell types and in quick succession leaving it difficult to determine an ordering; however, in the cases where we have enough power to detect a difference, the constraint was lost first in either the lens or cones before rods. This suggests that constraint among these related cell types is independent and hints that there could be a preferred process towards vision loss within mammals. This study revealed how a sensory system is lost by comparing how changes in constraint affect individual components of this complex system across a broad and diverse mammalian phylogeny.

762T **A polygenic explanation for Haldane's Rule in butterflies** Tianzhu Xiong[1], Shreeharsha Tarikere[2], Neil Rosser[2], Xueyan Li[3], Masaya Yago[4], James Mallet[5] [1]Molecular Biology and Genetics, Cornell University, [2]Organismic and Evolutionary Biology, Harvard University, [3]Kunming Institute of Zoology, Chinese Academy of Sciences, [4]The University Museum, The University of Tokyo, [5]Harvard University

Two robust rules have been discovered about animal hybrids: heterogametic hybrids are more unfit (Haldane's Rule), and sex

chromosomes are disproportionately involved in hybrid incompatibility (the large-X/Z effect). Exact mechanisms causing these rules in female heterogametic taxa such as butterflies are unknown, but are suggested by theory to involve dominance on the sex chromosome. We investigate hybrid incompatibilities adhering to both rules in *Papilio* and *Heliconius* butterflies, and show that dominance theory cannot explain our data. Instead, many defects coincide with unbalanced multilocus introgression between the Z chromosome and all autosomes. Our polygenic explanation predicts both rules because the imbalance is likely greater in heterogametic females, and the proportion of introgressed ancestry is more variable on the Z chromosome. We also show that mapping traits polygenic on a single chromosome in backcrosses can generate spurious large-effect QTLs. This mirage is caused by statistical linkage among polygenes that inflates estimated effect sizes. By controlling for statistical linkage, most incompatibility QTLs in our hybrid crosses are consistent with a polygenic basis. Since the two genera are very distantly related, polygenic hybrid incompatibilities are likely common in butterflies.

763T **Innovation, constraint, and the evolution of genetic networks in major eukaryotic lineages** Jacob Steenwyk[1], Maxwell C. Coyle[1], Noah Bradley[2], Xiaofan Zhou[3], Yuanning Li[4], Xing-Xing Shen[5], Chris Hittinger[6], Antonis Rokas[7], Nicole King[1] [1]UC-Berkeley / HHMI, [2]Northwestern University, [3]South China Agricultural University, [4]Shandong University, [5]Zhejiang Univeristy, [6]University of Wisconsin - Madison, [7]Vanderbilt University

Genetic networks depict the intricate relationships among genes, their pathways, and cellular functions. Here, we infer genetic networks using coevolutionary information across 26 major lineages of animals and fungi. Analysis of network features uncovers both analytical and biological factors influencing their structural properties, including evolutionary rate and signal-to-noise ratios. Ancestral reconstructions of complex gene-gene relationships uncover patterns of gain and loss, mirroring gene families, but substantially more dynamic. Guided by these findings, we construct individual genetic networks for Animals and Choanoflagellates and identify complex gene relationships shared in both lineages, thus likely predating animal origins. Shared hubs of genes encode ancient cellular functions, such as cell cycle regulation, DNA replication, and ciliary processes. The principle of 'guilt-by-association' emerges as a promising approach for uncovering genotype-to-phenotype relationships. These findings uncover innovation and constraint in genetic network evolution and suggest that gene-gene association changes are a dynamic and underexplored mode of genome evolution.

764T **Large genotype frequency fluctuations are linked to decorrelated offspring number stochasticity** Joao A Ascensao[1], Kristen Lok[2], Oskar Hallatschek[1] [1]University of California, Berkeley, [2]Duke University

Understanding the factors that drive population fluctuations is crucial for predicting and controlling ecological and evolutionary dynamics. In this context, the role of strain interactions and their impact on population fluctuations has remained largely unexplored. Our group and others have observed large population fluctuations that are difficult to explain through genetic drift, thought to be the primary source of genotype frequency fluctuations. We developed a model to delve deeper into this issue, focusing on the dynamics of genotypes within a community. Genetic drift arises from independent offspring number fluctuations. However, when offspring fluctuations are correlated between individuals, fluctuations appear with distinctive scaling behaviors. The correlated offspring fluctuations can strongly affect the total population abundance, and can also affect the genotype frequency if the correlated fluctuations between genotypes are sufficiently decoupled from each other. We thus refer to these frequency fluctuations as "decoupling fluctuations". Empirical measurements using model microbial populations quantitatively supported our model, revealing that decoupling fluctuations between strains can lead to frequency fluctuations far larger than those from genetic drift. We also explored the evolutionary implications of these decoupling fluctuations, showing that they can significantly influence the fixation probability of a strain and the site frequency spectrum. Notably, decoupling fluctuations arise from a sufficiently generic mechanism such that we expect they are common across biological populations, strongly affecting evolutionary dynamics. Overall, our findings highlight the importance of considering correlated fluctuations in understanding population dynamics and their evolutionary consequences.

765T **Recombination mitigates selection against Neanderthal introgression in shaping introgression landscape** David Y. Lu, Ziqing Pan, April Wei Computational Biology, Cornell University

Genome analyses have shown that present-day humans of non-African descent acquire 1-4% of their genetic material from Neanderthals as a result of human-Neanderthal admixture around 50,000 years ago. Previous studies suggest the initial fraction of Neanderthal introgression could be as high as 10% based on forward-time simulations with human demographic history and distribution of fitness effects (DFE). However, these simulations all adopt a uniform recombination rate, despite the fact that variation in recombination rate is expected to shape introgression patterns. The 10% initial introgression proportion is also unrealistic given the small effective population size of Neanderthals. Here, we examine selection against Neanderthal introgression by building a more realistic forward-time simulation framework utilizing annotated exonic regions from the UCSC Genome Browser, distribution of mutational fitness effects, and fine-scale recombination rates from deCODE genetics. Employing tree sequence encoding, we efficiently simulate the 2.9 Gbps whole-genome for 62,000 generations

and compute Neanderthal ancestry proportion across the human genome at 25 time points since introgression. We show that under mutation models that assume recessive, partial recessive, and additive fitness effects, an admixture fraction of around 5% instead of 10% would better explain the observed Neanderthal ancestry in present day humans. We find Neanderthal ancestry is enriched in high recombination rate regions. Furthermore, the purging of Neanderthal ancestry after introgression is influenced by both local recombination rate and fitness of the Neanderthal segment. Our simulation also better explains protein coding and non-coding specific patterns of Neanderthal ancestry, patterns of introgression deserts, and the relationships between gene density, recombination rate, and Neanderthal ancestry proportion. In conclusion, initial Neanderthal introgression could be much lower than previously suggested. Our results reiterate the importance of the interplay between recombination and purifying selection. A high resolution, realistic recombination map and gene annotation map are essential to understanding both genome-wide and localized patterns of introgression. It is particularly important to incorporate realistic maps in studies of genetic rescue, where variable recombination rates along the genome have not yet been utilized.

766T **Evaluating cluster-based transmissibility measures under a phylodynamic framework with the structured coalescent** Peiyu (Perry) Xu, Shenni Liang, Andrew G Clark, Jaehee Kim Cornell University

In the genetic epidemiology of infectious diseases, characterizing transmissibility and detecting high-transmissibility variants based on the genealogy of the pathogen is a major topic of interest. Current popular measures for transmissibility include the clustering rate (CLR), the size of clusters (CLS), and the length of terminal branches (TBL). These measures are largely based on clusters, which are defined as subtrees in which all descendant tips have a maximum patristic distance below a prespecified threshold, reflecting a group of recent transmission events. However, CLR, CLS, and TBL lack a rigorous theoretical foundation and are primarily based on empirical observations.

Bridging this gap, phylodynamic models offer a more rigorous approach by harnessing information from the sequences of disease agents, which allows for a deeper understanding of the evolutionary and epidemic dynamics of pathogens. The framework operates under the assumption that a genealogy represents a partially observed undirected transmission tree, with the sampled hosts represented by leaves and unobserved transmission events represented as internal nodes. Probabilistic models of genealogies, coalescent or birth-death-sampling (BDS) models, are employed to link observed genetic relationships among pathogens to unobserved epidemiological relationships between infected individuals.

Here, we leverage the phylodynamic framework with a structured coalescent model to 1) derive analytical expressions for CLR, CLS, and TBL under SIR and SEIR models; 2) examine their associations with transmissibility and other epidemiological parameters, assessing the validity of CLR, CLS, and TBL as proxies for transmissibility; and 3) validate our analytical results both with synthetic and real whole genome sequencing data of SARS-CoV-2 and *Mycobacterium tuberculosis*. Our work provides a foundation for current and future methods for transmissibility inference and can aid in the development of more accurate and robust computational tools for infectious disease control and prevention guided by phylodynamic principles.

767T **Genetic diversity and population structure of creole goats from northern Peru revealed by genome-wide SNP markers** Flor-Anita Corredor[1], Deyanira Figueroa[1], Richard Estrada[1], William Burgos-Paz[2], Wilian Salazar[1], Wilder Cruz[1], Roiser Lobato[1], Pedro Injante[1], David Godoy[1], Christian Barrantes[1], Juancarlos Cruz[1], Carlos I. Arbizu[1,3] [1]Instituto Nacional de Innovación Agraria - INIA, [2]Corporación Colombiana de Investigación Agropecuaria-AGROSAVIA, [3]Universidad Nacional Toribio Rodríguez de Mendoza de Amazonas

The single nucleotide polymorphisms (SNP) chips for massive genotyping, are useful for the effective management of genetic resources. This research represents the initial effort to assess the genetic variation and population composition of creole goats from northern Peru through SNP markers. This study involved the collection of 192 male creole goats from three key goat production regions in northern Peru. These goat samples were genotyped using the GGPGoat70k SNP panel. To investigate the genetic influence of other breeds on Peruvian creole goats, our dataset was combined with previously published SNP genotypes. Estimations for expected heterozygosity (He), observed heterozygosity (Ho), and inbreeding coefficient (F_{IS}) were computed for the Peruvian groups. Subsequently, we conducted principal component analysis (PCA), admixture analysis, and AMOVA using the consolidated data. The results revealed a considerable genetic diversity, with He values ranging from 0.41 to 0.42 for the Peruvian sampling groups. The inbreeding coefficient was notably low for Peruvian goat and population structure analysis demonstrated a distinction ($p< 0.05$) from other breeds. These findings suggest a level of differentiation of the Peruvian goat population among other breeds, although further research is needed considering samples from other production areas (work in progress). We expect this study will contribute to defining genetic management strategies to prevent the loss of genetic diversity in Peruvian goat populations and for upcoming advancements in this field.

768T **Utilizing Fractional Calculus to Investigate the Impact of Heterogeneity in Population Genetics** Somayeh Mashayekhi[1], Peter Beerli[2] [1]Mathematics, Kennesaw State University, [2]Florida State University

The Wright-Fisher model and Kingman coalescent model occupy an essential role in studying the evolutionary history of a population. The coalescent process, based on the backward process in time, is dual to the Wright-Fisher model, which describes the evolution of a population forward in time and is a mathematical framework for modeling allele frequency data. Although the dynamics of the Wright-Fisher model are well understood, a simple closed-form analytical expression for the distribution of allele frequencies (DAF) is unknown. The diffusion approximation is a well-known method for calculating the DAF by considering the effect of evolutionary and demographic forces such as genetic drift, mutation, selection, and immigration.

Although Natural populations reside in diverse environments, and individuals within these populations exhibit varying opportunities for reproduction, the existing population genetics models assume homogeneity within a population's environment. In recent developments, we have pioneered the application of fractional calculus in population genetics, introducing the fractional coalescent as an extension of the Kingman coalescent. This model enables the study of population heterogeneity, leveraging the Mittag-Leffler distribution function to model waiting times. The concept of altering the probability distribution of waiting times is rooted in the influence of heterogeneity on the number of offspring. We have demonstrated that when the variance in the number of offspring is not constant and fluctuates, perhaps due to the impact of heterogeneity, then the distribution of waiting times follows a Mittag-Leffler distribution.

Additionally, recognizing that the coalescent model is typically confined to a small number of individuals and does not incorporate allele frequency data, we have introduced a new framework based on the fractional diffusion equation. This framework focuses on the impact of heterogeneity by employing fractional calculus to estimate the distribution of allele frequencies (DAF). To derive the DAF using the diffusion equation, we've developed a computational method based on the well-established spectral method. This presentation will explore the fundamentals of fractional coalescent and fractional diffusion equations in population genetics. We will also provide illustrative examples to showcase the advantages of these methods.

769T **Non-heritable yet evolvable: increased developmental noise can be selected for despite average negative effect** Csenge Petak[1], Thomas Sgouros[2], Lapo Frati[1], Ignacio Bravo[3], Daniel Weinreich[2] [1]University of Vermont, [2]Brown University, [3]Centre National de la Recherche Scientifique

Population genetics typically considers the fate of genetic variants in the population that have direct fitness effects on the carrier. However, the effect of certain genetic variants is that they influence the distribution of phenotypic variation that is generated each generation. Previous studies have investigated the fate of mutations that increase noise during reproduction, resulting in increased mutation rate. In this study, we used a simple two-locus two-allele model to also investigate the fate of mutations that influence noise during development, increasing the range of adult phenotypes given the same genotype. We find that the specific phenotypic variation generated need not be heritable for the ability to generate a wider range of phenotypes to spread through indirect selection in the population. Moreover, an allele increasing developmental noise can reach fixation even when most (but not all) random variation is disadvantageous and thus on average the allele has a negative effect on fitness. Surprisingly, we find that the probability of fixation increases with increasing selection pressure, and decreases with increasing population size. The implications of these results are potentially far reaching. Selection resulting in higher developmental noise in the population could influence the ability of the population to adapt rapidly to sudden changes in the environment, which is essential in many fields of biology including climate change adaptation, antimicrobial and cancer treatment resistance.

770T **The Population Genetics of Biological Noise** Csenge Peták[1], Thomas Sgouros[2], Lapo Frati[1], Yevgeney Raynes[2], Ignacio Bravo[3], Daniel Weinreich[2] [1]University of Vermont, [2]Brown University, [3]CNRS

Each generation, biological information is transmitted from zygote to adult during development, and back to the zygote during reproduction. Both channels -- development and reproduction -- are susceptible to noise, which can have phenotypic consequences. And while noise is an inherent feature of information transmission, in biological systems its magnitude can be under heritable control. For example, DNA polymerase alleles can differ in mutation rate, promoter alleles can differ in the level of noise in gene expression, and ribosomal protein alleles can differ in translational accuracy. Consequently, populations can carry heritable variation in the amount of phenotypic variation they carry, the latter being precisely the substrate for natural selection. This raises the question of how natural selection regards variants that influence the amount of biological noise. While others have explored this issue in individual cases, we present what we believe is a novel, synthetic population genetic framework for understanding this problem in all settings. We argue from first principles that phenotypic noise will on average be deleterious, but can also occasionally give rise to rare, beneficial phenotypes. We find that the fate of noise-regulating alleles thus depends on the statistics of the phenotypic variation they engender and the persistence of their association with said phenotypic variation, as well as classical features of the population such as its size. We illustrate these ideas with specific biological examples as well as introducing several important, open questions.

771T **Modelling Human Population Growth with an Integrated Archeological-Genetic Framework** Gabriel Kennedy, Shyamalika Gopalan, Amy Goldberg Evolutionary Anthropology, Duke University

Inference of human population size over time is important for understanding human evolution, anthropological impacts, and other population genetic questions. Towards this goal, differing methods independently use genomic or archeological data to reconstruct population size over time. From the earliest days of population genetics, theory has linked genetic variation to estimates of effective population size. However, the relationship to census size is more complicated. Interpretation of population size from genomic data is further exacerbated by poor temporal resolution on recent timescales and varying generational times. In parallel, archeological models have used the distribution of radiocarbon dates as a proxy for human census size, under the assumption that greater numbers of people will leave more material behind, with fine-scale spatial and temporal resolution. However, these methods are sensitive to taphonomic and sampling biases and cannot differentiate between endogenous growth versus migration. Here, we present an Approximate Bayesian Computation framework to infer human population size over time using genomic and archeological data simultaneously to leverage their respective strengths. This method combines summary statistics from both types of data, using SLiM for genetic simulations and *rcarbon* for radiocarbon dates to estimate distributions of population growth parameters. Under the model, we can estimate population growth rates and the timing of size changes at high temporal resolution. We compare the information gained by the joint model to inference using each data type independently and consider which summary statistics are informative to create a combination that utilizes the strengths of both data types.

772T **The effect of heterogeneous recombination landscapes on the probability of sex chromosome turnover** Mark Hibbins, Stephen Wright Ecology and Evolutionary Biology, University of Toronto

Rates of sex chromosome turnover vary widely across the tree of life. Current models suggest that the turnover of sex chromosomes may be promoted by degeneration of existing sex chromosome systems and the accumulation of sexually antagonistic variation on autosomes. An overlooked factor in such models is the genomic landscape of recombination, which can interact with these mechanisms. In many organisms, recombination is not uniform across the genome, but is elevated in “hotspots” of high recombination separated by large regions of relatively low recombination. This landscape can additionally vary among the sexes; male recombination is often more biased towards the ends of chromosomes, for example. Pre-existing regions of low recombination may promote the turnover of sex chromosomes by capturing and linking sexually antagonistic variation, a reversal of the traditional framework of sex chromosome evolution in which recombination suppression evolves after the genesis of a sex-determining region. Here, we investigate how the landscape of recombination promotes the turnover of sex chromosomes using a forward simulation study. We allow sexually antagonistic variation to accumulate on simulated autosomes with different landscapes of recombination and track the fate of novel sex-determining loci introduced to these autosomes. Our results provide new insights into the mechanisms promoting sex chromosome turnover among lineages.

773T **Solving the Arizona search problem by imputation** Egor Lappo, Noah A. Rosenberg Biology, Stanford University

In forensic genetics, an “Arizona search” is an evaluation of the numbers of pairs of profiles in a forensic-genetic database that possess partial or complete genotypic matches. An Arizona search assists in establishing the extent to which a set of forensic loci provides unique identifications of individuals, and it also enables a test of the accuracy of mathematical models that predict match probabilities for locus sets. For sets of short-tandem-repeat (STR) loci in use in forensic genetic marker systems, however, the potential for performing Arizona searches is constrained by the limited availability of actual forensic profiles for research purposes. Here, we propose the use of genotype imputation as a method to circumvent this problem. From a database of genomes, we impute genotypes of STR loci based on profiles of neighboring single-nucleotide polymorphisms (SNPs), searching for partial STR matches in the database on the basis of the imputed profiles. We compare the numbers of partial matches in imputed profiles to those of the actual profiles, finding a close agreement in the fractions of pairs that possess various levels of partial match. As the size of publicly available datasets on SNPs and whole genomes continues to grow, the results suggest that despite the limited potential for performing Arizona searches with actual forensic STR profiles, the questions that such searches seek to answer can be posed by conducting Arizona searches using imputation in increasingly large SNP databases.

774T **LD and other between-LOCUS associations under drift, population structure, and tight linkage: A likelihood-based approach** Marcy Uyenoyama Biology, Duke University

Observations of genome- and planet-wide patterns in linkage disequilibrium and other forms of genomic associations have served as the basis of a variety of inferences regarding demographic history. In some applications, such indices are explicitly recognized as indicator phenomena associated with population structure. Clarification of the theoretical basis of the generation of genetic associations would facilitate the placement of such inferences within a likelihood-based framework.

I describe a compact method for deriving likelihoods based on samples of two-locus haplotypes under tight linkage. Of particular interest are associations that arise among sites separated by just tens of kilobases, implying rates of crossing-over on the order of 10^{-5}. Interactions among genetic drift, mutation, crossing-over, and regular inbreeding determine levels of within-locus genetic diversity and the nature of associations between loci. Analogues of classical measures of disequilibrium emerge from these likelihood distributions of identity.

775T **Ancient gene duplication and recent non-coding structural variation underpin pigmentation diversification in swordtail (*Xiphophorus*) fishes** Tristram O Dodge[1], Daniel L Powell[1], John J. Baczenas[1], Theresa R Gunn[1], Manfred Schartl[2,3], Molly Schumer[1,4] [1]Biology, Stanford University, [2]Developmental Biochemistry, University of Wuerzburg, [3]Xiphophorus Genetic Stock Center, Texas State University, [4]Howard Hughes Medical Institute

Pigment pattern variation has long interested biologists as striking examples of phenotypic diversification and is a tractable system to understand molecular genetics and development. While mammalian melanocytes have been most thoroughly studied, teleost fish provide an exciting avenue for pigmentation studies, due to their high levels of pattern variation and repertoire of five pigment cell types. This diversity is hypothesized to have arisen in part from the teleost whole-genome duplication 350 million years ago; however, few pigmentation genes have been identified in fish, making this hypothesis difficult to evaluate. Swordtail fish in the genus *Xiphophorus* are polymorphic for a dizzying array of pigmentation traits under balancing selection, providing unique opportunities to characterize their genetic architecture and evolution.

We leverage genome-wide association studies, long-read sequencing, chromatin accessibility assays, and gene expression data to uncover the genetic architecture of multiple pigmentation patterns in swordtails. We find that structural variants upstream and downstream of ancient *kit-ligand* paralogs underpin multiple distinct and convergent phenotypes across two clades. In one swordtail clade, we pinpoint the genetic basis of three distinct melanic ornaments on the body and tail to different non-coding regions upstream of *kitlga*, a duplicated gene thought to maintain the ancestral pigmentation function of *kit-ligand* in other vertebrates. We use long-read sequencing across populations and species to identify complex structural variation in these regions ranging from 30-100kb that increase tissue-specific expression of *kitlga*, and we profile the chromatin accessibility in these regions. In a second swordtail clade, we find a distinct series of tailspot phenotypes map to structural variation upstream and downstream of *kitlgb*. We show *kitlgb* functions a pigmentation gene in *Xiphophorus*, despite loss of this ability in zebrafish.

These results represent a remarkable case of convergent evolution and phenotypic diversification, where ancient *kit-ligand* paralogs have been recently and recurrently modified to produce an array of phenotypes. More generally, our results show that ancient whole-genome duplications can set the stage for recent phenotypic diversification. Moreover, long-read sequencing can uncover complex structural variants in non-coding regions, which may play an underappreciated role in gene regulation and trait evolution.

776T **Integrating epidemiological and population genetic models of *Plasmodium vivax* genomic variation** Shyamalika Gopalan[1], Jillian Grassia[2], Amy Goldberg[1] [1]Evolutionary Anthropology, Duke University, [2]Duke University

Plasmodium vivax, a causative agent of malaria, is a growing public health concern across Asia, South America, and Eastern Africa. Increasing quantities of genomic data are being generated from infected patients with the goal of improving our understanding of *P. vivax* transmission dynamics and parasite biology. However, interpreting these data to yield concrete insights remains difficult, and will require new models that account for *P. vivax*'s unusual life cycle. This life cycle involves obligate haploid and diploid stages within the human host and mosquito vector, respectively, as well as period of extreme exponential growth and extreme bottlenecks, features that would be expected to produce complex patterns of neutral genetic variation. Here, we present a model of *P. vivax* that captures important aspects of the parasite's biology in order to simulate neutral variation across its entire genome. A key feature of our model is that it connects classic epidemiological models (i.e. Ross-Macdonald style models) with recently developed forward genomic simulation methods to quantify the impact of epidemiological and population genetic parameters on *P. vivax* genetic diversity. In exploring this integrated model, we find that the severity of the human-mosquito transmission bottleneck has a much greater effect on pairwise diversity than does total host parasitemia (i.e. host carrying capacity). This result is consistent with population genetic theory, which predicts that population bottlenecks will have a disproportionately large impact on effective population size and diversity. More generally, by enabling simulations of realistic neutral variation, our work opens up opportunities for investigating many aspects of malaria parasite evolution, including the impact of natural selection on genomic loci that depart significantly from baseline expectations.

777T **Adaption to repeated long-term starvation illustrates how microbes navigate complex stress** Megan G Behringer[1], Wei-Chin Ho[2], Sarah Worthan[1], Robert McCarthy[1] [1]Biological Sciences, Vanderbilt University, [2]Biology, University of Texas at

Tyler

Microbes are evolutionarily robust organisms capable of rapid adaptation to complex stress, which enables colonization of harsh environments. In nature, microbes are regularly challenged by starvation, a particularly complex stress, as resource limitation often co-occurs with changes in pH, osmolarity, and toxin accumulation created by metabolic waste. Additionally, complications introduced by eventual resource replenishment are an often-overlooked challenge encountered by microbes adapting to starvation. Here, successful microbes must withstand rapid environmental shifts before swiftly capitalizing on replenished resources to avoid invasion by competing species.To understand how microbes navigate trade-offs between growth and survival, ultimately thriving in environments despite sporadic resource availability, we experimentally evolved *Escherichia coli* populations for 900 days to repeated cycles of 100-day starvation before resource replenishment. Metagenomic analysis revealed that reduced mutation rates, frequent parallel variants, significant mutational order, and successive selective sweeps are associated with adaptation to repeated long-term starvation. Parallel variants often arose in global gene expression regulators, and 7/16 populations evolved an R109H substitution in the transcriptional terminator Rho. Genetic reconstruction revealed Rho^{R109H} confers pH-sensing activity, contributing to increased fitness upon resource replenishment as environmental pH rapidly decreases. Rho^{R109H} also enables efficient resource scavenging from necromass by improving metabolic capability on exogenously acquired intermediates of central metabolism. We further identified naturally occurring Rho^{H109} residues in microbial species regularly challenged by alkaline to neutral pH shifts. Our results demonstrate that experimental evolution can provide insights into how microbes adapt to extreme environments, highlighting the previously unknown functional diversity of organisms that thrive in these environments.

778T **Using ancient genomes to analyze the history of Neanderthal DNA in Europeans and East Asians** Abigail E Kuntzleman[1], David Rinker[2], Laura Colbran[3], John A Capra[4] [1]Computational Biology, Brown University, [2]Vanderbilt, [3]University of Pennsylvania, [4]University of California San Francisco

All non-African human populations carry approximately 2% DNA of Neanderthal ancestry in their genomes. The growing number of genome sequences from ancient humans provides the opportunity to track trends of Neanderthal DNA frequency, selection, and populations-specificity in antiquity. Here we use 301 newly available ancient genomes from across Eurasia to demonstrate that Neanderthal ancestry in modern humans has remained consistently low over the past 50,000 years; this confirms previous work based on a smaller number of ancient human genomes. We then use evolutionary simulations to show that simple neutral selection admixture models are not sufficient to explain trends of introgressed haplotype frequencies observed in real data. To explore potential functional drivers of selection on introgressed haplotypes, we analyze Neanderthal-introgressed variants previously predicted to be under positive selection in OAS2, UBE2F, TLR1, BNC2, and GORAB using phenotype data from the UK Biobank. These loci are significantly associated with phenotypes related to immune function, hair and skin color, and male pattern baldness. We use ancient genomes to show that these variants have remained at high frequency in Europeans for at least 8,500 years and infer that these genes exhibit differing histories in East Asians. Our results trace trends of Neanderthal ancestry over time and identify population-specificity in some introgressed regions. Overall, we illustrate how ancient genomes can now be analyzed at the population-level, and we highlight the need for more ancient genomes, particularly in non-European populations.

779T **Characterization of the *Pristionchus pacificus* "epigenetic toolkit" reveals the evolutionary loss of the histone methyltransferase complex PRC2** Audrey Brown[1], Adriaan B Meiborg[2], Mirita Franz-Wachtel[3], Boris Macek[3], Spencer Gordon[1], Ofer Rog[1], Cameron J Weadick[4], Michael Werner[1] [1]School of Biological Sciences, University of Utah, [2]Developmental Biology, EMBL, [3]University of Tübingen, [4]Biosciences, University of Exeter

Comparative approaches have revealed both divergent and convergent paths to achieving shared developmental outcomes. Thus, only through assembling multiple case studies can we understand biological principles. Yet, despite appreciating the conservation – or lack thereof – of developmental networks, the conservation of epigenetic mechanisms, which regulate those networks, is poorly understood. The nematode *Pristionchus pacificus* has emerged as a model system of plasticity and epigenetic regulation as it exhibits a bacterivorous or omnivorous morph depending on its environment. Here, we determined the "epigenetic toolkit" available to *P. pacificus* as a resource for future functional work on plasticity, and as a comparison with *C. elegans* to investigate the conservation of epigenetic mechanisms. Broadly, we observed a similar cast of genes with putative epigenetic function between *C. elegans* and *P. pacificus*. However, we also found striking differences. Most notably, the histone methyltransferase complex PRC2 appears to be missing in *P. pacificus.*We describe the deletion/pseudogenization of the PRC2 genes *mes-2* and *mes-6* and conclude that both were lost in the last common ancestor of *P. pacificus* and a related species *P. arcanus.* Interestingly, we observed the enzymatic product of PRC2 (H3K27me3) by mass spectrometry and immunofluorescence , suggesting that a currently unknown methyltransferase has been co-opted for heterochromatin silencing. Altogether, we provide an inventory of epigenetic genes in *P. pacificus* to enable reverse-genetic experiments related to plasticity, and in doing so describe the first loss of PRC2 in a multicellular organism.

780T **Population genomics of unusually large white-footed mice in the Boston Harbor archipelago** Emma Howell[1], Lauren Nolfo-Clements[2], Bret Payseur[1] [1]Genetics, University of Wisconsin-Madison, [2]Biology, Suffolk University

Island populations often exhibit departures from their mainland counterparts in key behavioral, morphological, and life-history traits– a phenomenon termed the "island syndrome". Populations of white-footed mice (*Peromyscus leucopus*) inhabiting two islands within the Boston Harbor archipelago provide compelling examples of this rule, measuring between 40% and 50% larger in body weight than mainland mice. In contrast to the ecological and geographical conditions often thought to drive island syndrome phenotypes, the Boston Harbor islands are situated close to the mainland and harbor both predators and interspecific competitors of *P. leucopus*. In addition, these islands have undergone dramatic environmental transformations over the past 400 years owing to a history of human usage that spans agriculture, industry, and recreation. To characterize the demographic and selective forces that underlie island evolution in this unique system, we performed whole-genome sequencing of wild-caught individuals sampled from two islands and one mainland location. Using site frequency spectra of putatively neutrally evolving single nucleotide polymorphisms (SNPs), we estimated key parameters describing the colonization history of the islands. Our inferred demographic history suggests that divergence times between the islands and mainland largely coincide with the post-glacial formation of the islands. Surprisingly, this allele frequency-based analysis yields little evidence for migration between island and mainland locales. These findings raise the possibility that the Boston Harbor mice evolved concurrently with their changing island environments, providing a unique contrast to examples of rapid evolution of introduced species on islands. We use this inferred demographic history as a null model to evaluate the role that natural selection has played in shaping island-mainland differences. We detected instances of island-specific positive selection by implementing a machine-learning framework based on summaries of nucleotide diversity, allele frequencies, population differentiation, and haplotype structure. We leveraged comparisons of candidate loci between distinct island populations to evaluate the repeatability of adaptive evolution in this unique island system.

781T **Natural selection and random genetic drift in the evolution of genomic regulatory traits: application to epigenetic marks** Leandros Boukas[1], Afrooz Razi[2], Hans T. Bjornsson[3], Kasper D. Hansen[2] [1]Johns Hopkins University/Children's National Hospital, [2]Johns Hopkins University, [3]Johns Hopkins University/University of Iceland

Several molecular traits, such as epigenetic marks and the binding of transcription factors, act as global regulators throughout the genome. It is usually taken for granted that the pattern of the distribution of such traits across the genome reflects pervasive optimization via selection, and this thinking has long permeated efforts to understand their contribution to cellular function. However, we lack a formal framework for testing what genomic patterns are likely to arise under different evolutionary regimes. Without such a framework, it is not possible to know which genomic regulatory traits are indeed under selection, or the extent to which such selection - when present - is pervasive. Methods developed for traditional quantitative traits do not take into account the genome-wide nature of regulatory traits and are thus not ideally suited to answer the above questions.

Here, we develop a neutral null model and a test for directional selection on global regulatory traits. Our approach requires knowing the distribution of the trait of interest across gene-regulatory loci; for example, which promoters are methylated and which are hypomethylated in a given cell type. This allows us to consider variation between genes, and respects that such regulatory traits are often controlled in trans by upstream factors, such as chromatin modifying enzymes.

We then apply our test to epigenetic marks. We consider 3 different marks (DNA methylation, H3K4me3, H3K36me3) and a broad range of genomic compartments (promoters, gene bodies, transcriptional end regions). While we do detect signatures of directional selection, we find that this selection is not pervasive, and there are several genes whose epigenetic state can be explained purely as a result of drift. As an example, we find no evidence for selection promoting DNA methylation at promoters as a global silencing mechanism. We corroborate this with orthogonal empirical data, which reveal that genes with methylated promoters are in fact the genes with the most tolerance to duplications and to expression-level-increasing eQTLs.

A natural question is whether selection on epigenetic marks is purely a passive consequence of selection on gene expression. Our framework allows adjusting for confounders or other traits mediating effects on fitness, thus enabling us to approach this question. We find that, when present, selection on the epigenetic marks under consideration cannot be explained as a passive consequence of selection on expression levels. This supports a causal involvement of these marks in the regulation of gene expression and other processes.

In summary, we present a framework for selection inference on global genomic regulatory traits that is simple, easily applicable and general. We speculate that its application to diverse regulatory traits will help fill an important gap in our understanding of the evolution of this class of molecular traits.

782T **Genetics of color variation in a pair of sympatric butterflies.** Joe Hanly[1,2] [1]Biology, Duke University, [2]Biology, The

George Washington University

Color polymorphisms can serve as a tractable model for the genetic and developmental architecture of traits. Here we investigated continuous color variation in *Colias eurytheme* and *Colias philodice*, two species of sulphur butterflies that hybridize in sympatry. Using quantitative trait locus (QTL) analysis and high-throughput color quantification, we found two interacting large-effect loci affecting orange-to-yellow chromaticity. Knockouts of red Malpighian tubules (red), likely involved in endosomal maturation, result in depigmented wing scales. Additionally, the transcription factor bric-a-brac can act as a modulator of orange
pigmentation. We also describe the QTL architecture of other continuously varying traits, together supporting a large-X effect model where the genetic control of species-defining traits is enriched on sex chromosomes. This study sheds light on the range of possible genetic architectures that can underpin a continuously varying trait and illustrates the power of using automated measurement to score phenotypes that are not always conspicuous to the human eye

783T **Detecting genomic adaptations to freezing environment in right-eye flounder** Prabodh K Bajpai, Xuan Zhuang Biological Sciences, University of Arkansas

Many ectotherms living in subzero environments have evolved remarkable survival strategies to cope with freezing conditions. A notable example is the independent evolution of diverse antifreeze proteins (AFPs) in various cold-water marine fish lineages, such as a subset of right-eye flounder. While we have elucidated the evolution of AFPs in multiple cold-water fish lineages, a comprehensive understanding of freeze adaptation at the genome level across different species is lacking. Right-eye flounders from high latitudinal regions characteristically employ two distinct strategies to avoid freezing in cold waters, with deep-water species relying on undercooling/supercooling, while shallow-water species synthesize Type I antifreeze protein (AFPI). Interestingly, the phylogeny of this family indicates that deep-water species are ancestral to the AFPI-bearing clade. To explore how members within this family, inhabiting in the equivalent subzero waters, employ these two strategies to avoid freezing, we aim to identify genomic signatures of freezing-resistant adaptation using comparative genomics. Our focus extends beyond detecting selection in coding regions to include non-coding regions, which constitute a significant portion of eukaryotic genomes and are implicated in gene expression regulation. Leveraging previously assembled whole-genome sequences in our lab, along with other high-quality genomes available in GenBank, we will conduct selection tests to detect the positive/purifying selection as well as relaxed/intensifying selection on protein-coding sequences. Additionally, we will analyze non-coding regions to discern differences in their evolutionary rates, providing insights into regulatory changes associated with adaptations to freezing environment. By identifying genomic signatures of selection, this study will elucidate the functional classes of genes that have been driving evolution of two distinct freezing avoidance strategies in right-eye flounders. Furthermore, we seek to pinpoint altered biological pathways and gain crucial insights into regulatory regions that undergo modifications during freezing-resistant adaptation.

784T **Evolutionary genomics of trans-specific polymorphisms between cryptic species** Connor S Murray[1], Joaquin Nunez[2], David Bass[3], Madison Karram[1], Madison Doceti[1], Aakrosh S Ratan[4], Alan O Bergland[1] [1]Biology, University of Virginia, [2]Biology, University of Vermont, [3]Cell, Molecular, Developmental Biology, and Biophysics, Johns Hopkins, [4]Center for Public Health Genomics, University of Virginia

The exploration of genetic variation within and between related species represents a fundamental pursuit in genetics. This study aims to discern the evolutionary mechanisms that maintain diversity post-speciation while focusing on trans-specific polymorphisms, loci identical by state across species. The *Daphnia pulex* species complex serves as our focal system, with an emphasis on scrutinizing the abundance of trans-specific polymorphisms between taxa. The central question guiding our investigation is whether trans-specific polymorphisms emerge due to balancing selection or if alternative hypotheses, such as hybridization, incomplete lineage sorting, or convergent de-novo evolution underlie their existence across taxa. To address these hypotheses, we conducted analyses involving over 2,000 genomes of North American and European *D. pulex*, supplemented by several outgroup species. The primary objective of our study was to unravel the prevalence and distribution of trans-specific polymorphisms within the focal species pair, North American and European *D. pulex*. Despite a divergence time exceeding ten million years ago, both North American and European *D. pulex* retain thousands of shared trans-specific mutations. Importantly, the observed number of trans-specific polymorphism cannot be solely explained by hybridization or incomplete lineage sorting. Our analyses demonstrate that most trans-specific polymorphisms arose because of convergent de-novo mutation. However, balancing selection is acting upon recently evolved and ancient trans-specific mutations. In conclusion, our inquiry provides insights into the genetic underpinnings of adaptation and the mechanisms governing the persistence of diversity within the *D. pulex* species complex.

785T **Mathematical properties of allele-sharing dissimilarities** Xiran Liu[1], Zarif Ahsan[2], Tarun K Martheswaran[2], Noah A Rosenberg[2] [1]Brown University, [2]Stanford University

Allele-sharing statistics for a genetic locus measure the dissimilarity between two populations as a mean of the dissimilarity between random pairs of individuals, one from each population. Owing to within-population variation in genotype, allele-sharing dissimilarities can have the property that they have a nonzero value when computed between a population and itself. We consider the mathematical properties of allele-sharing dissimilarities in a pair of populations, treating the allele frequencies in the two populations parametrically. Examining two formulations of allele-sharing dissimilarity, we obtain the distributions of within-population and between-population dissimilarities for pairs of individuals. We use the mathematical results to explain two phenomena observed in human population-genetic data, namely (1) that members of a population can be empirically more genetically dissimilar from each other on average than they are from members of another population, and (2) that when averaging across loci, allele-sharing dissimilarities between pairs of individuals often tend to vary only within a relatively narrow range.

786T **The mechanisms of correlated evolution: Aposematism in Phyllobates poison-dart frogs** Roberto Márquez Ecology and Evolutionary Biology, University of Michigan

A wide array of organisms use conspicuous signals to warn predators of secondary defenses in order to avoid predation, a strategy known as aposematism. In poison-dart frogs aposematism has evolved quickly and dynamically, with multiple independent origins of conspicuously colored and chemically defended lineages. Although the ecological and behavioral processes guiding the evolution of aposematism in poison frogs are relatively well known, the underlying cellular, genetic, and molecular mechanisms remain largely unknown. In this talk I explore the possible molecular, evolutionary genetic, and developmental mechanisms behind the correlated evolution of aposematic coloration and toxicity in Phyllobates poison-dart frogs. Drawing from population genetic, biogeographic, cellular, and developmental perspectives, I focus on how these processes can lead to the convergent evolution of integrated multi-trait phenotypes. Until now, results point to the independent evolution of remarkably similar coloration phenotypes being underlied by changes in different genes, as well as a possible ontogenetic correlation between coloration and toxicity.

787T **Computational advances in inference from allele frequency spectra** Linh Tran[1], Xin Huang[2], Connie Sun[1], Mathews Sajan[1], Sean Davey[1], Travis Struck[1], Ryan Gutenkunst[3] [1]University of Arizona, [2]University of Vienna, [3]Molecular and Cellular Biology, University of Arizona

Inferences of demographic history and natural selection from allele frequency spectra have become a key part of population genomics. But running such inferences can be both computationally expensive and complex. We address these difficulties via two new software packages. First, donni (Demographic Optimization via Neural Network Inference) uses pretrained neural network models to replace the expensive parameter optimization step of demographic history inference, enabling almost instant inference for common models. Second, dadi-cli provides a convenient command-line interface to the software dadi, greatly simplifying inference of demographic history and distributions of fitness effects. In addition, dadi-cli enables distributed computing, including cloud environments. Together, these complementary advances dramatically reduce the computational cost and complexity of inference from allele frequency spectra.

788T **The effect of proto-sex Chromosomes on the reproductive behavior of male house flies (*Musca domestica*)** Farnam Ghaemmaghami[1], Richard Meisel[2] [1]Biology, University of Houston, [2]University of Houston

Female choice should lead to the favored male genotype spreading in the population, reducing genetic variation for male traits. Nevertheless, heritable variation exists in preferred male traits in what has been termed the paradox of the lek. One of the proposed solutions to this paradox is genotype by environment interactions (GEIs). Meaning that a single genotype is not superior over the others over different environmental conditions. Another proposed solution is female preference for unrelated males. When females mate based on their relatedness to males, different females mate with different males and therefore variation is kept. Trade-offs between survival and reproductive success can also contribute to the maintenance of this variation. House flies have a polygenic sex determination system in which the male determining gene (M) can be located on either the Y chromosome (Y^M males) or the third autosome (III^M males). III^M males outcompete Y^M males in population cage competition and mating competition. Yet both genotypes exist in natural populations, showing a clinal distribution, with Y^M males mostly found in the northern latitudes and III^M males more abundant in the southern latitudes. The thermal tolerance and preference of the two types of males is concordant with their geographical distribution. This suggests that temperature might be an influential factor for male performance and consequently could contribute to the maintenance of the two genotypes via GEIs. I am using the housefly system to determine the relative importance of factors maintaining genetic variation of male reproductive behaviors. To this end, I have done population cage experiments with 50% III^M and 50% Y^M males and females from either strain at two different developmental and environmental temperatures (22 and 29℃) and genotype the F1 progeny to see how the ratio of the Y chromosome genotypes changes after one generation. I have also run mating latency assays at the two different temperatures to see whether III^M males mate faster than Y^M males. Finally,

I will design mating competitions to assess female choice and the mating advantage of III^M males over Y^M males. In all my experiments, the background of the female is considered to assess to effect of relatedness to males. This study will help us understand how the interaction between Y chromosome genotype, temperature and female background affects reproductive behavior and how that in turn helps maintain the polygenic sex determination system in house flies.

789T **Genetic diversity loss continues long after habitat destruction ends** Kristy S Mualim[1,2], Jeffrey P Spence[3], Clemens Weiss[3], Meixi Lin[2], Moises Exposito-Alonso[1,2,4] [1]Department of Biology, Stanford University, [2]Department of Plant Biology, Carnegie Institution for Science, [3]Department of Genetics, Stanford University, [4]Department of Global Ecology, Carnegie Institution for Science

A major goal of conservation is maintaining high levels of genetic diversity across species. Recently, there have been calls to begin monitoring genetic diversity levels across species via large scale genotyping. The hope is that such monitoring will detect when too much of a species' genetic diversity has been lost (e.g., due to habitat loss or climate change) and actions can be taken to prevent further loss of genetic diversity. There are several definitions of genetic diversity, but one particularly important measure in terms of various population genetic processes such as adaptation is π, the pairwise heterozygosity. Here we develop mathematical machinery to compute the expected π under complex spatial scenarios. Our modelling, corroborated by realistic simulations and empirical analysis of geospatial genetic data, shows that initially, habitat destruction has almost no impact on π, but in the long term can result in extreme losses in genetic diversity. This result shows that simple monitoring is not enough – genetic diversity will continue to decrease long after habitat destruction ends. Yet, we also show that the time-scale of this genetic diversity loss is quite long – taking a number of generations on the order of the effective population size – giving hope that reversing habitat loss quickly enough can prevent catastrophic consequences.

790T **Biases in ARG-based inference of historical population size in populations experiencing background selection and recurrent sweeps** Jacob I Marsh[1], Parul Johri[2] [1]Biology, University of North Carolina, [2]Biology, Genetics, University of North Carolina

Accurately inferring the demographic histories of contemporary populations using population-genetic approaches provides fundamental insights into species dynamics at both micro- and macro-evolutionary scales. However, alternate evolutionary forces, notably background selection and selective sweeps, can produce genomic signatures that mimic or mask signals associated with historical population size change. While the theoretical biases introduced by linked effects of selection have been well established, it is unclear to what extent typical empirical analyses are susceptible to mis-inference due to these effects. We developed realistic forward simulations of human and *Drosophila melanogaster* populations, including variability of gene density, mutation rates, recombination rates, selection parameters, and historical demographic scenarios, to broadly assess the impacts of selection on demographic inference using the genealogy-based approach *Relate*. Our results suggest analysis of human population histories may be minimally impacted by linked effects of selection. However, in organisms with similar genome architecture, population parameters, and more widespread positive selection, a parameter space relevant to some other mammalian populations, dramatic mis-inference may occur if linked effects of selection are unaccounted for. Finally, we explore the accuracy of demographic inference in populations with compact genomes experiencing widespread selection modelled by our *D. melanogaster* simulations. Our findings identify scenarios in which demographic inference on empirical populations may be compromised by the effects of linked selection and suggest caution when inferring population history in compact genomes.

791T **A diffusion theory approach to model the allele frequency distribution during selective sweeps** Sachin Kaushik[1], Kavita Jain[2], Parul Johri[3] [1]Integrative Program for Biological & Genome Sciences, University of North Carolina at Chapel Hill, [2]Jawaharlal Nehru Centre for Advanced Scientific Research, [3]Department of Biology, Department of Genetics, Integrative Program for Biological & Genome Sciences, University of North Carolina at Chapel Hill

Selective sweeps, resulting from the spread of beneficial mutations in a population, shape the patterns of variation at linked neutral sites. Fixation of a beneficial mutation is expected to reduce nucleotide diversity and skew the site frequency spectrum (SFS) at linked neutral sites, which has been thoroughly investigated using a combined approach of coalescent and diffusion theory in the strong selection regime. We present a simple mathematical framework based on diffusion theory for obtaining the conditional site frequency spectrum at linked neutral sites, both during and immediately post-fixation of moderately or strongly beneficial mutations, assuming no recombination. We extend our approach to include varying dominance coefficients and rates of inbreeding and test the accuracy of our theoretical results when there is interference between segregating beneficial mutations. Our results will be helpful in understanding the effects of sweeps in asexual organisms, sex chromosomes, and in tumor populations

792T **Female mate choice, sexual selection and linkage disequilibrium** Michael Wade Indiana Univ

Linkage disequilibrium across a genome allows the mapping of quantitative traits to genotypes and affects estimates of fundamental genetic parameters like heritability and additive genetic variance. Several processes can create linkage disequilibrium, including epistatic selection, admixture of populations, and assortative mating, while other genomic features affect its rate of decay, including inversions, recombination, gene conversion and inbreeding. Nonrandom mating owing to female mate choice is a type of selective mating that also causes linkage disequilibrium, although it has been less well studied than inbreeding and assortative mating. Using two-locus haploid and diploid population genetic models, I derive the *LD* created by female mate choice between genes for male preferred traits and female preferences for them. Like some types of assortative mating, female mate choice creates selection that changes allele frequencies in males in addition to creating *LD*. In all cases, the stronger a female mating preference, the stronger is the selection on males and therefore, the shorter is the duration of the resulting *LD*, which must be zero when a preferred male allele fixes. This trade-off between the magnitude and duration of *LD* caused by female choice differs from that caused by assortative mating, which can lead to stable non-zero disequilibrium values of *LD*.

793T **Population genetics consequences of fragmentation processes on migration networks** Ryan Chaffee[1], Gili Greenbaum[2], Jaehee Kim[3] [1]Genetics, Genomics, and Development, Cornell University, [2]Ecology, Evolution and Behavior, Hebrew University, [3]Computational Biology, Cornell University

The loss of connectivity between habitable patches, a process known as fragmentation, is a leading cause of declines in animal and plant populations, species extinction, and the loss of biodiversity. Understanding the genetic effects of fragmentation, the loss of connectivity between habitable patches, is crucial in wildlife conservation. Advancements in genomic data enable precise monitoring and management of endangered populations. As human-induced fragmentation through activities such as road construction, deforestation, agriculture, and climate change is increasing globally, comprehending how fragmentation affects genetic variation and population viability becomes vital for conserving and managing wildlife.

To study the genetic consequences of population fragmentation, we developed a computational framework for modeling the fragmentation of migration networks and characterizing the relationships between the properties of the migration networks, the fragmentation process, and genetic measures. Using a structured coalescence model, we analyzed how F_{ST} values and expected heterozygosities change along fragmentation through analytical formulations and numerical simulations. We further assessed critical phase transition points in the F_{ST} and heterozygosity distributions along the fragmentation process to identify optimal intervention strategies that can aid in mitigating the negative genetic effects of population fragmentation.

The analytical formulation of the coalescent theory requires an idealized assumption of migration–drift equilibrium, which is often violated in natural populations. To study the impact of migration–drift disequilibrium on the relationship between migration and the distributions of F_{ST} and heterozygosity, we designed and conducted an agent-based forward time simulation study using SLiM software, which models arbitrarily complex evolutionary scenarios. Then, we further relaxed ecological assumptions of migration symmetry and population size and characterized the effects of simulated fragmentation on these more general systems. Our results highlight the flexibility of our general framework and show its capacity for studying and modeling habitat fragmentation.

794T **Investigating Recombination Rate Variation Through Population-Level Genetic Variation** LyAndra Lujan, Nadia Singh Biology, University of Oregon

Meiotic recombination is pivotal in generating genetic diversity and maintaining genomic stability. This study focuses on unravelling potential genetic determinants that underlie the variation in meiotic recombination rates within crow populations. Through a population genetics approach, we investigate genes associated with meiotic recombination and their potential impact on shaping the genetic landscape of crows.

This study delves into the intricate genetic mechanisms governing meiotic recombination by investigating the genes involved in this fundamental process. Through analysis of the genetic variation within these genes across diverse populations, this research aims to elucidate their impact on the variation of meiotic recombination.

Utilising population-level genomic data from diverse crow species, we conducted a comprehensive analysis of genes that contribute to processes involved in meiotic recombination. By exploring patterns of genetic variation and the evolutionary history of these meiotic recombination genes, we aim to elucidate the factors influencing recombination rate variation in crows.

Carrion crow and hooded crow habitat ranges alternate across Eurasia, creating a longitudinal striped habitat pattern. The overlap of their habitat ranges is small, but others have found hybrid species within these overlapping areas. This study aims to characterise the genetic variation of meiotic recombination genes that could be used to further our understanding of this

interesting pattern of crow habitat ranges.

The findings not only contribute to a deeper understanding of the genetic basis of meiotic recombination rate variation in crows but also provide insights into the divergence of carrion and hooded crows, the broader evolutionary processes within avian populations, and the genetic determinants driving meiotic recombination rate variation in other organisms.

795T **Using long reads to characterize structural variation across diverse species** Danielle Khost[1], Felix Wu[2], Erik Garrison[3], Andrea Guarracino[3], Robin Hopkins[2], Scott Edwards[2], Tim Sackton[2] [1]Informatics, Harvard University, [2]Harvard University, [3]University of Tennessee Health Science Center

Structural variants (SVs) are a broad class of mutations comprising deletions, insertions, duplications and inversions, and are important sources for genetic diversity for many species. In the past their study has been difficult due to technical constraints of short read sequencing. The availability of high-throughput long read sequencing allows improved resolution of these important areas of the genome. Here we discuss two different approaches to characterize SVs using long reads for two highly different sequencing projects: a large-scale pangenome of several scrub jay bird species encompassing 45 individuals, and a population resequencing approach for several *Phlox* wildflower species. The scrub jay genome is relatively small and compact at only ~1 Gb in size, while the *Phlox* genome is 6-7 Gb and is composed of almost 90% repetitive DNA. To construct the scrub jay pangenome, we aligned both haplotypes for all 45 individuals in an all-by-all fashion and constructed a graph using the PanGenome Graph Builder (PGGB), which we then used to call variants. In total we were able to identify >5 million indels across the data set. We compared our results to alternate methods of calling SVs, including using long read mapping and an alternate graph-based approach using Minigraph, and demonstrated general agreement between the different methods. For the *Phlox* species, we mapped Nanopore long reads from 12 individuals across four species to a high quality reference genome, and called SVs using a consensus approach between several different callers. After filtering, we identified ~580k SVs within and between species. We highlight the challenges and considerations for both SV detection methods, as well as contrast the differences in SV dynamics within and between species for these diverse organisms.

796T **Identifying long-lived balanced polymorphisms in humans** Hannah Munby[1], Molly Przeworski[2] [1]Columbia University, [2]Biological Sciences, Columbia University

Modes of natural selection, collectively referred to as “balancing selection,” maintain variation in a population longer than expected under neutrality. In humans, the best understood examples of balancing selection are cases of heterozygote advantage in response to pathogen pressures, which tend to be evolutionary recent. Other clear-cut cases of balancing selection are “trans-species polymorphism,” such as what is seen in the MHC or at the FREM3 locus: variation shared identical by descent between fairly diverged species. While this variation also appears to be maintained by host-pathogen mediated selection, much less is understood about their underpinnings. Here, we search for cases of balancing selection over intermediate time frames, taking an approach that does not rely on a demographic model or assumptions about the specific mode of balancing selection. We use population whole-genome sequencing data from 2504 humans and 59 chimpanzees in order to identify single nucleotide polymorphisms (SNPs) that are identical in the two species. This set of shared SNPs is statistically enriched for older alleles as compared to sets of human SNPs that are matched for allele frequencies, mutation types, and genomic properties, but are not shared with chimpanzees. Thus, the candidate SNPs include variants that have been maintained in humans for longer than expected. This set of candidates includes both previously identified trans-species polymorphism as well as 12 novel loci (at an estimated FDR of 0.3). These loci are either intronic (5) or intergenic (7), and lie near or in a number of genes plausibly involved in host-pathogen interaction. Moreover, an enrichment analysis indicates that our set of candidates is enriched for SNPs in or near glycoprotein genes. Thus, our analysis reveals a number of non-coding loci where variation has been actively maintained by natural selection and thus must be of functional importance, and helps to fill in the gap about our understanding of balancing selection at intermediate time scales.

797T **Trouble in paradox: k-mer diversity scales with population size more than SNP diversity** Miles D Roberts[1], Emily Josephs[2] [1]Genetics and Genome Sciences, Michigan State University, [2]Plant Biology, Michigan State University

At the molecular level, most evolution is expected to be neutral. A key prediction of this expectation is that the level of genetic diversity in a population should scale with population size. However, it was discovered by Richard Lewontin in 1974, and reaffirmed by later studies, that the genetic diversity of natural populations often does not cleanly scale with population size. This observation is known as Lewontin’s paradox. We hypothesize that one contributor to Lewontin’s paradox is that standard genotyping methods underestimate levels of genetic diversity in many species due to their omission of non-SNP forms of variation. To test our idea, we calculated SNP-based and k-mer-based metrics of genetic diversity across 93 plant species, amounting to 133 terabases of DNA sequencing data from over 16,000 plants. We then compared how these different metrics correlated with range size estimates - a proxy of population size - derived from both GBIF occurrence data and expert-drawn range maps. Although we are still refining our analyses, we so far have found that k-mer diversity correlates more

with population size and scales more rapidly with population size than SNP-based diversity estimates. This suggests that the omission of non-SNP forms of variation from diversity surveys may partially explain Lewontin's paradox. The importance of non-SNP variation compared to demography and linked selection in explaining Lewontin's paradox remains an exciting avenue for further research. In the coming months, we will repeat our analyses for approximately 130 plant species.

798T **Asymmetric patterns of postzygotic reproductive isolation within *Mimulus guttatus* species complex** Hagar K. Soliman, Jenn M. Coughlan Ecology & Evolutionary Biology, Yale University

Reproductive barriers are key to species formation and maintenance. Uncovering the evolutionary forces that govern these barriers is crucial for a better understanding of the speciation process. In plants, postzygotic isolation in the form of hybrid seed inviability (HSI) is one of the most common outcomes of interspecific crosses leading to reproductive isolation among various species. Here, we reciprocally crossed different lineages within the *Mimulus guttatus* group to uncover any patterns of HSI. The genus *Mimulus* encompasses a large group of flowering plants including *M. guttatus*, which is particularly considered a model system for speciation studies due to its genetic and phenotypic diversity. Despite their genetic similarity, we found asymmetric patterns of HSI in crosses between the southern and northern lineages collected across the West Coast of North America; crosses between the southern lines of *M. guttatus* as sires and northern lines as dams yielded large, inviable hybrid seeds while the reciprocal direction produced smaller, viable seeds. These results suggest that lineages within the *M. guttatus* group vary in Endosperm Balance Number (EBN). EBN theory could explain why intraploidy-interspecific crosses fail asymmetrically similar to interploidy by assigning each lineage a 'strength' level akin to a plant with a higher or lower physical ploidy number based on how it behaves in a certain cross. We further tested this theory by crossing the 'strong' southern lineages with the 'weak' northern *M. decorus*. Indeed, hybrid seeds were inviable in both directions. Conversely, hybrid seed viability was restored in both directions in crosses between the 'strong' southern lineages and the 'strong' southern *M. decorus*. Overall, our findings may suggest the presence of cryptic lineages within *M. guttatus* and further broaden our understanding of HSI patterns within and between species in the *M. guttatus* species complex.

799T **Investigation of cooperation-cheater games for public-goods driven resources in yeast.** Namratha Raj[1], Supreet Saini[2] [1]Chemical Engineering, IIT Bombay, [2]Indian Institute of Technology Bombay

The phenomenon of cooperation is prevalent at all levels of life. In one such manifestation of cooperation in microbial communities, some cells produce costly extracellular resources that are freely available to others. These resources are referred to as public goods. *Saccharomyces cerevis*iae secretes invertase (public good) in the periplasm to hydrolyse sucrose into glucose and fructose, which are then imported by the cells. After hydrolysis of sucrose, a co-operator retains only 1% of the monosaccharides, while 99% of the monosaccharides diffuse into the environment and can be utilised by any cell. The non-producers of invertase (cheaters) exploit the invertase-producing cells (cooperators) by utilising the monosaccharides and not paying the metabolic cost of producing the invertase. In this work, we investigate the evolutionary dynamics of this cheater-cooperator system. In a co-culture, if cheaters are selected for their higher fitness, the population will collapse. On the other hand, for co-operators to survive in the population, a strategy to increase fitness would likely be required. To understand the adaptation of cooperators in sucrose, we performed a coevolution experiment in sucrose. Our results show that cooperators increase in fitness as the experiment progresses. This phenomenon was not observed in environments which involved a non-public good system. Genome sequencing reveals duplication of several *HXT* transporters in the evolved cooperators. Based on these results, we hypothesize that increased privatization of the monosaccharides is the most likely explanation of spread of cooperators in the population. In another system, we investigate the cheater-cooperator dynamics for melibiose (a glucose-galactose disaccharide). Our results show that in the absence of partial privatization, the results of the public-goods driven game are qualitatively different.

800T **Utilizing a "deep homolog scan" approach to evaluate the theoretical host range of poxviruses** Sophie B Scobell, Michael Chambers, Meru Sadhu National Human Genome Research Institute, NIH

As zoonotic spillovers and epidemics become increasingly common, knowledge of the host range of viruses is vital. Poxviruses have extremely broad and variable host ranges that are largely unknown. One determinant of poxviral host range is the poxvirus protein K3. K3 antagonizes a component of an animal's innate antiviral immune response named protein kinase R (PKR), but a given poxvirus K3 protein only inhibits some animal species' PKRs. We are using a high throughput approach to model the ability of a given poxvirus K3 to inhibit a given animal species' PKR. We are testing several hundred animal species' PKR genes representing a diverse range of animals and mammals. Due to the length of the EIF2AK2 gene that encodes PKR, we design chimeric PKR proteins by replacing a K3-binding region of human PKR with the homologous region from each species in our library. This enables a "deep homolog scan" approach where we can investigate the behavior of critical regions of PKR across diverse phylogeny. In this case, we will characterize both the resilience of PKR and the theoretical host range of 16 poxviruses based on the ability of these virus's K3 proteins to inhibit diverse PKRs in our yeast growth assay. Interestingly,

we find that extremely distantly related species' chimeras yield functional PKR proteins that are also inhibitable by multiple poxvirus K3s. Ultimately, the deep homolog scan approach may be applied to study other host-virus protein/protein interactions in high-throughput, characterizing the potential for infection and giving us new evolutionary insights.

801T **What is the role of epistasis in dictating the evolution of a gene?** Pavithra Venkataraman[1,2], Neetika Ahlawat[1], Sergey Kryazhimskiy[2], Supreet Saini[1] [1]Chemical Engineering, Indian Institute of Technology Bombay, [2]Ecology, Behavior and Evolution, University of California San Deigo

Idiosyncratic epistatic interactions between regions of the genome alter adaptation. However, there exists very little evidence to help predict these effects. I use two model genes in *S. cerevisiae* to understand how interactions between regions of the same gene (intramolecular epistasis) and different regions of the genome (intermolecular epistasis) alter their adaptive trajectories.

To understand how intramolecular epistasis operates, I use a model system in which AmtA (an ammonia transporter in the amoeba *Dictyostelium*) is shifted to the yeast *S. cerevisiae* lacking its native ammonia transporters. The horizontally transferred gene suffers from a localization problem and is non-functional in the new host. Screening of 700 AmtA mutants leads to the identification of 19 variants that restore the functionality of the ammonia transporter. Interestingly, the functionality of the AmtA gene is restored via the acquisition of a small number (one to three) of SNPs. On testing the evolvability of these mutants, we identify that intramolecular epistasis strongly inhibits the evolution of these mutants. I am working towards constructing the intragenic fitness landscape of the AmtA gene in *S. cerevisiae* and understanding the intramolecular constraints on the adaptation of this gene.

Intermolecular epistasis acts in an erratic fashion. I use an ill-adapted allele of Hsp90, a molecular chaperone in *S. cerevisiae*, whose intragenic fitness landscape has been reported to be rugged. Using a high-throughput CRISPR-based method to generate thousands of SNPs in the yeast genome, I am working on understanding how this ill-adapted Hsp90 evolves in different genetic backgrounds, and investigating if there exists any predictability associated with the adaptation of a gene.

802T **Using experimental evolution of hybrid genomes to identify genetic incompatibilities in yeast** Artemiza A Martinez, Gregory I Lang Biological Sciences, Lehigh University

Saccharomyces yeast species are known for their relatively low pre-zygotic barriers to mating, which allows for the occurrence of interspecific hybridization both in the natural environment and within laboratory settings. However, the resultant diploid hybrids are sterile due to significant sequence divergence among *Saccharomyces* yeasts, particularly impeding proper chromosome segregation during meiosis.

Here, we used experimental evolution to investigate the presence of weak but pervasive negative-genetic interactions between nuclear genes within the genomes of sibling species, *S. cerevisiae* and *S. paradoxus.* We generated and sequenced 20 F1 hybrid progeny (using a method developed by *Bozdag, et al. 2019).* Our phenotypic assessments of these interspecific hybrids revealed a spectrum of growth rates at different temperatures and notable fitness defects.

We initiated the evolution of 320 independent populations of haploid and homozygous diploid hybrids for over 2,500 generations in a rich glucose medium. We observed substantial fitness improvements in the evolved populations. We conducted whole-genome sequencing after 1000 generations of haploid hybrids and the 2400 generations of diploid hybrids. We are identifying specific target genes that are mutated more often than we expected by chance when compared to their parental backgrounds, with the goal of identifying advantageous alterations that potentially compensate for genetic incompatibilities within hybrid genomes.

803T **Reversion dynamics of copy number variants: fitness costs versus benefits in the absence of selection pressure** Titir De, Ina Suresh, Pieter Spealman, David Gresham Biology, New York University

Copy number variants (CNVs) -duplications and deletions of genomic regions- are a major source of natural genetic variation between individuals of the same species, leading to rapid adaptive evolution. Under selection pressures, copy numbers of certain genes can increase if they confer a survival advantage, but CNVs can also incur fitness costs associated with increased gene expression. My work investigates the evolutionary dynamics of adaptive CNVs in absence of the selection pressure under which they arose- using the general amino acid permease gene (*GAP1*) in *Saccharomyces cerevisiae* as a model locus. Prior research showed that evolution in glutamine limitation recurrently selects for increase in *GAP1* copy number. However, it is unknown whether acquired CNVs are maintained or lost when this selection pressure is removed.

To study the cost-benefit tradeoffs of CNVs upon removal of a selection pressure, we tested several CNV-containing strains

in nutrient-rich media. These strains emerged from a common one-copy ancestor but differ in CNV structure. In absence of nutrient limitation, we found that CNV strains have lower fitness than their ancestor. We experimentally evolved the strains in rich media for 150 generations, tracking *GAP1* copy number via a fluorescent reporter. Between 60 and 110 generations of evolution, 65% of populations underwent rapid CNV loss. Whole-genome sequencing of multiple clones from each evolved population confirmed that in almost all clones with decreased fluorescence, CNVs underwent reversion to a single-copy genome. Pairwise competition assays show that in rich media, most single-copy revertants have higher fitness than their CNV-containing parent strains. We are performing long-read sequencing to reveal the molecular mechanisms of reversion.

To expand this study to other loci, we are doing similar investigations for CNVs at additional genes, including *MEP2* and *PUT4*. Overall, our results indicate that in the absence of a selection pressure, it is often beneficial for the organism to lose extra gene copies that it had acquired under strong selection, and to revert to a single-copy genome. This suggests that the fitness costs associated with CNVs outweigh their benefits upon removal of the selection pressure under which they arose.

804T **Defining quiescence in Candida albicans** Ozan B Imir, David Gresham Biology, New York University

Candida albicans is the leading cause of fungal infections in the United States and its infection rates are on the rise globally. Studying Candida albicans is vital, as it causes numerous superficial and systemic infections annually, particularly harming immunocompromised individuals. The rising drug resistance in Candida albicans, amidst limited treatment options, urgently demands investigation into the factors behind resistance development. This study zeroes in on quiescence, a critical mechanism that halts growth in response to environmental stimuli.We hypothesized that quiescence could be a contributing mechanism for improved resistance to therapy in Candida albicans. By defining quiescence in Candida albicans, this study aims to provide a deeper understanding of how environmental factors like nutrient availability and downstream signaling pathways could influence fungal tolerance to stress and drug treatments. Our results show that nitrogen and carbon limitations significantly reduce the growth rate of Candida albicans in a concentration dependent manner. Furthermore, we observe an increase in temperature tolerance when Candida albicans is subjected to starvation due to continual culturing. A critical finding of this study is the reduced susceptibility of Candida albicans to fungicidal drugs, specifically caspofungin and micafungin, during quiescent states. Starvation-induced quiescence leads to a dose-dependent increase in cell survival, challenging the efficacy of these commonly used antifungals. Understanding the dynamics of quiescence in Candida albicans opens new avenues for therapeutic strategies and better management of fungal infections, particularly in immunocompromised patients where such infections are most perilous.

805F **Quantification of Environmentally-Dependent Selection via Barcoded Animal Lineage Tracking** Zachary C Stevenson, Ellie A Laufer, Kristin Robinson, Patrick C Phillips Biology, University of Oregon, Institute of Ecology and Evolution

Caenorhabditis elegans is a widely used model organism for studying various biological processes, including neurobiology, aging and experimental evolution. *C. elegans* have many advantages for experimental evolution, such as a rapid life cycle, large brood size, the capacity to freeze and revive populations, self-fertilization reproduction and easy genetic manipulation via CRISPR. We used *C. elegans* as the first genomically-barcoded experimental evolutionary animal model to compete two different strains under various concentrations of ivermectin as a environmental selective pressure. We used N2 as our susceptible strain and JD608 *avr-14*(ad1302), *avr-15*(ad1051), and *glc-1*(pk54), as our resistance strain. We introduced a genomic barcode sequence into lineages of each strain using CRISPR genome editing by TARDIS (Transgenic Arrays Resulting in Diversity of Integrated Sequences), a high-throughput library transgenesis method that allows inducible integration of individual sequences from transgenic arrays into engineered genomic sites. Mixed populations are grown in liquid medium for approximately five generations with various concentrations of ivermectin. By adopting a liquid protocol, we can grow populations in the millions, making this one of the largest animal experimental evolutions to date. We then quantified the relative frequency of each strain in the mixed population by PCR amplification and sequencing of the barcode. Barcode frequencies are then used to measure the fitness of the individual lineages in the population. We found that at low concentration of ivermectin, the sensitive strain holds an advantage, while higher concentrations tend to favor the resistant strain. We also find that the sensitive strain tends to develop slower on increasing ivermectin concentrations, whereas the resistant strain remains mostly stable. We hypothesize this time to reproductive adult is the leading cause of the advantage for either genotype in their respective advantaged conditions. Our results demonstrate that *C. elegans* can be used as a high-throughput barcoded animal experimental evolutionary model to compete different strains and provide replicated high-resolution estimates of fitness within an environmental context.

806F **Multiple distinct evolutionary mechanisms achieve stable coexistence of selfish and cooperative mitochondrial genomes** Bryan L Gitschlag[1], Claudia V Pereira[2], James P Held[3], David M McCandlish[1], Maulik R Patel[3] [1]Simons Center for Quantitative Biology, Cold Spring Harbor Laboratory, [2]Takeda Pharmaceuticals, [3]Vanderbilt University

Cells possess multiple copies of mitochondrial DNA (mtDNA). This creates opportunities for selfish mtDNA variants with pathogenic mutations to arise and compete with cooperative (wildtype) mtDNA. These selfish variants are benign at low levels but become costly to host fitness as their frequency rises. Selfish mtDNA variants are thus subject to selection at multiple levels of the biological hierarchy: they compete directly against wildtype mtDNA within host organisms and indirectly due to organismal selection. However, disentangling the relative contributions of the different selection forces operating on mutant mtDNA has proven challenging. We overcome this challenge by combining mathematical modeling with experiments designed to isolate the levels of selection. Applying this approach to many selfish mtDNA genotypes in *Caenorhabditis elegans* revealed an unexpected diversity in the contribution of evolutionary forces. A subset of the mutant mtDNA variants persist at high levels for many generations, despite a heavy host fitness cost, by aggressively outcompeting cooperative (wildtype) genomes within individual hosts. In contrast, some mutant genomes persist by evading organismal selection. Additionally, we also discovered that the mutant variants vary dramatically in their susceptibility to neutral drift. Although these different mechanisms can maintain mutant genomes at similarly high levels, our approach shows how they can give rise to characteristically different distributions of mutant levels among host organisms. Given that mutant levels within an individual represents a key determinant of phenotypic severity, this work outlines an evolutionary theoretic framework for predicting the distribution of phenotypic consequences among individuals carrying a selfish mitochondrial genome.

807F **Limitations of the inference of the distribution of fitness effects of new mutations in partially-selfing populations with linkage** Austin Daigle, Parul Johri UNC Chapel Hill

The accurate estimation of the distribution of fitness effects (DFE) of new mutations is critical for population genetic inference but remains a challenging task. While various methods have been developed for DFE inference using the site frequency spectrum of putatively neutral and selected sites in a population, their applicability in species with diverse life history traits and complex demographic scenarios is not well understood. Selfing is common among eukaryotic species and can lead to decreased effective recombination rates in such populations, increasing Hill-Robertson interference between selected mutations. We employ forward simulations to investigate the limitations of current DFE estimation approaches in the presence of selfing and linked effects of selection. We find that Hill-Robertson interference distorts the site frequency spectrum of highly selfing populations. As a result, inferred deleterious DFEs contain a higher proportion of mildly deleterious mutations compared to the simulated proportions. In addition, the proportion of adaptive substitutions estimated at high rates of selfing is overestimated. Our results better clarify the parameter space where current DFE methods might be problematic and where they remain robust in the presence of selfing and other model violations like departures from semi-dominance, population structure, and uneven sampling.

808F **Intra-genomic coevolution between a DNA satellite and Topoisomerase II triggers a cross-species incompatibility in *Drosophila*** Cara Brand, Mia Levine University of Pennsylvania

Non-coding tandem repeats, called DNA satellites, span megabases of eukaryotic genomes and evolve rapidly. Paradoxically, satellite-rich genomic regions mediate strictly conserved, essential processes like chromosome segregation and genome integrity. A classic resolution to this paradox posits that DNA satellite-associated proteins evolve adaptively to mitigate deleterious proliferation of DNA satellite sequence variants. This intra-genomic coevolution plays out between the 11Mb *Drosophila melanogaster*-specific *359bp* satellite and the DNA repair protein, Maternal Haploid. The *maternal haploid* locus evolves adaptively to ensure that the enzyme, Topoisomerase II (Top2), efficiently resolves DNA entanglements at the *359bp* array. We discovered that, like *maternal haploid*, *Top2* evolves adaptively between *D. melanogaster* and its sister species, *D. simulans.* This signature of adaptive evolution raised the possibility that Top2 also coevolves with *359bp*. To genetically probe this model of coevolution, we overexpressed the diverged *D. simulans* Top2 protein ("Top2[sim]") in the *D. melanogaster* female germline and found that Top2[sim] causes female sterility. These females produced abundant mature eggs, but these eggs failed to hatch, suggesting that maternally provisioned Top2[sim] is toxic to embryogenesis in a *D. melanogaster* background. Furthermore, combining Top2[sim] overexpression with a deletion of the maternal and/or paternal *X*-linked *359bp* array rescues male and/or female embryos in a predictable, *X* chromosome-dependent manner. This finding is consistent with a cross-species incompatibility between the *D. melanogaster*-specific *359bp* array and the maternally provisioned *D. simulans* Top2 protein. Intriguingly, *359bp* entanglement during embryogenesis is reminiscent of a long-studied reproductive barrier between *D. melanogaster* and *D. simulans*. When *D. simulans* females are crossed to *D. melanogaster* males, an unknown, maternally deposited *D. simulans* genetic factor—termed Maternal hybrid rescue (Mhr)—is incompatible with the paternally contributed, *359bp* satellite on the *X* chromosome. This incompatibility manifests as mitotic catastrophe in female embryos. We speculate that Top2 is the elusive *D. simulans* maternal factor, which has remained unmapped for over 100 years. Our study highlights how rapid satellite DNA turnover is as a potent selective pressure shaping genome integrity and may drive the origin of species.

809F **Characterizing allelic changes in Drosophila melanogaster due to selected pressures using various statistical**

models Carmen Martin, Enoch Ng›oma, Elizabeth King University of Missouri

Complex traits are the result of genetic variation within multiple genes and the interaction within their environment. Identifying the genetic basis of these complex traits is highly challenging because the effects at individual loci are difficult to isolate when many genes influence a trait. One approach to identifying the connection between genotype and complex phenotypes is to use experimental evolution to drive phenotypic differences while tracking concurrent changes in allele frequencies in the population. The best approach to identifying and characterizing these changes in allele frequency remains an open question in the research field. Finding different methods to analyze how these allelic changes occur, what are the pressures they are responding to, and how often these changes are continuing into the next generation is a challenge we're exploring. To explore these different methods, we have taken advantage of a highly replicated experimental evolution dataset sampled across multiple time points. This project uses Drosophila melanogaster, a well-characterized model system, to observe how these evolutionary changes are affected by resource availability with three different regimens. We've used twelve replicate lines from an admixed synthetic population (DSPR) and three different resource availability regimens designed to select for evolutionary changes throughout generations. Fluctuating resource availability (FA) to mimic selection during human evolution, constant high resource availability (CH) to mirror the current state of human populations and, a deteriorating resource availability (DA) to mimic the populations with less resources available.

Utilizing different statistical methods to measure the rate of allelic change within each group of our diet regime will give insight into the best methods to identify different types of allele frequency trajectories. In addition, identifying the alleles showing the greatest change over time will identify what variants are more beneficial to different resources available. This type of accurate mapping and analysis gives us insight into how these complex genes are affected while also providing the scientific community with more robust methods to track these highly variable alleles.

810F **Evolved Changes in the Insulin/IGF Signaling Pathway in Response to Diet Regime in Drosophila melanogaster** Elliett J Baca, Joseph Gunn, Elizabeth King University of Missouri

The nutrients within one's environment affect how resources are allocated within organisms as well as their metabolism. The insulin/IGF (insulin-like growth factor) signaling pathway (IIS), a conserved pathway required for metabolism within Drosophila, is crucial for regulating glucose and energy metabolism in the body. Dysregulation of this pathway can result in serious health problems, such as diabetes and obesity. To gain insights into the genetic factors underlying these conditions, we used three experimental evolution treatments to select for divergent resource allocation patterns in Drosophila melanogaster for multiple generations. A fluctuating availability treatment (FA) that goes from standard diet to low yeast to standard, a deteriorating availability treatment (DA) that goes from standard diet to low yeast, and a constant high availability treatment (CHA) that consists of high sugar throughout adulthood. At multiple timepoints during experimental evolution, we assessed how gene expression was evolving in the different diet regimes. First, all lines were placed on a low yeast diet, a standard diet, and a high sugar diet. Then, we collected genome-wide gene expression data of female heads, ovaries, and bodies through RNAseq in generations 5, 10, 19 and 31 to track these expression levels during adaptation to their respective diet regimes. Our primary objective is to find differences in expression within the IIS, a conserved pathway required for metabolism within Drosophila in different generations. This comprehensive dataset provides a picture of how expression in the IIS pathway is affected by selection regime, diet treatment, and organ type.

811F **Functional diversification of duplicate genes in Drosophila** Nathan Duda[1,2], Rob J Kulathinal[1,2] [1]Department of Biology, Temple University, [2]Institute for Genomics and Evolutionary Medicine, Temple University

Gene duplications provide an important source of genetic and functional variation, yet how these duplicates arise, diverge, and are maintained remains an outstanding evolutionary question. In this work, we use a computational evolutionary approach to investigate the functional fate of recently duplicated genes across eight species lineages of Drosophila. Our results reveal a highly dynamic evolutionary history of gene duplication and gene loss across nearly two-thirds of all genes in these eight phylogenetically divergent species. To differentiate between models of functional divergence including neofunctionalization, specialization, subfunctionalization, and conservation, we map the expression profile of ~1,100 lineage-specific duplicates using an extensive and standardized library of transcriptomes derived across seven different tissues (Yang et al. 2018). The genomic structure and function of duplicates was also compared to ~1,600 single-copy ortholog pairs. We find that the majority of duplicates gained a new function in either both copies (specialization) or in only one copy (neofunctionalization). Compared to single-copy genes, duplicates that altered ancestral function experienced strikingly different structural and functional properties, such as lower structural stability and testis-specific expression patterns. This research highlights the role of gene amplification events in generating functional diversity in tissue expression, novel genetic innovations, and species differences at the phenotypic level.

812F **How prevalent are the effects of associative overdominance under realistic evolutionary scenarios?** Parul Johri[1], Brian Charlesworth[2] [1]Biology, University of North Carolina at Chapel Hill, [2]Institute of Ecology and Evolution, School of Biological Sciences, University of Edinburgh

Associative overdominance (AOD) at a neutral locus due to linkage disequilibrium with a closely linked locus subject to mutation to deleterious alleles is expected to occur when $Ns < 1$, $h < 0.5$. It is thus most likely to occur in very low recombining regions, partially selfing populations, or populations that have experienced a recent reduction in population size bottleneck, such as laboratory populations. It has recently been suggested that AOD effects can be quite strong when multiple linked selected sites are involved, and can occur even when $Ns \gg 1$. Using simulations of *Drosophila*-like populations, we examine the effects of AOD on levels of diversity, the distribution of allele frequencies, and patterns of linkage disequilibrium, under a variety of realistic scenarios with multiple selected sites, gene conversion, a distribution of fitness effects (DFE), and strong population bottlenecks, asking when AOD might be detectable in population genomic data. We observe only a weak effect when the DFE is skewed towards highly deleterious mutations but find a substantial effect when the DFE is skewed towards mildly deleterious mutations. However, in the presence of gene conversion and after drastic bottlenecks (mimicking evolution in small laboratory populations), we fail to identify easily detectable effects of AOD. We discuss how commonly made assumptions about modeling fitness at multiple sites can lead to differences in predicted AOD effects.

813F ***Wolbachia* abundance and localization in *Drosophila* hosts diverged up to 50 million years** John P Statz, Brandon Cooper The University of Montana

Many organisms, but especially insects, associate with intracellular microbes. Following establishment, these endosymbionts are typically transmitted vertically through the female germline. Regulation of endosymbiont abundance within and among host tissues is essential for stable host associations. Hosts can contain obligate endosymbionts in specialized organs to regulate them, but facultative endosymbionts are often widely distributed across host tissues in ways that affect host physiology and fitness. This is exemplified by the most common endosymbionts in nature, *Wolbachia* bacteria, that associate with all major insect orders and usually form facultative associations. Using confocal microscopy of whole-mount tissues, we quantify intra- and interspecific variation in *Wolbachia* abundance and localization within *Drosophila* hosts diverged up to 50 million years. We then ask several questions about the relative contributions of host and *Wolbachia* genomes to the regulation of this variation. First, we ask whether germ and somatic tissue regulation is decoupled by testing for covariance and tradeoffs in *Wolbachia* abundance between host tissues. Second, using reciprocally introgressed *Wolbachia*-host genotypes, we test whether *Wolbachia* generally provide positive regulation, while hosts generally provide negative regulation, of *Wolbachia* abundance in germ and somatic tissues. Finally, we ask whether *Wolbachia* abundance and its regulation differ significantly among *Wolbachia* clades that have spread across divergent hosts at differential timescales. Our results contribute to a deeper general understanding of interactions between hosts and the most common endosymbionts in nature. Because *Wolbachia* abundance in specific host tissues covaries with the strength of *Wolbachia*-induced traits like cytoplasmic incompatibility and virus blocking, our results also contribute to a deeper understanding of *Wolbachia* spread in natural systems and to improving the application of *Wolbachia* from *Drosophila* for the biocontrol of diseases and pests in transinfected systems.

814F **'UnLocking' Protein Degradation in *C. elegans*** Adam P Berg[1], Michael Bertram[1], Jakob Faber[1], Henry Giesel[1], Austin Johnson[1], Joseph Kaefer[1], Mitchell Keeling[1], William Keeling[1], Mason Naaman[1], Mawuli Nevis[1], Jordan Scott[1], Connor Wakefield[1], Walter R.P. Novak[1], Erika B Sorensen[2] [1]Wabash College, [2]Biology, Wabash College

Our lab is developing an *in vivo* method to inactivate gene function to better understand normal and disease development. While gene inactivation using RNAi or genetic mutation allows researchers to reduce or eliminate a gene product, these techniques have limitations, including 1) slow protein turnover, which can impair the use of RNAi, and 2) the inability to characterize essential gene function later in development. As a result, effective methods for conditional protein degradation offer a powerful alternative to gene inactivation at the RNA or DNA level. Recent work to develop methods to conditionally deplete proteins (e.g. AID, ZIF-1, PSD) have been effective, but these methods are limiting because they use a single input signal to control protein levels, preventing simultaneous differential control of multiple proteins with only one approach. Our lab is developing the *de novo* 'Latching Orthogonal Cage/Key pRoteins' (LOCKR) technique to control protein degradation in *C. elegans*. LOCKR uses designed protein Switches, which can be genetically fused to proteins of interest, and peptide Keys. The Switch cages a protein sequence, in this case a degron, in the "locked" state (degronSwitch). Upon addition of the Key, the degronSwitch is "unlocked," exposing the degron and causing degradation of degronSwitch fusion protein. Because Keys can be expressed using tissue-specific promoters, degronSwitch fusion protein degradation can be spatially controlled within the animal. In addition, LOCKR Keys and degronSwitches can be designed as orthogonal pairs, allowing for the differential control of multiple proteins simultaneously. To pilot the efficacy of the LOCKR system, we created an inert wrm-Scarlet::degronSwitch reporter via MosSCI. This inert reporter ubiquitously expresses the degronSwitch *in vivo,* and is used to assess tissue-specific

depletion of the degronSwitch in *C.elegans* in the presence of tissue-specific Keys. Similarly, the degronSwitch can be fused to proteins of interest, such as *dhc-1* (dynein heavy chain), a cytosolic motor protein used for molecular transport within a cell, and *snt-1 (*synaptotagimin), an important transmembrane protein for synaptic vesicle exocytosis, to assess the efficacy of degronLOCKR to degrade cytosolic and membrane-associated proteins. This work establishes a novel and tissue-specific method for regulating protein function in *C. elega*ns.

815F **The Evolution Trends of Structural Variants at A Large Population Scale** Jen-Yu Wang, James J. Emerson Department of Ecology and Evolutionary Biology, University of California Irvine

Long-read sequencing simplifies genome assembly and enhances the discovery of structural variants (SVs). Employing *Drosophila melanogaster* as our model, we investigated SV evolution at a population level using over sixty whole-genome long-read sequencing datasets. Comparative analysis of contemporary SV-calling methods yielded population statistics, unfolded site frequency spectra and selection signals.

Traditionally, single nucleotide polymorphisms (SNPs) have been pivotal in inferring phylogeny, population evolution, and disease causation, owing to their detectability with cost-effective methods. Unlike SNPs, SVs, which often span and impact multiple genes, are more likely to influence an organism's phenotype. Despite their significance, SVs have eluded scrutiny due to their complex nature and the limitations of short reads from next-generation sequencing (NGS).

This study bridges the gap by leveraging state-of-the-art long-read sequencing to unveil SVs in *Drosophila melanogaster* populations worldwide. Utilizing Pacific Biosciences and Oxford Nanopore Technology sequences from NCBI SRA, we assessed two major SV detection approaches. Mapping-based programs, though computationally efficient, exhibited lower sensitivity, while assembly-based methods, dependent on well-constructed genomes, captured larger-scale changes. Our validated pipelines are open source on GitHub. Diversity and selection signals varied among SV types, and we sought SVs contributing to population differentiation and chromosomal evolution. Additionally, we constructed the largest *Drosophila* pangenome so far for comprehensive representation of polymorphisms.

816F **Machine learning identifies species differences in *Drosophila* female aggressive behavior that is correlated with reproductive traits** Jennifer M Gleason[1], Eleanor Bath[2] [1]Ecology and Evolutionary Biology, University of Kansas, [2]University of Oxford

Aggression provides access to resources and is therefore a fundamental component of fitness. Species vary greatly in their expression of aggression because of differences in resource needs as dictated by their biology. In *Drosophila melanogaster*, male aggression has been extensively studied, but females are also aggressive and behave in ways that maximize offspring quantity and quality. Notably, mated females are more aggressive than virgin females in the presence of yeast, presumably to increase protein acquisition for eggs. Little is known about the aggressive behavior of females of other *Drosophila* species. We applied machine learning to identify and quantify two aggression behaviors, headbutting and fencing, that are shared among eight *Drosophila* species. The machine learning methods that were validated with *D. melanogaster* work well with these species; however, researcher observations are needed because species-specific agonistic interactions may exist that are missed by relying entirely on classifiers trained on a single species. Across all the species, a notable difference from *D. melanogaster* is that mating sometimes decreased, rather than increased, aggression. We tested if reproductive traits of females (notably ovariole number) are associated with aggression finding that females with high fecundity (more ovarioles) are more aggressive than females with fewer ovarioles in the presence of yeast. Sperm traits (size and number) were weakly correlated with aggression. Species adaptations for reproductive fitness may be associated with aggression in females.

817F **Selection for improved flight performance in laboratory populations of *Drosophila melanogaster*: phenotypic and genomic consequences** Srikant Venkitachalam[1], Natalie Heath[2], Mik Kuehnel[2], Adam Albright[2], Elizabeth King[1] [1]Biological Sciences, University of Missouri, [2]University of Missouri

Quantitative traits are known to result from complex inter- (and intra-) associations of the underlying genetic background and the external environment of organisms. Although mapping genotype-to-phenotype relationships in such complex traits is difficult, long-term experimental evolution studies may help in unravelling some of these connections. This may be achieved through tracking the evolution of the target complex trait, correlated phenotypic markers and sequencing the genomes in the experimentally selected populations, compared to the unselected control populations. In the current study, we have carried out a long-term selection experiment in laboratory populations of fruit flies *Drosophila melanogaster* for a quantitative trait – flight performance. Flight in insects is known to be a complex trait involving nuanced neuromuscular coordination, high motivation to fly, and high energetic demands. Thus, selection for flight performance and subsequent phenotypic and genomic studies would be likely to reveal patterns of genomic evolution and its associative trait changes, pleiotropic relations and shared mechanisms for this complex trait. The selection process involved a custom-built wind tunnel set-up inspired

from a previous study. This wind tunnel was a dark chamber wherein a point of light was provided at one end, and wind resistance increased in gradients closer to the point of light. Each generation, at the start of the selection process, flies were added to the dark end of the chamber. The traversal ability of flies, towards the light and against the wind resistance across this wind tunnel, in a 15-minute window, was defined as their flight performance. In order to determine the true target(s) of selection after 10 generations of adaptation, we performed a factorial experiment wherein we tested the extent of evolution of phototaxis as well as flight performance in the wind tunnel setup. We further measured pre-adult survivorship, dry body mass at eclosion and fecundity as some general phenotypic markers of fitness in the selected populations, compared to their unselected controls. Finally, we sequenced the genome of each population in order to determine how their underlying genetic backgrounds had changed as a consequence of selection.

818F **DEST 2.0: an expanded genomic resource reveals new insights on fly phylogeography and adaptation** Alan Bergland[1], Joaquin Nunez[2], Marta Coronado-Zamora[3], Mathieu Gautier[4], Matin Kapun[5], Sonja Steindl[5,5], Lino Ometto[6], Paris Margot[7], Katja Hoedjes[8], Julia Beets[8], R. Axel Wiberg[9], Giovanni Mazzeo[10], David Bass[10], Dmitri Petrov[11], Paul Schmidt[12], Thomas Flatt[7], Josefa Gonzalez[13] [1]Biology, University of Virginia, [2]University of Vermont, [3]ESCI-UPF, [4]INRAE, [5]National History Museum, Vienna, [6]University of Pavia, [7]University of Fribourg, [8]University Amsterdam, [9]Uppsala University, [10]University of Virginia, [11]Stanford University, [12]University of Pennsylvania, [13]Spanish Scientific Research Council

The rapid development of genomic resources for many species has led to discoveries that contextualize patterns of genetic variation in an ecologically-informed context. To advance our understanding of patterns of genetic variation in Drosophila melanogaster, we present Drosophila Evolution over Space and Time 2.0 (DEST 2.0), a community-generated population-genomic resource that incorporates over 500 population samples (Pool-Seq) of nearly 50,000 flies collected across six continents, some at multiple points in time per year, for over a decade. Using this resource, we characterize the demographic history and signals of adaptive evolution across spatial and temporal dimensions. We identify a suture zone in Europe between the Eastern and Western D. melanogaster clades that aligns with other well known post-glacial secondary contact zones in Europe and present signals of secondary contact between European and African populations in both North and South America as well as Australia. We show that the spatial genetic structure of fly populations is stable over time, but that temporal drift caused by seasonal population contractions is causing populations to diverge over time. We identify signals of adaptation between continents and show that regions of the genome associated with xenobiotic resistance show high levels of spatial differentiation, consistent with heterogeneity in pesticide applications across the world and with independent adaptation to common pesticides. We show evidence of seasonal evolution, using fly samples collected during the spring and fall in localities across Europe highlighting that rapid evolutionary change is a ubiquitous feature of D. melanogaster populations living in temperate habitats. Genomic data, along with standardized metadata is freely available from the DEST website (https://dest.bio). We also provide a genome browser that displays many informative tracks that could be useful for researchers studying the genetic variation and the evolutionary history of this classic model system.

819F **Backyard Evolution – a citizen science project to track seasonal evolution and metapopulation structure in fly communities in backyard compost piles** Megan Stephenson[1], Megan Delamont[1], Abbey Hayes[1], Joaquin Nunez[2,3], Alan Bergland[1] [1]Biology, University of Virgina, [2]Biology, University of Vermont, [3]University of Virginia

Drosophila species living in temperate environments adapt as they evolve to temporal and spatial changes in selection pressure. Contemporary work on adaptive tracking and local adaptation in flies has focused on samples collected from orchards, predominantly from wind-fall fruit. Orchard populations are likely large, permanent and may be subject to temporally varying selective pressures unique to that habitat type, such as pesticide usage. Another habitat for many drosophilids are compost-piles, such as those found in backyards and gardens. This habitat likely harbors smaller and more ephemeral populations that may be subject to different selection pressures than flies from orchards. To test this hypothesis, we initiated Backyard Evolution, a citizen science project to sample flies from backyard compost piles throughout the year. We recruit volunteers primarily from demonstrations at Master Gardeners clubs throughout central Virginia, although volunteers from across the USA have contributed. Backyard Evolution has been running every summer since 2020 and these samples will be combined with seasonal sampling at multiple orchards throughout central Virginia. In total, we have worked with 45 volunteers and collected flies from a half dozen orchards, yielding over 56,000 flies from over 14 species. We show that the community composition of orchard and compost pile samples are different, with more species present in compost piles than in orchards. We will be conducting whole-genome resequencing of samples from selected species to test for: (1) adaptive differentiation between orchards and compost piles; (2) differences in population persistence and turnover between species and habitat types; and (3) signals of parallel seasonal evolution in highly divergent Drosophila species. Backyard Evolution is always taking new recruits so stop by if you would like to learn how to participate.

820F **Intraspecific variation in heat-shock transcriptional response in *Drosophila melanogaster*** Nikale Pettie[1], Ana Llopart[1,2], Josep Comeron[1,2] [1]Department of Biology, University of Iowa, [2]Interdisciplinary Program in Genetics, University of

Iowa

An organism's ability to respond to stressors is essential for survival. One of the trademark features of heat stress response is a significant increase in expression of heat shock proteins (HSPs), such as the evolutionarily conserved chaperone Hsp70, after heat shock. Here, we characterized the transcriptional response to acute heat shock (39°C, 5 minutes) in *D. melanogaster* strains from different geographic locations: Raleigh, NC, which experiences a wide range of temperatures (with average lows and highs varying more than 30°C between winter and summer) and Fiche, Ethiopia, with much more limited seasonal variation. We generated total RNA-seq data from ovaries immediately after heat shock as well as after recovery for 60 and 240 minutes. As expected, transcripts for HSPs significantly increased in strains from both populations. There were, however, critical differences between populations in the response of the nonsense-mediated mRNA decay (NMD) pathway as well as in the total number of genes that change transcript levels after heat-shock. The NMD is a conserved and highly selective RNA degradation pathway that also serves as a major regulator of the unfolded protein response (UPR), modulating stress responses in species across the phylogenetic scale. Our results, therefore, suggest population-specific NMD regulation in association with the different natural environments. To study the long-term effects of recurrent heat stress, we also investigated transcriptional responses after multigenerational heat-shock.

821F **Segregation Distorter requires Overdrive for gamete elimination** Jackson Ridges[1], Jackson Bladen[1], Raphaëlle Dubruille[2], Benjamin Loppin[2], Nitin Phadnis[1] [1]School of Biological Sciences, University of Utah, [2]Laboratoire de Biologie et Modélisation de la Cellule, University of Lyon

Intragenomic conflict involving selfish chromosomes is a powerful force in evolution that shapes the evolution of genomes, cells, and species. Segregation distorters that operate in the male germline work through the selective elimination of sperm bearing the competing homologous chromosome. Although selfish systems are known across species, the molecular mechanisms underlying selfish chromosomes remain mysterious. *Overdrive (Ovd)* is necessary for both segregation distortion and male sterility in *Drosophila pseudoobscura Bogota-USA* hybrids. Here, we show that *Ovd* is a non-essential gene that is also required for the selfish action of the nonorthologous selfish system *Segregation Distorter* in *D. melanogaster*. In particular, *Ovd* is required for the targeted elimination of competing gametes by SD. Our results suggest that tricking germline checkpoints may be a common mechanism of selfish chromosomes.

822F **Egg laying behavior in response to CO_2 exposure in *D. suzukii* subgroup** Sasha A Mills[1], Alice Gadau[1], Xin Yu Zhu Jiang[2], Li Zhao[1] [1]The Rockefeller University, [2]Hunter College

All organisms interpret, understand, and react to their environments via an array of inputs to their nervous system. Studying these inputs and the corresponding behaviors may elucidate the genetic basis of these behaviors. The model system Drosophila provides an excellent opportunity to study both the genetic basis and behavioral consequences of exposure to stimuli. Several Drosophila species such as *D. melanogaster* are known to prefer to oviposit on rotten fruits, but the closely related pest species *D. suzukii* and its sister species *D. subpulchrella* have adapted a preference for ripe fruit. This preferential difference is especially interesting to study because ripe fruits have a different odor, texture, and chemical composition than rotten fruits. Ripe fruit also emit more carbon dioxide (CO_2) because of respiration during ripening. In this study, we investigated how CO_2 influences the egg-laying preference of the aforementioned Drosophila species. We used a four-field olfactometer to conduct two-choice egg-laying trials in the presence and absence of CO_2 with *D. melanogaster*, *D. subpulchrella*, and *D. suzukii*. We looked at both positional and oviposition preference and found that the presence of CO_2 severely inhibits egg-laying in *D. melanogaster* but is not aversive to the other two species. We hypothesized that *D. subpulchrella* and *D. suzukii*'s adaptation to higher CO_2 levels may be due to changes in the CO_2 receptors coding region or cis-regulatory element. To substantiate this hypothesis, we designed transgenic D. melanogaster lines that express the *D. subpulchrella*, *D. suzukii* or *D. melanogaster* Gr63a Coding Sequence (CDS) under each species cis-regulatory element. We found that the *D. subpulchrella* CDS shows an increased preference to CO_2 while flies with the *D. suzukii* CDS show an extreme aversion to CO_2. The *D. suzukii* cis-regulatory elements returned some preference for CO_2 in the transgenic lines. This finding could be critical in explaining why and how *D. suzukii* prefer ripe rather than rotten fruit.

823F **Investigating ZAD Gene Evolution on Muller D** Andrew M Arsham[1], Anthony D Cole[2], Tom Giarla[3], Anthony M Howard[2] [1]Department of Biology, Bemidji State University, [2]Bemidji State University, [3]Siena College

The ZAD gene family is defined by the presence of an N-terminal zinc finger associated domain (zf-AD or ZAD), often accompanied by one or more C-terminal C2H2 zinc finger domains. There are more than 90 ZAD proteins in *Drosophila melanogaster* and many are implicated in the regulation or function of heterochromatin. While a small handful of ZAD genes are present in all Arthropods, the family has expanded dramatically in Insects since their divergence from Crustaceans. Accurate characterization of large gene families has historically been hampered by the absence of high quality gene

annotations the difficulty of distinguishing orthologs from paralogs within expanding gene clusters. Here we use recently released high quality gene models generated by the NCBI Eukaryotic Genome Annotation Pipeline to characterize ZAD family evolution across several insect orders. We retrieved all NCBI-annotated transcripts for 257 refSeq Insect genome assemblies and searched their predicted proteins for the presence of ZADs. Preliminary analysis reveals that the ZAD family has expanded by almost 40 fold during insect evolution, from fewer than 20 in some hemipteran aphids to over 600 in the dipteran mosquito *Aedes albopictus*. Detailed analysis of all ZAD genes on the Muller D Element (corresponding to D. melanogaster chromosome 3L) in 21 species of the *Drosophila* genus reveals clade-specific expansions in D. *virilis* and *novamexicana* (25 Myr), the D. *Takahashii* clade, and most notably in D. *kikkawai* where a single ZAD gene appears to have generated a cluster of 16 paralogous copies within the last 8 million years. Interestingly the first two expansions consist mostly of genes with a single coding exon, suggesting possible retroduplication, while the genes of the D. *kikkawai* expansion are all highly expressed predominantly in the embryo. The duplication of ZAD genes appears to follow a similar pattern to olfactory and gustatory receptors and detoxification enzymes in that some phylogenetic branches are virtually unchanged in 50 million years while others spawn multiple independent clade-specific expansions, forming phylogenetic "blooms" suggesting that some members of the gene family are inherently duplication-prone and others are not.

824F **Molecular evolution of a maize hybrid barrier over 12 million years** Elli Cryan[1,2], A Garnet Phinney[1], Arun S Seetharam[3,4], Matthew M S Evans[5], Daniel J Kliebenstein[2], Jeffrey Ross-Ibarra[1] [1]Evolution & Ecology, UC Davis, [2]Plant Sciences, UC Davis, [3]Ecology, Evolution and Organismal Biology, Iowa State University, [4]Genetics, Development and Cell Biology, Iowa State University, [5]Plant Biology, Carnegie Institution for Science

The *Zea mays* species includes three main subspecies: domesticated maize (*mays*), and two teosinte subspecies (*parviglumis* and *mexicana*). All three can readily hybridize, yet remain distinct. Mating incompatibility loci provide one mechanism that can allow populations to maintain reproductive isolation. In *Zea mays*, three complex mating incompatibility loci encode genes that disrupt directional pollen tube growth down the silk. When a maternal plant receives pollen with incompatible alleles, fertilization is impeded, creating a prezygotic reproductive barrier. However, this barrier is not complete. Infrequent fertilization of incompatible gametes facilitates introgression of incompatibility genes into other populations. Previous modeling shows that each factor should only undergo brief periods of strong selection, on a timescale shorter than time to speciation in this clade. Against this expectation of transient benefit, we find evidence of syntenic gametophytic factor loci across modern maize lines, *Zea mays* teosinte subspecies, other members of the *Zea* genus and Tripsacinae subtribe, and species as diverged as *Sorghum bicolor*. All of the loci display presence absence variation and copy number variation. To reconstruct the evolutionary history of these complex loci, we classify haplotype diversity at all three loci in the over 30 *Zea mays* genomes, identify syntenic loci in related species, construct gene trees of known and candidate functional genes, and analyze rates of molecular evolution. We find new evidence of potentially functional reproductive barrier loci and genes in lineages that have been estimated to be twelve million years diverged. We also find evidence of loci driving epigenetic silencing of interacting loci. These loci may have played a role in *Zea* genus speciation.

825F **Inferring Distributions of Fitness Effects of Wild House Mice from Allele Frequency Spectra** Olivia Fernflores, David Castellano, Emanuel Fonseca, Travis Struck, Ryan Gutenkunst University of Arizona

The distribution of fitness effects (DFE) of new mutations is a key input into the evolutionary process. We aim to infer the DFE among multiple populations of wild house mice, so that the extensive knowledge of mouse molecular biology can be leveraged to understand the biological basis of the DFE. To infer the DFE, we first use synonymous mutations to infer a model of demographic history. Here we present preliminary demographic history inferences for populations from Iran and France. We find the best models are those that include a distinct split between the two populations and account for inbreeding between closely related individuals.

826F **On the demographic history of the Western European house mouse, *Mus musculus domesticus*** Kennedy Agwamba Computational Biology, UC Berkeley

Human commensal, *Mus mus domesticus*, is native to the European continent, with a range extending from the Middle East to western Europe by the end of the Iron Age. Wild populations of *M. m. domesticus* are now distributed across Africa, the Americas, and Oceania, a range notably consistent with the global migration patterns of western Europeans that began in the early 16th century. Despite its standing as the premier mammalian model organism for biomedical, ecological, and evolutionary research, important details surrounding the population history of wild house mice remain a mystery. To investigate patterns of genetic structure and infer the demographic history of the Western European house mice, we analyze a collection of 183 mice sampled from western Europe and the Americas, including 59 new whole genome sequences from historically relevant regions of western Europe. Unsupervised clustering analysis groups all samples by geographic location, uniquely identifying a northern European, Mediterranean, and Atlantic Iberian population clade among European samples. Admixture graphs reveal

the Atlantic Iberian clade to be sister to all populations of house mice in the Americas, and a migration edge from the UK to the base of the North America clade indicates a distinct secondary introduction of house mice to the Americas. Demographic models reveal that American populations diverged largely within the last 500 years, consistent with the timing of European colonization history in the Americas. Altogether, these results provide clarity around the recent introduction of Western European house mice to the Americas, highlighting the effects of human migration and global colonization on the concurrent spread of an invasive human commensal.

827F **Differential evolution of gene sequences, expression profiles, and protein structures** Antara Anika Piya[1], Raquel Assis[2] [1]EECS, Florida Atlantic University, [2]Florida Atlantic University

Evolution of genes can occur through modifications at their DNA, RNA, or protein levels. However, the role of each of these changes in genic evolution is currently unclear. Here we address this problem by comparing divergence rates of protein-coding sequences, multi-tissue expression profiles, and protein structural flexibilities in rodents, primates, and grasses. Our analysis reveals that divergence rates are generally lowest for sequences and highest for protein flexibilities in all taxa, consistent with the idea that higher levels of biological organization are closer proxies for the functions on which selection acts. However, divergence rates across these levels are minimally correlated, suggesting that evolutionary targets vary across genes. Indeed, different functions are enriched in genes with high sequence, expression, and protein structural divergence rates. Together, these findings support the hypothesis that evolutionary targets of genes depend on their functions, shedding light on how selection may alter different levels of biological organization in animals and plants.

828F **Effect of chloroplast size and abundance on photosynthesis in diploid vs. polyploid wheat** Damilola Odumade, Joel Sharbrough Biology, New Mexico Institute of Mining and Technology

The plant genome is partitioned into three separate compartments: nucleus, plastid, and mitochondrion. Rubisco (Ribulose-1,5-biphosphate carboxylase/oxygenase) performs carbon fixation in plant chloroplasts and, similar to other jointly encoded plastid-nuclear enzyme complexes, consists of an equimolar ratio of nuclear-encoded small subunits and chloroplast-encoded large subunits. Elevation of nuclear genome copy via whole-genome duplication perturbs the delicate stoichiometry between the nuclear and plastid genomes, potentially affecting the assembly dynamics and/or abundance of plastid-nuclear enzyme complexes like Rubisco. In response to such profound genomic changes, recent work has shown that polyploids exhibit elevated chloroplast abundance and chloroplast genome copy number per cell to compensate for the perturbed stoichiometric imbalance. Consequently, polyploids are expected to exhibit higher photosynthetic capacity than related diploids. We are testing this hypothesis at the genomic and phenotypic level in diploid (*Triticum urartu*, *Aegilops speltoides*) vs. polyploid wheat (tetraploid pasta wheat – *Triticum turgidum*, hexaploid bread wheat – *Triticum aestivum*). At the genomic level, we determined the ratio of the nuclear: chloroplast genome copy number per cell using quantitative PCR. Phenotypically, we imaged chloroplasts in the mesophyll of leaf tissue using light microscopy and counted and measured chloroplast size with ImageJ. We are currently measuring photosynthetic rate using an Oxigraph+ respirometer and will use linear models to test for relationships between the genomic, tissue, and organismal level traits. Together, the data that will be produced during this project will provide important evidence regarding the question of how polyploids are able to overcome the constraints of polyploidy and remain an evolutionary success.

829F **Genomics of Brazilian howler monkeys reveals adaptation to malaria** Katherine McVay[1], Erick Figueroa-Ildefonso[1], Katharine Korunes[1], Luana Portela[2], Patricia Domingues de Freitas[2], Victor Y. Guimarães[3], Ligia S. L. Silveira da Mota[3], Cauê Monticelli[4], João Valsecchi[5], Fernando A. Perini[6], Alcides Pissinatti[7], Amy Goldberg[1] [1]Duke University, [2]Federal University of São Carlos, [3]São Paulo State University, [4]São Paulo Wildlife Coordination, [5]Mamirauá Sustainable Development Institute, [6]Federal University of Minas Gerais, [7]Primatology Center of Rio de Janeiro

Malaria is one of the strongest selective pressures in human evolution, with dozens of genes implicated in adaptation to different Plasmodium parasites. Over 30 Plasmodium species infect non-human primates, including regular parasite sharing with humans. Plasmodium is hypothesized to have arrived in South America ~500 years ago through European Colonization and the Trans-Atlantic Slave Trade. Thus, South American primates provide an opportunity to understand adaptation in a malaria-naïve primate system. In particular, howler monkeys (genus Alouatta) are the primary reservoirs for P. simium, a vivax-like zoonotic malaria infecting humans in southern Brazil, and regularly share P. malariae/brasilianum with humans. We conducted whole-genome sequencing on 88 howler monkeys (average coverage ~11X) to understand broad patterns of shared or unique adaptations to malaria between humans and multiple howler species. Based on 43 host genes known to interact with malaria (adapted from Ebel et al. 2017, PLoS Genetics), we find preliminary evidence for shared and species-specific variation and adaptation in genes associated with red blood cell structure and invasion using a combination of allele-frequency and haplotype-based summary statistics. Additionally, we detect species-level infections with Plasmodium parasites in 14 howler individuals using KrakenUniq, with a higher proportion of infections in the Legal Amazon than other regions. We further

reconstruct broader population structure and demographic history of 4 howler monkey species from across Brazil, finding differences in rates of inbreeding and population size by species. Despite prior ecological suggestions of hybridization, we do not detect evidence of gene flow in our sample.

830F **Multilocus phylogenetic tree estimation using topic modeling** Marzieh (Tara) Khodaei[1], Scott Edwards[2], Peter Beerli[1] [1]Scientific Computing, Florida State University, [2]Department of Organismic and Evolutionary Biology and Museum of Comparative Zoology, Harvard

Inferring the evolutionary history of species or populations employing multilocus analysis is gaining ground in phylogenetic analysis. We developed an alignment-free method to infer the multilocus species tree, which is implemented in the Python package TopicContml. The method operates in two primary stages. First, it uses probabilistic topic modeling (specifically, Latent Dirichlet Allocation or LDA) to extract topic frequencies from k-mers, which are in turn derived from multilocus DNA sequences. Second, these extracted frequencies serve as an input for the program Contml in the PHYLIP package, which is used to generate a species tree. We evaluated the performance of our method with two datasets: a biological dataset with 14 DNA sequence loci from 78-92 individuals from 9 locations and simulated datasets. Both our empirical results and simulated data suggest that our method is efficient and statistically accurate. We also assessed the uncertainty of the estimated relationships among clades using a bootstrap procedure for both unaligned and aligned multilocus sequence data. TopicContml proves a valuable contribution to the computational toolkit for phylogenetics by efficiently constructing evolutionary trees without sequence alignment. It is capable of efficiently extracting the tree by inferring large multilocus dataset, and to our best knowledge, there are no current software packages for constructing multilocus phylogenetic trees using unaligned input data.

831F **Inference of the structured coalescence in the fractional coalescent framework.** Peter Beerli[1], Somayeh Mashayekhi[2] [1]Florida State Univ, [2]Mathematics, Kennesaw State University

We introduced the fractional coalescent to discuss potential heterogeneity affecting offspring number within a single population in 2019. Here, we extended this framework to infer differences of heterogeneity among different populations that are linked by recurrent migration. Our approach uses multilocus DNA data as input and estimates parameters of a structured coalescent model with multiple populations linked by migration. Each population has an additional parameter alpha, that changes according to the magnitude of heterogeneity within the population.

For simulation testing of our inference program, we created a 2-population extension of the Nest Site Model, introduced by Wakeley, to generate synthetic DNA data. This simulated data is then used to estimate population sizes, immigration rates, and the parameters alpha that describe the potential differences in response to environmental heterogeneity. We report accuracy and timing for various numbers of loci and different parameter settings.

832F **Differentiating mechanism from outcome for ancestry-assortative mating in admixed populations** Dashiell J Massey[1], Zachary A Szpiech[2,3], Amy Goldberg[1] [1]Evolutionary Anthropology, Duke University, [2]Department of Biology, Pennsylvania State University, [3]Institute for Computational and Data Sciences, Pennsylvania State University

Non-random mating is an important source of genetic structure in natural populations. Empirical studies across multiple animals, including humans, have found positive correlations in trait values between mates, potentially confounding genome-wide association studies, selection scans, and demographic inference. In particular, within recently admixed human populations – who derive ancestry contributions from multiple source populations – previous work has observed a correlation in global ancestry proportion between spouses, known as ancestry-assortative mating. Population genetic models of ancestry-assortative mating typically calculate the likelihood of mating using ancestry proportion. Here, we use whole-genome forward simulations in SLiM to interrogate the relationship between the mechanistic process of mate choice and observed outcomes for the potential correlation in ancestry between mating pairs. We consider commonly-used ancestry-based mate choice models alongside a discrete sociological model based on group identity. In humans, sociodemographic factors strongly influence mating, and are often correlated with genetic ancestry, providing the opportunity for social group identity to serve as the link between ancestry and mate choice. We find that even a mate-choice model that does not explicitly include preferences based on ancestry, but rather uses group identity as a proxy, can produce correlations in ancestry between mating pairs, with similar results for summaries of global and local ancestry. That is, multiple potential mate-choice processes can produce similar ancestry correlation plots, suggesting caution in interpretation of empirical data. Conversely, even when the underlying process involves biased mate choice, the observed outcome may not show a correlation in ancestry because without further migration, some common models do not maintain sufficiently high variance in ancestry proportion to sustain ancestry-assortative mating over tens of generations.

833F **Inferring Demographic History in the Presence of Low-Coverage Sequencing** Emanuel Masiero da Fonseca, Ryan Gutenkunst Molecular and Cellular Biology, University of Arizona

The emergence of low-coverage genome sequencing as a cost-effective approach has opened avenues for the comprehensive analysis of large cohorts. Nevertheless, the inherent reduction in heterozygous genotypes associated with this strategy introduces a notable source of bias in downstream analyses, including demographic history inference. In response to this challenge, we developed a novel probabilistic model expressly designed to reduce the distortions induced by low-coverage sequencing and implemented it in the inference software dadi. We assessed the accuracy of this framework by examining simulated low-coverage datasets that portrayed two distinct demographic scenarios: an exponential growth model and a strict isolation model. We found that the incorporation of distortion correction led to a close alignment between the inferred and true demographic parameters. Conversely, failing to consider the distortion introduced by low-coverage sequencing resulted in a notable bias during parameter estimation. To complement our simulations, we conducted real-data analyses, downsampling the 1000 Genomes Project data and analyzing low-coverage data from three distinct fish species. The application of our probabilistic model to these datasets further validated the efficacy of our correction method, demonstrating its utility in addressing challenges associated with reduced heterozygosity in real-world scenarios. In conclusion, our research underscores the critical importance of mitigating bias introduced by low-coverage sequencing through the application of a probabilistic model. By implementing this correction, we not only address the challenges associated with reduced heterozygosity but also enhance the accuracy of demographic parameter inference, thereby increasing the reliability of population genetic studies in the genomic era.

834F **Co-existing strains drive rapid and reversible genetic turnover in antibiotic treated human gut microbiomes** Sophie J Walton[1], Katherine S Xue[2], Daniel PGH Wong[3], David A Relman[3], Dmitri A Petrov[2], Benjamin H Good[4] [1]Biophysics, Stanford University, [2]Biology, Stanford University, [3]Stanford University, [4]Applied Physics, Stanford University

Transient perturbations can rapidly alter the composition of microbial communities like the human gut microbiome, but the evolutionary processes that underlie this collective response are still poorly understood. In particular, it remains unclear to what degree evolutionary change is driven by selection on de novo mutations rather than displacement of dominant strains by distantly related strains of the same species. To address this gap, we examined longitudinal metagenomic sequencing data from the gut microbiomes of 22 participants who took a 5-day course of the antibiotic ciprofloxacin. These participants experienced transient or permanent shifts in microbiome composition at the onset of antibiotic treatment, which suggested antibiotics induced transient selection pressures on microbiota populations. We found few examples of de novo mutations in the core genome that swept during or after antibiotic perturbation, even in populations that expanded substantially during antibiotics and persisted at a high frequency. However, we found many instances of strain displacement by distantly related populations of the same species events during antibiotic administration, which were often driven by expansions of pre-existing strains within a host from low to high frequency, rather than colonization by external strains. One third of the displaced strains reverted back to high frequency after the antibiotic perturbation ended, such that the strain after antibiotics closely resembles the pre-antibiotic composition even if the host microbiome composition shifts to an alternative stable state. To investigate whether this reversible genetic turnover is driven by selection, we are simulating neutral population genetic models to examine whether demography alone can drive the observed frequency trajectories. These results suggest that the coexistence of multiple strains of the same species in a person's gut microbiome can drive reversible genetic turnover in response to transient perturbations without core genome evolution.

835F **Enrichment of sex-biased genes associates with the origins of multiple neo-sex chromosomes in Danaini butterflies** Pablo Mora[1,2], Monika Hospodářská[2], Anna Voleníková[2], Petr Koutecký[2], Jana Štundlová[2], Martina Dalíková[2,3], James Walters[3], Petr Nguyen[2] [1]University of Jaén, [2]Faculty of Science, University of South Bohemia, [3]Ecology & Evolutionary Biology, University of Kansas

Sex chromosomes play an outsized role in adaptation and speciation, and thus deserve particular attention in evolutionary genomics. In particular, fusions between sex chromosomes and autosomes can produce neo-sex chromosomes, which offer important insights into the evolutionary dynamics of sex chromosomes. Here we investigate the evolutionary origin of the previously reported *Danaus* neo-sex chromosome within the tribe Danaini. We assembled and annotated genomes of *Tirumala septentrionis* (subtribe Danaina), *Ideopsis similis* (Amaurina), *Idea leuconoe* (Euploeina), and *Lycorea halia* (Itunina) and identified their Z-linked scaffolds. We found that neo-sex chromosomes shared by *Danaus* spp. arose in a common ancestor of Danaina, Amaurina, and Euploina. We also identified two additional independently evolved neo-Z chromosomes in *I. similis* and *L. halia.* We further tested a possible role of sexually antagonistic selection in sex chromosome turnover by analyzing the genomic distribution of sex-biased genes in *I. leuconoe* and *L. halia*. The synteny blocks involved in the fusions are enriched in sex-biased genes, consistent with the hypothesis that this could facilitate fixation of neo-sex chromosomes. This suggests a role of sexual antagonism in sex chromosome turnover in Lepidoptera. The neo-Z chromosomes of both *I. leuconoe* and *L. halia* appear fully compensated in somatic tissues, but the extent of dosage compensation for the ancestral Z is variable across tissues and species.

836F **The unreasonable effectiveness of Graph Convolutional Networks in population genetic inference** Logan S Whitehouse[1], Dylan D Ray[1], Daniel R Schrider[2] [1]University of North Carolina, [2]Department of Genetics, University of North Carolina

In recent years researchers have begun adapting machine learning methods to population genomics, including the development of deep neural networks that act directly on population genetic alignments. In general, these deep learning methods show enormous promise for more accurate inference. There have also been a number of exciting recent advances related to the development and deployment of novel tree-based representations of genotype data, including the release of several methods that seek to rapidly infer the sequence of trees along a recombining chromosome for large cohorts. Importantly, these tree sequences not only represent a hypothesized evolutionary history of a set of genomes, they also enable highly compressed storage of population-scale sequence data. These advancements have led some researchers to explore the possibility of using tree-sequences, or summaries thereof, as input to machine learning methods. However, one may notice that this approach appears to be an especially severe violation of Vapnik's aphorism: "When solving a problem of interest, do not solve a more general problem as an intermediate step." Here, the intermediate step is to first infer the entire evolutionary history of every locus across the genome for a population sample, prior to, say, asking whether locus *A* has experienced a recent selective sweep. Another potential caveat with such approaches is that tree-sequence inferences are error-prone, and it is unclear to what extent using erroneous trees as input will hinder subsequent inference. With these potential issues in mind, we sought to evaluate the general utility of tree sequences for population genetic inference. To this end, we trained graph convolutional networks (GCNs) to take inferred tree sequences as input and perform four different tasks: detecting recent selective sweeps, detecting introgressed loci, inferring recombination rates, and inferring the parameters of a simple demographic model. We compared the performance of this GCN to a convolutional neutral network (CNN) that we previously showed to achieve excellent performance on these problems. Surprisingly, we found that for each task the performance of the GCN was comparable to that of the CNN. This implies that inferred tree sequences can be used as input for accurate downstream inference for more specific population genetic questions. Importantly, because we used inferred tree sequences that were likely reconstructed with a fair amount of error, our results imply that erroneous tree sequences do not preclude accurate subsequent inference so long as the model has been trained on tree sequences inferred in the same manner. Overall, we conclude that tree sequence-based machine learning methods may prove to be just as powerful and flexible for population genetic inference as CNNs, and have the potential to be more computationally efficient as well.

837F **Inference of the demographic histories and selective effects of human gut commensal microbiota over the course of human history** Jonathan C Mah[1], Kirk E Lohmueller[2], Nandita Garud[3] [1]Bioinformatics Interdepartmental Program, University of California, Los Angeles, [2]Ecology and Evolutionary Biology, University of California, Los Angeles, [3]Bioinformatics, University of California, Los Angeles

Despite the importance of gut commensal microbiota to human health, there is little knowledge about their evolutionary histories, including their population demographic histories and their distributions of fitness effects (DFE) of new mutations. Here, we infer the demographic histories and DFEs of 27 of the most highly prevalent and abundant commensal gut microbial species in North Americans over timescales exceeding human generations using a collection of lineages inferred from a panel of healthy hosts. We find overall reductions in genetic variation among commensal gut microbes sampled from a Western population relative to an African rural population. Additionally, some species in North American microbiomes display contractions in population size and others expansions, potentially occurring at several key historical moments in human history. DFEs across species vary from highly to mildly deleterious, with accessory genes experiencing more drift compared to core genes. Within genera, DFEs tend to be more congruent, reflective of underlying phylogenetic relationships. Taken together, these findings suggest that human commensal gut microbes have distinct evolutionary histories, possibly reflecting the unique roles of individual members of the microbiome.

838F **Phylogenetic Approach to Understand the Evolution of Drug Resistance in Mycobacterium Tuberculosis in Russia, China and South Africa** Pleuni S. Pennings, Marisol Fermin Flores Biology, San Francisco State University

Mycobacterium tuberculosis (Mtb) is the causal agent for a severe bacterial disease that affects the lungs and causes tuberculosis (TB). Due to the increase of drug resistance in Mtb, treating TB effectively has become harder. It is critical to understand the evolution and spread of drug resistance in TB to find ways to prevent drug-resistant infections. In principle, there are two ways in which a patient can get infected with an Mtb strain that is resistant to a given drug: through de novo evolution or via transmission of an already resistant strain. In de novo evolution, the patient is infected with a susceptible strain, which then evolves to become resistant. Alternatively, an already resistant strain is transmitted from another host. It is expected that host-to-host transmission of resistant strains leads to clusters of phylogenetically related strains that share drug resistance mutations. It is not well understood how much resistance is due to transmission. Understanding the importance of transmission for a given drug or country can help guide new policies or interventions to prevent transmission.

Our objective is to determine the relative roles of de novo and transmitted resistance using publicly available data and a phylogenetic approach. The plan is to use a previously established approach in the Pennings lab to (1) create a phylogenetic tree from a publicly available genome sequences and (2) to identify phylogenetic clusters of drug resistant strains (using phytools in R) and (3) compare cluster sizes for resistances to different drugs and for different countries: Russia, China and South Africa. Findings from this study will help us understand the relative roles of de novo evolution and transmission for resistance in Mtb. Understanding Mtb drug resistance in tuberculosis can have a significant impact, as we might be able to provide personalized medicine and uncover ways to mitigate rates of evolution and transmission of resistant Mtb.

839F **The effects of demographic history and linked selection on patterns of genomic diversity in the globally invasive mosquito *Aedes aegypti*** Tyler V Kent, Daniel R Matute, Dan R Schrider University of North Carolina at Chapel Hill

Aedes aegypti, the primary vector of the human arboviruses—dengue, Zika, yellow fever, and chikungunya—was introduced to the Americas beginning with European colonization of South America, and more recently spread throughout the southern United States. Throughout its invasive range, *Ae. aegypti* has faced strong selective pressure from eradication methods, and previous work has suggested there are multiple competing selected haplotypes at loci known to confer insecticide resistance within populations. However, the demographic history of the spread of *Ae. aegypti* within the Americas and the genomic effects of extreme anthropogenic selective pressure are poorly characterized. Here we infer the demographic history of *Ae. aegypti* using previously published resequencing data from 131 samples from Africa and the Americas, including 75 samples from Colombia, Brazil, and the USA. We find evidence for separate introductions throughout the Americas, with strong population structure at fine and coarse scales, variation in the timing of introduction bottlenecks among older and more recently introduced populations, and strong recoveries in population size over short timescales. All introduced populations show an approximately 1.5-fold reduction in neutral diversity, but only minor reductions in the genome-wide efficacy of selection; however, the efficacy of selection is substantially reduced in regions surrounding inferred selective sweeps. Thus, we use a combination of the of the decay of the reduced efficacy of selection around selective sweep signals and forward-in-time population genetics simulations under the inferred demography to estimate the proportion of the genome where linked selection is the primary driver of reduced diversity and efficacy of selection genome-wide in both the native and introduced ranges. This work provides the first detailed population demographic history of *Ae. aegypti* in both its native and introduced range, and more broadly contributes to our understanding of the genomic consequences of the spread of highly invasive species and adaptation to anthropogenic control efforts.

840F **Fat-tailed dispersal facilitate local adaptation in some habitats** Sherif Negm[1], John Novembre[2,3] [1]Human genetics, The University of Chicago, [2]Department of Human Genetics, The University of Chicago, [3]Department of Ecology and Evolution, The University of Chicago

Local adaptation is a central problem in evolutionary biology that arises when individuals in populations exist along an environmental gradient experiencing different selection pressures. This combines two of the major forces that shape the evolution of populations: gene flow and natural selection. Haldane (1930) and Wright (1931) studied the condition when migration overwhelms selection, leading to ‘swamping’ of the locally beneficial allele in the Island-continent model. However, this model assumes discrete population structure while realistically, individuals lie continuously along the environmental gradient. An alternative way to model this is the ‘patch-cline’ model, studied by Slatkin (1973). Here, an allele is favored within a finite length patch in a habitat where individuals can disperse continuously. Under this model, Slatkin (1973) derived a differential equation describing the cline and a ‘characteristic length’ for the patch to show a response to selection while not being overwhelmed by dispersal. However, a main limitation is that this was only confined to short-distance ‘diffusive’ dispersal. Long distance dispersal consequences has been studied for species range expansion (Nichols et Hewitt, 1994) and (Kot et Lewis, 1996). In addition, it has recently been used to model the spread of adaptive alleles (Ralph and Coop, 2010). However, we lack understanding of the effect of fat-tailed dispersal on local adaptation. In this study, we approximate the cline under long distance dispersal by deriving a simple approximate diffusion-convection differential equation for the cline shape under a fat-tailed dispersal kernel. We show that our approximate model matches simulations of the full model under fat-tailed kernel with high accuracy. Counterintuitively, We find that the response to selection in the patch tends to be stronger under fat-tailed dispersal kernels in some habitats, as predicted by the characteristic length. Our results highlight the importance of studying local adaptation under more general dispersal kernels.

841F **Wild bines to beer steins: Exploring the evolutionary genomics of hops domestication** Alexandra McElwee-Adame, Arun Sethuraman Biology, San Diego State University

Humulus lupulus, commonly known as hops, is a perennial crop that natively grows in Asia, Europe, and the United States. For hundreds of years, hops have provided several medicinal, pharmacological, cosmetic, and culinary applications. Of all the industries that the hops plant serves, the largest is the brewing industry. Hops is one of the four key ingredients in

the process of making beer, often added to produce a necessary bitterness from secondary metabolites produced by the lupulin gland in the hop's cones to offset the sweetness of grain. Commercially, there are over 250 different hops cultivars developed worldwide displaying a variety of characteristics in aroma profiles, bittering properties, vigor, and disease tolerance/vulnerability. Previous genomic studies on hops have been dedicated to exploring the genes associated with desirable traits to breeders and brewers alike and how these traits respond to different environmental stimuli, however no studies have explored the evolutionary history of how this plant became domesticated and the genomic consequences of domestication. Our study aims to explore the evolutionary genomics of hops domestication and identify signatures of selection in the domestication process. DNA was extracted from more than 150 cultivars and wild-type samples provided by the USDA Agricultural Research Services. These samples encompassed the total global distribution and purified DNA was sent off for whole-genome sequencing. Assembled genomes will be used to explore the global population structuring, genetic diversity, phylogenetic relationships both between wild and domesticated hops as well as between hops cultivars. Additionally, whole genome sequences will be used to identify regions within cultivar genomes that may display signatures of selection and investigate patterns of gene loss, gain or changes as well as estimate the origin of the hops domestication process. We hope that our findings will provide insight into how hops not only became domesticated but identify the genes responsible for the qualities that are sought after by breeders and brewers.

842F **The effect of long-range linkage disequilibrium on allele frequency dynamics under stabilizing selection** Sherif Negm[1], Carl Veller[2] [1]Department of Human Genetics, The University of Chicago, [2]Department of Ecology and Evolution, The University of Chicago

To understand how selection shapes complex traits in humans, we need to connect population genetic models with data from genome-wide association studies (GWASs). For non-disease traits, a particularly plausible scenario to model is stabilizing selection, which penalizes deviations from an optimal trait value. The basic effect of stabilizing selection on a heritable trait is to reduce the trait's genetic variance. It achieves this in two ways. First, by selecting for compensating combinations of trait-increasing and trait-decreasing alleles, stabilizing selection generates systematic negative linkage disequilibrium between alleles with the same directional effect on the trait (Bulmer 1971). Second, stabilizing selection disfavors rare alleles relative to common ones, causing rare alleles to decrease in frequency in a way that mimics under-dominant selection. The second process, the effect of stabilizing selection on allele frequency dynamics, has recently been shown to be consistent with the genetic architectures of many human traits, as inferred from GWASs (Simons et al. 2018, 2022). Here, we show that these allele frequency dynamics are also influenced by the linkage disequilibrium that stabilizing selection necessarily generates. We exploit a separation of time-scales to quantify this effect, showing that linkage disequilibrium slows down allele frequency changes in a predictable way that depends on measurable parameters of the selection process. Using forward simulations in SLiM, we test our approximation across various genetic architectures, allowing for variation in minor-allele frequencies and effect sizes across loci, and variable genome-wide linkage maps. We explore the implications of the slowdown caused by the Bulmer effect for analyses of the genetic architecture of human traits. We further characterize the effect of this slowdown on population differentiation of traits under stabilizing selection, exploring implications for the "portability" of genomic analyses from one population to another.

843F **Genetic incompatibility increases meiotic nondisjunction in intra-species *C. briggsae* hybrids** Lesly Pereira-Fita[1], Kyle-Asa Lee[1], Joseph Ross[2] [1]California State University, Fresno, [2]Biology, California State University, Fresno

Postzygotic reproductive isolation barriers can arise from genetic divergence between two populations. Such Dobzhansky-Muller interactions involve alleles in different genes that cannot function properly together in the context of an inter-population hybrid genetic background. Because the faithful segregation of sister chromatids during gametogenesis is critical to fertility, and because this process is regulated by many protein complexes, hybrid genetic incompatibilities involving meiosis-related genes could lead to decreased fitness, and potentially thereafter to speciation. It is widely appreciated that the natural frequency of males in androdioecious species of *Caenorhabditis* (e.g. *C. elegans*, which has two sexes: males and self-fertile hermaphrodites) is very low compared to the 1:1 sex ratio that typifies gonochoristic species, which have males and females and are obligately sexually reproducing. *Caenorhabditis* males are genetically XO, and the spontaneous production of males is caused by X chromosome nondisjunction. Thus, male frequency is a proxy for meiotic nondisjunction rates, which are often reported in *Caenorhabditis* as producing about 1 male per 1,000 individuals. *C. briggsae* populations have been useful for investigating genetic incompatibilities, particularly because of their phylogeographic clustering and genetic divergence. We have investigated the existence of genetic incompatibilities between the temperate and tropical circles of latitude clades by establishing multiple crosses between and within clades and populations. We find that many inter-clade crosses produce F1 hybrids with increased meiotic nondisjunction rates compared to within-population control crosses. Thus, spontaneous high incidence of males (*him*) mutations cannot explain the observed data. The results raise the possibility that a dominant genetic incompatibility interferes with meiotic sister chromatid segregation. Although X chromosome nondisjunction is tolerated as a result of dosage compensation, it is possible that nondisjunction of autosomes could simultaneously be producing F2

individuals that have reduced fitness and represent the onset of speciation between the temperate and tropical clades of *C. briggsae*.

844F **Molecular evolution of genes underlying toothed whale acoustic behavior** Leticia Magpali Moura Estevao[1], Elisa Ramos[2], Agnello Picorelli[3], Lucas Freitas[3], Sarvang Dave[4], Mariana Nery[3], Joseph Bielawski[5] [1]Biology, Dalhousie University, [2]Universität Basel, [3]Genética, Evolução, Microbiologia e Imunologia, Universidade Estadual de Campinas, [4]Computer Science, Dalhousie University, [5]Biology; Mathematics and Statistics, Dalhousie University

Acoustic behavior plays a fundamental role in the survival of most animals. For marine mammals, in particular, producing and receiving sounds is the most efficient way of communicating underwater, where vision is often limited. Toothed whales rely on sounds for all aspects of their lives: for instance, they use echolocation to hunt for food, and social sounds like whistles to communicate. Their acoustic behavior depends on specialized biological functions, such as hearing, sound production, cognitive processing and vocal learning. It has been suggested that the environment plays a crucial role in shaping the evolution of toothed whale sounds, however, this hypothesis has yet to be addressed under a phylogenetic framework. Furthermore, little is known about the genes underlying toothed whale acoustics and how they evolved in species that colonized different habitats. To address these questions, we analyzed a set of candidate genes potentially involved in acoustic behavior across 37 species of toothed whales. We used a combination of statistical models to compare the evolutionary rates of these genes across riverine, coastal, and oceanic toothed whales. For the hearing genes CDH23, TMC1 and SLC26A5, we found significant rate variation among toothed whales from distinct habitats, in combination with strong evidence of positive Darwinian selection. We also uncovered positively selected sites located near functional protein regions, and statistically associated with radical amino acid changes or habitat differences. Overall, coastal and riverine lineages experienced accelerated evolution compared to oceanic species. Lineages under positive selection, or enriched for positively selected sites, were either from riverine/coastal shallow waters, or deep diving oceanic species. Coastal dolphins under positive selection have recently diverged from riverine sister species, suggesting that historical selective pressures could have triggered rapid adaptation to the coastal environment. Finally, we uncovered potentially convergent substitutions among species that share similar sonars, such as river dolphins and Narrow-Band High-Frequency echolocators. Our findings corroborate and extend previous suggestions that specific environments imposed unique selective pressures on toothed whale echolocation genes and phenotypes. Our study suggests multiple pathways for the evolution of the toothed whale sonar, and contributes to unraveling the molecular basis of environmental adaptation. Future work will focus on a network of genes functionally connected to sound production, hearing, processing and vocal learning. Joint analysis of phenotype-genotype within the context of a functional network could illuminate new genetic systems associated with acoustic behavior in cetaceans, and further improve our understanding of how toothed whale sounds evolved in different habitats.

845F **The Impact of Treatment Timing on the Probability of Cure in Two-strike Therapy Protocols** Amjad Dabi[1], Daniel Schrider[2] [1]University of North Carolina at Chapel Hill, [2]Bioinformatics and Computational Biology, UNC Chapel Hill

The emergence of resistance to therapeutic agents poses a difficult challenge to treatments involving clonal populations such as bacteria or cancer cells. When resistance to first-line treatments becomes evident, a standard practice is to switch to second-line treatments. However, it is not yet clear what the optimal timing of the second-line treatments is, and whether administering such treatments before evidence of resistance is present would yield better outcomes. In this study, we use forward-in-time genetic simulations, adapting evolutionary rescue models to simulate the expansion and treatment of a clonal population in a two-strike therapy regime and investigate the impact of various parameters, including the pre-treatment population size, mutation rate, treatment efficacy, and the fitness advantage of resistance. The simulated population expands exponentially from a single cell until reaching a specified size, after which two treatments are applied serially. Treatment efficacy is modeled as the per-generation death probability of cells during treatment, and each treatment has an associated rate of mutations that confer resistance to that treatment by lowering the per-generation death probability of cells harboring them. Consistent with previous work in evolutionary rescue, we find that increasing the mutation rate or pre-treatment population size increases the likelihood of rescue, while increasing treatment efficacy results in the opposite effect. Given the clinical importance of treatment timing, we also explore its effect on outcomes. Our results indicate that the timing of the second strike is an

important factor and that in some cases, second strikes that precede the emergence of resistance to the first strike are more effective at preventing the emergence of resistance and subsequent evolutionary rescue.

846F **Pervasive paternal mitochondrial transmission in *C. briggsae* hybrids** Joshua Proctor[1], Kevin Helwick[1], Joseph Ross[2] [1]California State University, Fresno, [2]Biology, California State University, Fresno

Strictly maternal mitochondrial transmission to offspring might have evolved to prevent heteroplasmy, which is the presence in a cell of mitochondria with different mitochondrial genotypes (mitotypes). Paternal mitochondrial transmission (PMT), though an unexpected phenomenon, has been occasionally observed in several species in crosses between genetically diverse parents, including in *Caenorhabditis briggsae*. However, the molecular mechanism by which PMT occurs is unclear. Hybrids of genetically divergent parents might experience PMT as a result of genetic incompatibilities. Thus, we hypothesized that PMT frequency is directly related to the amount of genetic divergence between parents. Essential resources that supported this work include the availability of multiple *C. briggsae* populations at the CGC as well as known phylogeographical relationships between them. We first created restriction fragment length polymorphism (RFLP) PCR assays that can distinguish the mitotypes of various *C. briggsae* populations. We then created multiple cytoplasmic-nuclear hybrid (cybrid) lines: some from crosses between more genetically similar populations (e.g. within-clade tropical x tropical), and others from crosses of populations from different clades (e.g. between-clade temperate x tropical). Each line was created by a five-generation serial paternal backcross followed by five generations of selfing. DNA from each line was purified and genotyped to detect heteroplasmy. PMT, evident as heteroplasmy, was observed in the majority of lines, regardless of whether a within-clade or a between-clade cross. There was no significant difference in the frequency, which suggests that genetic divergence between populations does not directly influence PMT rates. One interpretation of these results is that *C. briggsae* might be inherently unable to prevent PMT. Future work should monitor mitochondrial transmission dynamics at fertilization (both in self-fertilization and also in crosses between genetically identical males and hermaphrodites), which cannot be accomplished using our PCR-based approach. The prevalence of PMT in *C. briggsae* crosses motivates further work to investigate the genetic and molecular basis of mitochondrial transmission regulation.

847F **Signatures of selective sweeps in continuous-space populations** Meera Chotai, April Wei, Philipp W Messer Computational Biology, Cornell University

Selective sweeps describe the process by which an initially rare advantageous mutation increases in frequency in a population, thereby removing genetic variation in its genomic vicinity. Hard sweeps originate from a single haplotype, while soft sweeps describe scenarios where multiple haplotypes carrying the beneficial allele spread at the same time. The signatures of hard and soft sweeps have been studied primarily under panmictic models, but natural populations are often structured spatially, which could affect sweep signatures. To investigate this effect, we simulated selective sweeps in populations inhabiting two-dimensional continuous space, where the dispersal range of offspring from their parents can be varied from limited to extensive, at which point it is equivalent to a panmictic population. We found that advantageous mutations spread more slowly in a population with limited dispersal as compared to a panmictic population, leading to a lower fixation probability. At the same time, recombination is less effective at breaking up genetic linkage in populations with limited dispersal. Together, these effects result in selective sweeps that extend over similar genomic sizes across dispersal rates. However, hard sweeps in the low-dispersal regime tend to have higher haplotype heterozygosity, bearing a resemblance to soft sweeps. These results highlight the need for better accounting of spatial population structure when making inferences about selective sweeps.

848F **A genealogical interpretation of LD at a small locus** Mariadaria K Ianni-Ravn[1], John Novembre[2] [1]Human Genetics, University of Chicago, [2]University of Chicago

When mutations occur in close proximity to each other, they are correlated until recombination breaks down the linkage disequilibrium (LD) between them. The signed LD between pairs of mutations describes the probability of them being found on the same or different haplotypes more or less often than expected if they were unlinked. Although in principle mutations can exhibit positive or negative epistatic fitness interactions (Crow 2010), LD decreases the overall efficacy of selection and increases the probability of deleterious alleles fixing in a population - a phenomenon known as ‘selective interference’ (Hill and Robertson, 1966). Although the emergence of LD has been studied extensively (for example, McVean, 2002; Ragsdale and Gravel, 2019; Good, 2022), most focus has been on modelling patterns over many generations due to recombination; there has been less theoretical work on the dynamics within a small locus over short timescales, before recombination can cause the correlation structure to decay. However, without an understanding of this, it is difficult to interpret patterns of variation and the allelic structure at genomic regions in the kilobase scale.

In this study, we focus on the signed LD resulting from “genealogical correlation” - the linkage implied by the relative

placement of mutations on the genealogy describing a locus. This allows us to understand how often pairs of mutations should be in positive or negative LD, given that they occur in close proximity to each other. In short, mutations located “downstream” of each other on a genealogy exhibit positive correlation, while those on opposing sides of the genealogy display negative correlation. We derive the probabilities of these relationships under neutrality, and use a simulation approach to show that they can be affected by forces which distort the genealogical process - such as non-equilibrium demography and selection. Finally, we apply our reasoning to interpret patterns of signed LD at specific genomic loci in humans, such as CFTR and MHC. These results help us to understand the emergence of dominance, and emphasize that LD is not a static feature, but rather is a dynamic force which both affects and is affected by population genetic processes.

849F **Investigation of putative parthenogenesis in the vulnerable Jamaican Boa (*Chilabothrus subflavus*)** David Graber, Kyle Mara, Kimberly Delaney Biology, University of Southern Indiana

Facultative parthenogenesis (FP) has been demonstrated in numerous animal taxa such as: sharks, varanid lizards, birds, and snakes. There are multiple mechanisms by which a female of a dioicous species can produce offspring asexually without genetic material from a male mate including apomixis, central fusion automixis, and terminal fusion automixis. While FP via terminal fusion automixis has been demonstrated in multiple boa species, the Jamaican boa (*Chilabothrus subflavus*) has not previously demonstrated FP. An eight-year-old captive female Jamaican boa, housed in a private collection, gave birth to two living and multiple nonliving offspring after a period of isolation lasting her entire adult life. This female was separated from all other individuals from at least six months of age and any previous contact with males came from her own clutch. We isolated DNA samples from the female, her offspring, and a male clutch mate. Using short tandem repeat analysis of multiple nuclear microsatellite loci previously described in this species, we will present genetic data from these samples which will help elucidate the origin of this reproduction event. Neither sperm storage of this duration nor parthenogenesis have been previously documented in this species. While a sperm storage event is theoretically possible, it is highly unlikely as the last potential contact the female had with a male mate would have been just after birth. We believe this reproduction event represents the first documented case of parthenogenesis in this species. Events of this nature may have significant implications for the genetic diversity of the endemic population of this vulnerable species and the captive breeding programs in place to preserve the species.

850F **When does adaptation arise from a polygenic response versus few large effect changes** William Milligan[1], Laura Hayward[2], Guy Sella[1] [1]Biological Sciences, Columbia University, [2]Institute of Science and Technology Austria

When does adaptation arise from a polygenic response versus few large effect changes? This question traces back to early debates sorounding Darwin’s “Origin of species” and remains wide open today. Strong but indirect evidence suggest that polygenic adaptation should be ubiquitous, but demonstrations have proven elusive. In turn, there are hundreds of examples of large effect adaptations in many species, but it remains unclear whether they represent a common mode of adaptation in any given species. Translating these disparate evidence into general answers is complicated by the fact that the approaches to studying adaptation are designed to answer different questions and differ in their limitations and biases. We propose that a productive way forawrd starts with reframing the question in terms of traits and asking: how does the genetic basis of adaptation depend on the properties of genetic variation in a trait and on changes in selection pressures acting on it. We study this question in a simple yet highly relevant setting. We consider a quantitative trait subject to stabilizing selection around an optimal value, and model the response to selection when a population at MSDB experiences a sudden shift in this optimal value. We characterize the adaptive response in this setting both quantitatively and qualitatively, specifically, we delimit how the adaptive contributions of large-effect and polygenic changes depend on a trait’s genetics and ecology. We discuss other salient factors that affect adaptation, how the theory we present and its future development could help us to understand when different modes of adaptation are expected, and how such theory can provide a framework within which to interpret the diverse and growing body of evidence about the genetic basis of adaptation.

851F **Genetic variation in prey size and movement interacts to affect predation risk in *Paramecium caudatum*** Kyle Coblentz, Kristi Montooth, John DeLong School of Biological Sciences, University of Nebraska-Lincoln

Species’ traits play a key role in determining the outcomes of predator-prey interactions with consequences for population dynamics, food webs, and trait evolution. Few studies have evaluated the heritability of traits related to predation risk and their potential genetic correlations to predict how selection will shape predator-avoidance traits of prey. Moreover, given the pervasive effects of temperature on the development of traits related to size and movement in ectotherms and the fact that temperature also affects how predators and prey interact, it is likely that prey trait evolution to temperature will be impacted by the presence of predators. We are using the freshwater ciliate *Paramecium caudatum* as a model system to investigate how predators shape prey trait evolution and how this evolution impacts predator-prey dynamics in the context of a warming thermal environment. We will present data demonstrating significant genetic variation for morphology and movement behavior in outcrossed, clonal lines of *P. caudatum* from Nebraska ponds. Genetic variation in prey traits significantly affected

fitness, as it altered *Paramecium* susceptibility to predation by the copepod *Macrocyclops albidus* also collected from Nebraska ponds. The proportion of *Paramecium* consumed by copepods was positively associated with *Paramecium* body size and greater velocity as one might expect from interspecific relationships. However, we also found evidence of an interaction such that greater velocities led to greater predation for large body-sized *Paramecium* but did not alter predation risk for smaller body-sized *Paramecium*. In contrast to what has been observed in interspecific allometric relationships, body size and movement speed did not positively covary across clonal lines. These patterns of predation risk and heritable variation in the traits of *Paramecium* together suggest that copepod predation likely acts as a selective force that could operate independently on movement speed and body size and operate most strongly on large, fast *Paramecium*. We are testing these predictions using this pool of genetic variation in a long-term evolution experiment that evolves *Paramecium* to warmer and colder thermal environments in the presence or absence of predators.

852F **Investigating the effects of voltinism polymorphism on the rate of molecular evolution in the European corn borer (*Ostrinia nubilalis)*** Alejandro Calderon, Erik Dopman, Lawrence Uricchio Biology, Tufts University

Adaptation may be a crucially important driver of population outcomes for species experiencing variable environments. Many terrestrial arthropod species have intraspecific variation of voltinism (number of generations per year) due to seasonal variation, and population genetics theory suggests that generation time may be a determinant of the rate of molecular evolution. However, the adaptive significance of polymorphic voltinism has not been fully elucidated, despite of genomic characterization of some species' circannual variation. Species with polymorphic voltinism may provide a unique view of molecular evolution because intraspecific variation in generation time may have detectable effects on patterns of polymorphism and divergence. In this study, we investigate the role of polymorphic voltinism in shaping the rate of molecular evolution in *Ostrinia nubilalis*, the European corn borer (ECB) moth. Prior studies revealed that two clock genes, period (*per*) and pigment-dispersing receptor factor (*Pdfr*) might be the genomic determinants of circannual rhythm in ECB. Our project leverages pool seq data from 14 populations that vary in voltinism, allowing us to explore the relationship between generation time and patterns of polymorphism within ECB. We use a molecular evolution model that incorporates demographic and selective effects to investigate how generation time variation may affect variation in voltinism loci (*per* and *Pdfr*) as well as the background genome.

853F **Constraining models of dominance of deleterious mutations in the human genome** Christopher D. Kyriazis, Maria Izabel Cavassim, Kirk E Lohmueller UCLA

Dominance is a fundamental parameter in genetics, determining the mode of natural selection on deleterious and beneficial mutations, the relationship between population size and deleterious genetic variation, and the severity of inbreeding depression in a population. Despite this importance, very little is known about dominance, particularly in humans or other non-model organisms. A key reason for this lack of information about dominance is that it is extremely challenging to disentangle the selection coefficient (*s*) of a mutation from its dominance coefficient (*h*). Here, we explore dominance and selection parameters in humans by fitting models to the site frequency spectrum (SFS) for nonsynonymous mutations. We employ the diffusion-based approximation of allele frequency change in the Poisson Random Field framework. We find that numerous selection and dominance models can fit the data, so long as mean h>~0.15 and weakly deleterious mutations ($10^{-4}<s<10^{-3}$) are not too recessive. Moreover, we also find that theoretically-predicted models with a relationship between *h* and *s*, where deleterious mutations tend to be more recessive, can also fit the data well. Through model averaging, we estimate a mean *h* for nonsynonymous mutations of ~0.3, though with considerable uncertainty in *h* for individual selection coefficient bins. For models that fit the data, the inferred distributions of fitness effects (DFE) are relatively robust to different values of *h*, validating previous estimates of the DFE. Finally, we use our estimated dominance and selection parameters to inform simulations revisiting the question of whether the out-of-Africa bottleneck has led to differences in genetic load between African and non-African human populations. This analysis suggests that, under realistic dominance models with partially recessive mutations, genetic load is slightly elevated in non-African human populations, a result that cannot be detected by counting the number of derived deleterious alleles. Moreover, these results also suggest that models of partially recessive nonsynonymous mutations can also explain the observed severity of inbreeding depression in humans. Our work represents a comprehensive assessment of dominance in humans, with implications for parameterizing models of deleterious variation in humans and other mammalian species.

854F **Whole genome sequence data elucidates signatures of cattle domestication and global bovid migration patterns** John L Miraszek[1], Robert Schnabel[2], Jared Decker[2] [1]Genetics Area Program, University of Missouri, [2]University of Missouri

Domesticated cattle and its wild bovid relatives are a clade with rich evolutionary history intrinsically linked with anthropogenic forces. Of particular interest to the fields of population genetics, anthropology and evolutionary biology, is

the process of domestication. While directional-selection on the complex of traits encompassed in 'domestication syndrome' has been previously identified with soft-sweeps, it remains unclear whether this polygenic selection was a gradual process, or an initial confluence of related molecular events allowed this compounded phenotype to arise relatively quickly, as in the neurocristopathic hypothesis. Additionally, the classical view that domestication resulted from a bottleneck event with persistent isolation has been questioned due to the high pervasiveness of gene flow between wild and non-wild animals. Considering that within the Bos clade, animals from traditionally wild populations such as the yak and gaur were subsequently domesticated through hybridizing with the previously domesticated taurine and indicine cattle, there is ample opportunity to investigate domestication as emergent through distinct mechanisms within this genus. Past efforts in cattle and other domestic mammalian species either lacked samples with enough diversity, quality or overall size to uncover many of the genetic signatures of selection or accurately map dynamics of migration and admixture on a global scale. We use 1810 resequenced genomes from over 200 breeds of wild and domestic animals from the genus Bos and utilizing the latest demographic methods which proved highly effective and scalable for large sample sizes in human studies, estimate a genealogy for domestic cattle across thousands of individuals of diverse origins, the relative time scale of coalescent events, ancestral allele frequencies, and mutation rates following introgression. This will allow us to detect evolutionary forces that were present during domestication, such as selective pressure on polygenic traits, and the impacts of wild species interbreeding to better elucidate the genetics behind domestication in the context of human history and biogeographical space and time.

855F **Associating Genes with Diet through Convergent Evolution**

Michael Tene[1], Mathew Pollard[2], Emily Puckett[2], Wynn Meyer[1] [1]Biology, Lehigh University, [2]University of Memphis

Convergent evolution is when multiple species evolve the same trait independently. By examining the genes with common patterns of relative evolutionary rate across these independent replicates of evolution, we can detect genes which are associated with the evolution of the trait. Using this method, we have identified several genes and pathways associated with diet evolution in mammals. Our work is focused on the evolution of carnivory, and we have additionally examined the evolution of omnivory and herbivory.

We have examined different definitions of carnivory: carnivory as binary opposed to herbivory, carnivory as a continuous scale based on the percentage of diet composed of vertebrates, and carnivory as one of multiple diet categories. Using differences in which genes are associated with each definition of carnivory, we provide insight into which aspects of carnivory may drive evolutionary rate changes.

To perform this analysis, we must determine the phenotype of all of the branches in the phylogenetic tree. Particularly relevant are branches corresponding to the ancestors of extant species, which cannot be directly measured. We can estimate ancestral states either through ancestral state reconstruction, or through referencing the fossil record. Additionally, we can only assign ancestral branches phenotypes included in the analysis, meaning some branches may be incorrectly assigned, particularly by phylogenetic inference. We have examined the effect of ancestral branch phenotype assignment by using different methods of ancestral state inference and inclusion of different non-carnivory phenotypes in the analysis.

We have found metabolic genes to be evolving at different rates in carnivores and herbivores. Amino acid and lipid metabolism evolve more slowly in carnivores than herbivores. We find genes expressed in the brain, liver, kidney, and thyroid to evolve more slowly in carnivores than herbivores. The reduced evolutionary rate of amino acid metabolism and the above tissues suggests they have been subject to increased purifying selection in carnivores, thus implying greater importance in carnivores. We have also found that various muscle function genes and muscle tissues evolve more rapidly in carnivores than herbivores, implying either increased conservation in herbivores or positive selection in carnivores. In the future, we hope to look for associations in non-coding element evolution, and assess the three dimensional structural effects of the residues driving the different rates of coding sequence evolution that we detect here.

856F **Inferring the distribution of fitness effects from genetic variation with convolutional neural network** Linh Tran, Ryan Gutenkunst University of Arizona

The distribution of fitness effects (DFE) of new mutations quantifies the input of mutations with certain selective effects (deleterious, neutral, advantageous) into natural populations and is fundamental to evolution by natural selection. The DFE is particularly important for understanding quantitative traits, such as the genetic architecture of complex diseases. All previous studies that estimated the DFE from genetic variation data used summary statistics describing some aspects of the data, such as the allele frequency spectrum and/or linkage disequilibrium statistics. While powerful, these existing approaches either neglect substantial information from the data not included in the chosen summary statistics or demand careful curation of the appropriate set of summary statistics.

Here we introduce the first deep learning approach for DFE inference using convolutional neural network (CNN) and a novel representation of genetic variation data. Single nucleotide polymorphism (SNP) alignment is represented by a three-dimensional tensor in which each layer corresponds to a functional class, such as synonymous and nonsynonymous coding variants. With this representation, our approach allows direct processing of genetic variation data in which the CNN implicitly learns the most informative features in the data, bypassing summary statistics selection and assumption.

We trained and validated the CNN using data simulated under varied gamma DFE distributions and human demographic histories. We found that the trained CNN achieves better inference accuracy on simulated data than a commonly used summary-statistics-based DFE inference method. Our result demonstrates that deep learning is a promising and powerful approach for fully harnessing the information available in modern genomic data sets to infer the DFE with higher precision.

857F **Inter-chromosomal linkage disequilibrium in rice populations** Anthony Greenberg Bayesic Research

Levels of linkage disequilibrium (LD) among unlinked sites reflect the interplay of population genetic forces shaping the history of a species. For example, theory suggests that LD is more sensitive to population stratification than sequence divergence at individual sites. However, enumerating pairs of unlinked correlated loci normally requires the examination of all pairwise relationships in a genome. This task becomes computationally prohibitive with modern data sets comprising millions of polymorphisms. I have developed an approximate hash table based method to identify groups of loci in LD across the whole genome that does not require computing associations between uncorrelated pairs. I used this method to study LD among unlinked sites in populations of Asian domesticated rice, *Oryza sativa*. This species consists of two well-defined varietal groups, *INDCIA* and *JAPONICA*, with further shallower subpopulation division into *indica*, *aus*, and tropical and temperate *japonica*. These populations vary in the extent of local linkage disequilibrium, with *indica* the lowest and *temperate japonica* the highest. *O. sativa* is thus a good testing ground for the application of my method, taking advantage of the rich genomic resources including whole-genome sequence of 3000 accessions and a well-annotated reference. I will describe the analyses and several permutation tests enabled by the fast whole-genome LD estimation. These tests shed new light on the sources of among-population variation in LD among unlinked sites.

858F **Non-coding Variant Discovery with Evolutionarily-Informed Probabilistic Machine Learning Models** Courtney Shearer, Evan Cofer, Rose Orenbuch Harvard

Non-coding regions make up the majority of the genome and house thousands of variants associated with human disease. Unfortunately, when non-coding variants are identified in genomics studies, we are unable to identify whether these variants are actually causal or simply in linkage disequilibrium with the causal variants. Existing methods to prioritize non-coding variants generally rely on training convolutional neural networks on epigenetic data, and fail to identify variants that may function in biological contexts for which no such data exist. Clearly, there is a need for models that can uncover pathogenic non-coding variants associated with heritable traits and diseases irrespective of the available high-throughput regulatory sequencing studies (e.g. ChIP-seq). Here, we borrow modeling approaches from evolutionarily-informed generative models for proteins, and apply them to non-coding regions such as promoters to accurately predict the pathogenicity of non-coding variants. We outperform existing methods, and demonstrate our model's utility for prioritizing both rare and common novel disease-associated variants for a range of heritable diseases. Finally, we establish a set of public and rigorous benchmarks for future non-coding variant prioritization tools to accelerate community efforts in this area.

859F **The contribution of transposable element insertions to genetic diversity and recent adaptation in *Aedes aegypti* populations** Gabriela Valente-Almeida[1], Austin Daigle[2], Daniel Schrider[2] [1]University of North Carolina Chapel Hill, [2]Genetics, University of North Carolina Chapel Hill

Transposable elements (TEs) are mobile DNA sequences that can replicate themselves and be inserted in different genome regions. These are present in almost all organisms and comprise a significant part of the genome. TE insertions often have deleterious effects, as they may disrupt genes or regulator elements. Because of their repetitive nature, identifying these structural variants from short-read sequencing technology is a major challenge, and therefore much is still unknown about the population genetic dynamics of TEs. Here we characterize the diversity of TE insertions within populations of Aedes aegypti, an important vector of pathogens that cause multiple tropical diseases, such as Dengue, Zika, Chikungunya, and Yellow Fever. Cataloging genetic diversity within this species is of great interest, and surveying TE composition is an important component of this effort, as such mutations have been shown to facilitate insecticide resistance in other species. Our aim in this project is to gain a deeper understanding of the composition and potential effects of transposable elements in Aedes aegypti populations. To this end, we detected TE insertions from 110 samples from six different locations spanning Africa, North America, and South America, and sought to identify the evolutionary effects of these TEs on these different populations. We were able to accurately identify both reference and non-reference TEs in this dataset and therefore examine patterns of diversity within

and between populations. In total, 371134 insertions were identified in all our reference TE datasets, and 282034 insertions were identified in all our non-reference TE datasets. We found that, as expected, TEs were confined to lower allele frequencies than intergenic SNPs, consistent with negative selection Lastly, we compare the frequencies of TEs across geographic locations, discovering several candidates for local adaptation in this important vector species that is rapidly adapting to anthropogenic selective pressures.

860F **Non-adaptive mechanisms of metabolic evolution of *Escherichia coli* in a complex environment** Wei-Chin Ho[1,2], Lily King[2], Ryan Stikeleather[2], Michael Lynch[2] [1]University of Texas at Tyler, [2]Arizona State University

The capacities to utilize carbon sources are critical for microbes to propagate and mediate essential ecological functions in ecosystems. Although the existing carbon sources are thus expected to largely dictate the microbial evolution of metabolic competencies, the observation can sometimes be puzzling. For example, microorganisms adapting to one carbon source can simultaneously lose and gain the abilities to grow in other carbon sources, suggesting the involvement of neutral accumulation of loss-of-function mutations and/or pleiotropic adaptations. However, the relative contributions of these forces remain unclear, especially for complex environments with multiple carbon sources. To address this gap, we surveyed 32 *Escherichia coli* populations that had experienced 900 days of experimental evolution under two mutation rates and two transfer sizes in lysogenic broth, which comprises a mixture of amino acids. Specifically, their metabolic competencies were evaluated by growth in single amino acids. As a result, we found cases of increased growth in glutamic acid, histidine, or proline as well as decreased growth in alanine. More evolution of decreased growth is related to higher mutation rates but not higher adaptive efficacies owing to higher transfer sizes. This finding suggests that loss-of-function mutations are critical for metabolic-competency evolution. Additionally, we identified a substitution in proQ that enhanced growth in alanine. Interestingly, this substitution is not beneficial in lysogenic broth, highlighting the role of non-adaptive forces in novel metabolic competencies. Overall, our results identify pivotal molecular and evolutionary mechanisms influencing metabolic evolution, demonstrating the possibility of niche partitioning and specialist evolution even in complex environments.

861F **The cellular evolution underlying variation in innate social behavior across *Peromyscus* deer mice** Jenny Chen, Chris Kirby, Phoebe Richardson, Hopi Hoekstra, Sean Eddy Harvard University

Understanding how genes encode for something as complex as social behavior is an open question in biology. Variation in innate social behaviors across species offers an opportunity to use a comparative approach to identify the genetic building blocks of behavioral traits. Here, we investigate two closely-related species of *Peromyscus, P. maniculatus and P. polionotus,* that lie on opposite ends of the promiscuity-monogamy spectrum and exhibit vast differences in mating and parentin behavior. We focus on the hypothalamic medial preoptic area (MPOA), a region known for its role in social behavior, and asked how differences in the cellular and molecular composition of this region contribute to the differences in social behavior of these two species. We perform single nuclei RNA-sequencing in 6 females and 6 males of each species. Across species, we find several differentially abundant cell types, two of which have been previously implicated in parental care behavior. Across sexes, we found significantly fewer sex-biased genes in the monogamous *P. polionotus* compared to *P. maniculatus*, consistent with the reduction of sexual dimorphism observed in monogamous species. Both differentially abundant cell types and sex-biased genes are significantly enriched to be neuropeptidergic. Together, we find evolution of social behaviors involve changes in both cell abundance and sex-biased expression, with neuropeptide regulation likely playing a crucial role

862F **balselr - Balancing Selection Tests in R** Daphne Hansell[1], Barbara Domingues Bitarello[2] [1]Bryn Mawr College, [2]Biology, Bryn Mawr College

Long-term balancing selection (LTBS) is vital for population adaptability and resilience. LTBS includes mechanisms such as heterozygote advantage, negative frequency dependency selection, and fluctuating selection, all of which maintain polymorphisms segregating in populations. We previously introduced the Non-central Deviation (NCD) statistic as a statistically powerful and fast method to identify LTBS. Widespread adoption of NCD and several other LTBS methods developed since has been limited due to specialized knowledge requirements and implementation inaccuracies. Our package described here bridges this gap by providing an accessible interface, enabling researchers to leverage single-locus and genomic data effortlessly, even with basic R proficiency. We name this package balselr — balancing selection in R. balselr is a comprehensive R package designed to detect LTBS using the NCD statistics as initially described. balselr features include: a) preparation of input files from popular data formats, such as VCF files for SNP data (e.g. functions read_vcf() and parse_vcf()); b) implementation of NCD1 and NCD2 calculations (ncd1() and ncd2() functions, respectively); help pages and tutorials to further aid researchers in understanding LTBS prevalence and implications in population and evolutionary genetics. This dedicated package will make it easier for individuals with basic proficiency in R to run the NCD method effectively, allowing wider adoption of NCD and advancing understanding of balancing selection's evolutionary significance across organisms. We implemented comprehensive automated package tests to ensure, for example, that if a function code is changed, the output

stays the same, that functions produce the correct type of object, and to compare an expected calculation to the functions' output. Ongoing and future work include: implementing more tests for the existing functions; including other LTBS methods beyond NCD that are currently not implemented in R (e.g. BetaScan and BalLeRMix)); integrating the balselr and slendr (Population Genetic Simulations in R) packages and providing tutorial materials on how to properly assess statistical power for different organisms with forward simulations. In brief, the current package and the planned updates will make it easier for researchers with minimal programming experience to use NCD and other LTBS methods on their data. The development version is available at https://github.com/bitarellolab/balselr.

863F **Adaptive significance of amphicarpy as a bet-hedging strategy in American hog-peanut** Neal Yin, Maya Weissman, David Peede, Daniel Weinreich Ecology, Evolution, and Organismal Biology, Brown University

Environmental instabilities call for organisms to develop adaptations for long-term survival. Bet-hedging is one such strategy aimed at reducing the risk of extinction in changing environments, where a population sacrifices its short-term population-wide mean fitness in order to minimize long-term variance fitness in the long run. One potential bet-hedging strategy in plants is amphicarpy, a reproductive strategy where individuals produce two morphologically distinct types of seeds: subterranean seeds and aerial seeds. Subterranean seeds are produced asexually and are large, robust, and fecund when mature. On the other hand, aerial seeds are less fit than their underground counterparts but are more abundant, occasionally result from sexual reproduction, and experience delayed seed germination. It has been hypothesized that amphicarpy is a bet-hedging strategy, however rigorous tests of whether or not amphicarpy is adaptive and meets the criteria for bet-hedging are lacking. We evaluate amphicarpy as a form of bet-hedging in the American hog-peanut (Amphicarpaea bracteata), an amphicarpic annual native to a wide range of environments. We simulated the evolution of amphicarpy using stochastic Wright-Fisher models incorporating other annual plant reproductive behavior, including seed-banking (delayed seed-germination) and predation. Empirical parameters were drawn from prior in-field studies and approximately 200 American hog-peanut plants grown in the university greenhouse. We find that amphicarpy in the hog-peanut is a bet-hedging strategy, but seed banking alone does not explain the observed amphicarpic ratio. Rather, predation, biological constraints, and other fitness effects are necessary to capture the adaptive significance of amphicarpy.

864F **Scaling the fitness effects of mutations with respect to differentially adapted *Arabidopsis thaliana* accessions under natural conditions** Frank Stearns[1], Juannan Zhou[2], Charles Fenster[3] [1]Biology, Stevenson University, [2]Biology, University of Florida, [3]Biology and Microbiology, South Dakota State University

Mutations are the ultimate source of genetic variation for natural selection to act upon. A major question in evolutionary biology is the extent to which new mutations can generate genetic variation under natural conditions to permit adaptive evolution over ecological time scales. Here we collected fitness data for chemically induced (ethylmethane sulfonate, EMS) mutant lines descended from two *Arabidopsis thaliana* ecotypes that show differential adaptation to the local environment of our common garden plot. Using a novel nonparametric Bayesian statistical approach, we found that both ecotypes accumulated substantial proportions of beneficial mutations. The poorly adapted ecotype showed higher variance in the fitness effect of mutations than the well-adapted ecotype. Furthermore, we predict that it takes less than 4000 generations for the fitness space of the two ecotypes to overlap through mutation accumulation, and that a single founder, through mutation accumulation, is able to achieve the species-wide genetic variation in less than 10,000 generations. Our results provide evidence for relatively rapid local adaptation of *Arabidopsis thaliana* in natural conditions through new mutations, as well as the utility of nonparametric Bayesian method for modeling the distribution of fitness effects for field-collected data.

865F **Identifying candidate loci for hybrid seed inviability within *Mimulus* interspecific crosses** Natalie M. Gonzalez Genetics, University of Georgia

A common barrier to plant hybridization is the failed development of endosperm which leads to hybrid seed inviability. Despite its potential importance in angiosperm speciation, the genetic basis of hybrid seed failure remains almost completely unknown. Within the genus *Mimulus*, hybrid seed inviability has been described in several interspecific crosses including those of the recently diverged species *M. tilingii* and *M. caespitosa*. In this species pair, F1 hybrid seeds in one direction of the cross (*M. tilingii* as the pollen parent) are almost always inviable, whereas F1 seeds from the reciprocal cross are normal. Here we use a powerful crossing design, generating reciprocal backcross progeny to both species, to genetically map loci involved in *M. caespitosa-M. tilingii* F1 seed lethality. We have generated RADseq genotypes for each of the four backcross populations and are now characterizing genome-wide patterns of transmission ratio distortion to identify regions associated with seed failure. Paired with our recent characterization of genomic imprinting in this system, this dataset is an important step toward discovering the molecular genetic basis of *Mimulus* hybrid seed inviability.

866F **Genome architecture influences copy number variant dynamics in adapting populations** Julie Chuong, Ina Suresh,

Julia Matthews, Titir De, Grace Avecilla, Farah Abdul-Rahman, David Gresham Biology, New York University

DNA mutations are the raw material for genetic variation, evolution, and biodiversity. Copy number variants (CNVs)— gains and losses of genomic sequences—are a pervasive class of mutation that frequently underlie rapid adaptation. Despite their central role in evolution, it is unknown how genomic features influence CNV formation rate, location, size, and dynamics in evolving populations. Here we investigate the effect of proximate sequence elements at the *GAP1* locus, which encodes the general amino acid permease gene, on CNV dynamics in Saccharomyces cerevisiae.

The *GAP1* gene has a unique genomic architecture consisting of two flanking Ty1 long terminal repeats (LTRs) and an autonomously replicating sequence (ARS), which are thought to facilitate CNV formation at high rates. To test the effects of local genome architecture on *GAP1* CNV dynamics, we engineered three strains: any one lacking either an ARS, two LTRs, or all three elements. Then we experimentally evolved populations in glutamine-limited chemostats, a selective environment in which we have previously observed *de novo GAP1* CNVs. We detected *GAP1* CNVs in evolving populations over 200 generations using a fluorescent CNV reporter system.

Our results recapitulate previous findings that *de novo GAP1* CNVs are repeatedly formed and selected for early during adaptive evolution before undergoing more complex dynamics. Surprisingly, we found the local architecture elements were not required for *GAP1* CNV formation, highlighting the pervasiveness of CNVs during adaptive evolution. Whole-genome-sequencing of isolated CNV clones and subsequent inference of CNV mechanisms showed that in the absence of local features, CNVs form using distal ones. This study shows that local and distal DNA features facilitate CNV formation at high rates thereby fueling rapid adaptation in selective environments.

867F **The histone deacetylase Hos2 regulates protein expression noise by modulating protein translation machinery** Wei-Han Lin, Jun-Yi Leu Institute of Molecular Biology, Academia Sinica, Taiwan

Non-genetic variations derived from expression noise at the transcript or protein levels can lead to cell-to-cell heterogeneity within an isogenic population. While cells have developed strategies to reduce noise in some cellular functions, this heterogeneity can also facilitate different levels of regulation and provide evolutionary benefits in fluctuating environments. Although several general characteristics of expression noise have been revealed, detailed molecular pathways underlying noise regulation remain elusive. Here, we established a dual-noise reporter system in *Saccharomyces cerevisiae* and performed experimental evolution to search for mutations that increase the expression noise. By analyzing evolved cells using bulk segregant analysis coupled with whole-genome sequencing, we identified histone deacetylase, Hos2, as a negative noise regulator. *hos2* mutants down-regulate multiple ribosomal protein genes and exhibit compromised protein translation, suggesting that Hos2 may regulate noise by modulating translation machinery. Consistently, treating cells with translation inhibitors as well as mutations in several Hos2 targets, *RPS9A*, *RPS28B*, and *RPL42A*, led to increased noise. Our study provides an effective strategy for identifying noise regulators and sheds light on how cells regulate non-genetic variation through protein translation.

868F **Unraveling the complex world of drug resistance tradeoffs** Kara Schmidlin[1], Sam Apodaca[1], Alexander Sastokas[1], Daphne Newell[1], Grant Kinsler[2], Kerry Geiler-Samerotte[1] [1]CME, Arizona State University, [2]Department of Bioengineering, University of Pennsylvania

There is growing interest in designing multidrug therapies that leverage tradeoffs to combat resistance. Tradeoffs are common in evolution and occur when, for example, resistance to one drug results in sensitivity to another. Major questions remain about the extent to which tradeoffs are reliable–specifically, whether the mutants that provide resistance to a given drug all suffer similar tradeoffs to other drugs. This question is difficult because the drug-resistant mutants observed in the clinic, and even those evolved in controlled laboratory settings, are often biased towards those that provide large fitness benefits. Thus, the mutations (and mechanisms) that provide drug resistance may be more diverse than current data suggest. Here, we perform evolution experiments utilizing lineage-tracking to capture a fuller spectrum of mutations that give yeast cells a fitness advantage in fluconazole, a common antifungal drug. We then quantify fitness tradeoffs for each of 774 evolved mutants across 12 environments, finding that these mutants group into 6 classes with characteristically different tradeoffs. Their unique tradeoffs may imply that each group of mutants affects fitness through different underlying mechanisms. Some of the groupings we find are surprising. For example, we find some mutants that resist multiple drugs in isolation do not resist their combination, and some mutations to the same gene have different tradeoffs than others. These findings, on one hand, demonstrate the difficulty in relying on consistent or intuitive tradeoffs when designing multidrug treatments. On the other hand, by demonstrating that hundreds of adaptive mutations can be reduced to a few groups with characteristic tradeoffs, our findings empower multidrug strategies that leverage these tradeoffs to combat resistance. Finally, by grouping mutants that likely affect fitness through similar underlying mechanisms, our work guides efforts to map the phenotypic effects of mutation.

869F **From macro- to microevolution in the yeast *S. cerevisiae*** Walter P. Pfliegler[1], Alexandra Imre[2], Hanna V. Rácz[3], Bálint P. Németh[3], Andrea P. Harmath[3], Katalin P. Pappné Murvai[3], Rizagul P. Bazenova[3], Malika P. Kultazina[3], Marium P. Farooq[3], Reda M. Lemsali[3], Zsuzsa P. Antunovics[4], Renátó P. Kovács[5], István P. Pócsi[3] [1]Molecular Biotechnology and Microbiology, University of Debrecen, [2]Department of Chemical and Biomolecular Engineering, North Carolina State University, [3]Department of Molecular Biotechnology and Microbiology, University of Debrecen, [4]Department of Genetics and Applied Microbiology, University of Debrecen, [5]Department of Medical Microbiology, University of Debrecen

The yeast *Saccharomyces cerevisiae* is ubiquitous in the food industry and widely used as a probiotic. It may become a long-term commensal and even an opportunistic pathogen. In terms of macroevolution, many of the species' described clades are specifically adapted to traditional or modern industrial fermentation environments. Extensive microevolutionary phenomena, as genome structure variations, and the ability for rapid adaptation are also very characteristic for these yeasts. We aimed to study the phenomena of macro- and microevolution in the genomes of human isolates of the species, by expanding the number of sequenced genomes from clinical samples and food sources (sourdough, lambic, mead, animal feed, etc.) and by conducting in vitro and in vivo experimental evolution.

We sequenced 200 isolates from food and clinical samples, compared whole genome sequences of these along with 1400 previously sequenced samples of food/industrial and human origin together with metagenome-derived yeast genomes, and analyzed *in vitro* and *in vivo* experimentally evolved lineages of three yeast strains to understand how domestication and deliberate breeding affected the adaptability and pathogenic potential of *Saccharomyces* throughout its shared history with humans.

Our results on the phylogenomic relationships of isolate genomes and metagenome-derived yeasts highlighted several industrial clades that are able to colonize the human host at least temporarily. We could also recreate genome structure variations among clinical and food isolates using experimental evolution. We show that genomic characteristics and breeding history had remarkable effects on the in-host microevolution especially in the case of polyploid baking strains. These preferably colonize the female genital tract and display large-scale and rapidly arising genome structure variations independent of meiotic processes. Such an anatomic niche preference and such levels of variation are not characteristic to human isolates of other clades. Similar genome structure variations were characteristic to baker's yeasts evolving in sourdough as well. Remarkably, our phylogenomic analysis identified novel associations between clinical and food industry strains, and also showed that isolates from a two Hungarian hospitals are so diverse that they represent almost all known clades that have ever been recorded from human hosts, although with very different abundances, highlighting the importance of extended sampling efforts.

870F **Predicting population evolution in response to fluctuating environmental conditions** Esdras Tuyishimire, Elizabeth G King Biology, University of Missouri

Undeniably, changes in environmental conditions affect an organism's cellular and physiological functions, which extends to the observed population's behavior regarding genetics. The variability in selection pressure leads to genetic variations in a population that cannot be predicted by the current models. The main goal of the current study is to predict the genotypic and phenotypic changes within a population in response to varying environmental conditions. Advances in computational and genomic technology have allowed scientists to build models to understand the genomic processes underlying the changes we observe in populations under different selection pressures. Yet, results from theoretical models tend not to be consistent with those from empirical models. This study combines quantitative and population genetics theories to make models that can accurately predict population evolution in response to fluctuating environmental conditions. We use a forward evolutionary simulator, SLiM v4.1, to model a quantitative trait while considering a combination of four parameters. We deployed neutral, constant, and fluctuating selection models. Locus effects are derived from a random exponential distribution, with most having a small effect. We used spectral analysis to find the periodic patterns of selection. The results show that monogenic model behaves differently from oligogenic and polygenic models. They also suggest that predicting polygenic and oligogenic models might be easier than the monogenic model. Both allele frequencies and the mean population phenotypes had distinctive patterns for the fluctuating selection models compared to neutral and constant selection models. However, neutral selection tended to behave like complex fluctuating selection, but spectral analysis could differentiate both models. In conclusion, it is possible to predict the effect of fluctuating selection if the assumptions of our models are held, and the models can be extended to predict complex systems like the ones we observe in nature. For future study, we recommend simulating a model that considers additional parameters, for instance, fluctuating population, new mutation, various fitness functions, and other genetic components like epistasis and dominance. This research contributes to understanding the fundamentals that drive population evolution and how the populations respond to ongoing climate change.

871F **Developing a model for predicting the fitness of yeast mutants in antifungal drugs by utilizing Singular Value**

Decomposition
Mohammad Hossein Donyavi[1,2], Kara Schmidlin[1,2], Grant Kinsler[3], Kerry Geiler-Samerotte[1,2] [1]School of Life Sciences, Arizona State University, [2]Center for Mechanisms of Evolution, Biodesign Institute, [3]University of Pennsylvania

Evolving populations are complex and dynamic systems, which makes predicting evolutionary outcomes difficult. Two primary challenges that hinder evolutionary predictions are the extensive scope of genetic target of adaptation and the variable effects these mutations, even those that appear similar, have on phenotype. Antimicrobial resistance continues to pose a serious threat to human health. As the development of new drugs has stalled the ability to predict how mutations behave in a wide range of existing drugs could be invaluable for informing more effective sequential drug treatment strategies. Here, we used a dataset consisting of 774 drug-resistant yeast lineages to train a prediction model via Singular Value Decomposition (SVD). The dataset includes fitness measurements for all 774 yeast lineages in 12 different conditions each of which represents a different concentration or combination of fluconazole (Flu), a common antifungal drug, and radicicol (Rad), an Hsp90 inhibitor. Our study builds upon previous work by investigating how the prediction accuracy changes when we train our model on different subsets of the data. For example, we find we can achieve more accurate fitness predictions in multidrug conditions (Flu + Rad) when training the model on data from Flu environments rather than Rad environments. As this dataset contains a diverse collection of mutations measured in multiple conditions we have the power to address some of the problems that make predicting evolution difficult.Further, this work provides valuable information about when and why mutations that provide drug resistance are more difficult to predict. Finally, the foundational knowledge gained here contributes to the potential incorporation of predicted evolutionary outcomes into designing sequential drug treatments for clinical use.

872F **The Histone Deacetylase Hos2 Regulates Protein Expression Noise by Modulating Protein Translation Machinery** Wei-Han Lin, Florica Jean Ganaden Opoc, Chia-Wei Liao, Jun-Yi Leu Institute of Molecular Biology, Academia Sinica

Non-genetic variations may come from expression noise at the transcript or protein levels, resulting in cell-to-cell heterogeneity within an isogenic population. While cells have developed strategies to reduce expression noise in some cellular functions, this heterogeneity can also facilitate different levels of regulation and provide evolutionary benefits in fluctuating environments. Although several general characteristics of cellular noise have been revealed, detailed molecular pathways underlying noise regulation remained elusive. Here, we established a dual-fluorescent reporter system in *Saccharomyces cerevisiae* and performed experimental evolution to search for mutations increasing the protein expression noise. By analyzing evolved cells using bulk segregant analysis coupled with whole-genome sequencing, we identified the histone deacetylase, Hos2, as a negative protein expression noise regulator. *hos2* mutants down-regulated multiple ribosomal protein genes, leading to compromised protein translation. It suggests that Hos2 may regulate protein expression noise by modulating translation machinery. Consistently, treating cells with translation inhibitors as well as mutations in several Hos2 targets, *RPS9A*, *RPS28B* and *RPL42A*, led to increased protein expression noise. Our study provides an effective strategy for identifying protein expression noise regulators and also sheds light on how cells regulate non-genetic variation through protein translation.

873F **Functional validation of reported genes associated with skin pigmentation in a Native American Caribbean population** Kathryn A Early, Thaddeus D Harbaugh, Victor A Canfield, Keith C Cheng, Khai C Ang Penn State College of Medicine

Skin pigmentation is a phenotype that varies widely between populations of different genetic ancestries. To investigate the genetic determinants of skin color variation between East Asian/ Native American and African ancestries, we sought a Native American population with African ancestry and minimal European contribution that exhibits a wide range of skin pigmentation. The Kalinago, a Native American population from the Commonwealth of Dominica in the Caribbean, fulfill these criteria. Genomic analysis using Admixture of 458 individuals residing in the Kalinago Territory of Dominica revealed genetic contribution of approximately 55% Native American, 32% African, and 12% European ancestry, reflecting the highest reported Native American genetic ancestry among Caribbean populations. Their skin pigmentation measurements ranged from 20 to 80 melanin units, and averaged 46. The most pervasive European skin color alleles, $SLC24A5^{A111T}$ and $SLC45A2^{L374F}$ had allele frequencies of 0.14 and 0.06, and the calculated single allele effect sizes were –6 and –4, respectively. Native American genetic ancestry alone was associated with a pigmentation reduction of 24 to 29 melanin units in the Kalinago. However, the genetic variants responsible for this skin lightening effect remains to be identified, as none of the previously reported polymorphisms associated with skin color in the Native Americans caused a measureable reduction in pigmentation in the Kalinago. In particular, none of the variants proposed to contribute towards skin pigmentation differences between Native Americans and Africans in the genes *CNKSR3 (*rs6917661), *IPCEF1 (*rs2333857), *EFGR* (rs12668421 and rs11238349) and *MFSD12 (Y182H)* reached genome-wide significance, or, in the case of the latter, reached fixation in the Kalinago. To study the potential contributions of these genes towards human skin pigmentation differences and elucidate their role in melanogenesis, we will report on functional validation studies using antisense morpholino (MO) knock-downs of *CNKSR3*, *IPCEF1*, *EGFR*, and *MFSD12* orthologues in zebrafish (*Danio rerio*).

874S **Inherently having more males makes difference in the response of strains to different mutagens in *C. elegans.*** Sayran Saber[1], Rohit Kapila[2], Rahul Verma[2], Janna Fierst[2] [1]Biological Sciences, Florida International University, [2]Florida International University

Cinorhabditis elegans is a hermaphroditic nematode species, with a rare occurrence of males. Males can arise through successful outcrossing between hermaphrodites and males, resulting in an equal ratio of males to hermaphrodites, or through non-disjunction mutations that lead to the formation of spermatids lacking X chromosomes in hermaphrodites. Since the frequency of males in the population is roughly equivalent to the mutation rate, it suggests that males are primarily produced through non-disjunction mutations. The variation in male frequency due to mutational input is specific to different strains.

To investigate this further, we induced inbreeding depression in strains of C. elegans, specifically N2, AB1, and CB4856, which inherently exhibit different male frequencies of 0.1%, 1%, and 5%-20%, respectively. We employed Ethyl methanesulfonate (EMS) and Formaldehyde (FA) treatments for five generations to achieve two objectives: 1) assess changes in male frequency and outcrossing rates, and 2) evaluate the fitness consequences of male frequencies under these mutagenized conditions. Our findings demonstrate that a higher presence of males enhances recovery from mutational stress, and the specific mutational composition influences the extent of male-dependent mutational recovery."

875S **Selection on the length of *C. elegans* giant ankyrin (UNC-44)** Matthew S Rich[1], Erik M Jorgensen[1,2] [1]Biology, University of Utah, [2]Howard Hughes Medical Institute

Many proteins act as linkers in the cell, interacting with multiple partners at specific distances to perform their functions. As such, selection must act on the lengths of these proteins, often through—or in spite of—the expansion and contraction of repeats. We study these selective pressures by examining how they affect the evolution and function of one such long, repetitive protein: giant ankyrin. Ankyrins are conserved, ubiquitous proteins that regulate cell shape by linking membrane proteins to the cytoskeleton. All animals with a nervous system have a giant, neuron-specific isoform of ankyrin that encodes thousands of extra residues, often through the inclusion of long repetitive exons. The sequences of giant ankyrin orthologs are not conserved; instead the giant length and the protein's function are conserved.

While studying the role of *C. elegans* giant ankyrin (*unc-44*) on neuron morphology, we found that only the last 100aa of the over 5000aa neuron-specific, repetitive C-terminus is required for function; deleting the rest of the giant isoform causes only subtle phenotypes. Despite this, the repeat content and length of this exon is highly constrained for nearly 100 million years' evolution among nematodes. Gains and losses of the repeats are observed in natural isolates, but the fixed length is maintained in all species. We are localizing giant ankyrin in *C. elegans* neurons and performing barcoded fitness assays to determine what and how much selection is acting on repeat number, as well as using lab evolution experiments to characterize the genomic mechanism by which the exon expands and contracts. Through these experiments, we hope to be able to define the selective pressures acting on the length of the protein to make it seemingly dispensible, yet nearly immutable.

876S **Functional consequences of the rapid evolution of a putative *de novo* evolved gene required for male fertility in *D. melanogaster*** Alexander S Thurber, Brenna K McCormick, Kerry L McDermott, Prajal H Patel, Geoff Findlay Department of Biology, College of the Holy Cross

De novo evolved genes arise from previously non-coding regions of DNA. Some of these genes can evolve functions that become essential to the organism. We previously identified a putative *de novo* evolved gene, *saturn*, which is required for proper sperm production and sperm motility in *Drosophila melanogaster*. The *saturn* gene has evolved rapidly, under positive selection, across *Drosophila* species. To examine the functional consequences of this rapid evolution, we inserted HA-tagged *saturn* orthologs from different *Drosophila* species into *D. melanogaster* flies lacking an endogenous copy of *saturn* and assessed the ability of each ortholog to restore *D. melanogaster* fertility. We observed that orthologs from species closely related to *D. melanogaster* fully restored fertility, while more divergent orthologs were less effective. The ortholog of *D. ananassae*, in particular, yielded fertility results similar to that of saturn null males. Corresponding to the lack of fertility rescue, the *D. ananassae* ortholog showed a different subcellular localization pattern in developing spermatids. While native Saturn protein and closely related orthologs localized to the nuclear periphery, the *D. ananassae* ortholog localized to elongating sperm tails, suggesting a potential mismatch between this ortholog and other proteins in *D. melanogaster* with which Saturn may normally interact. We are currently raising an antibody to the *D. ananassae* Saturn ortholog to investigate its localization in this species. We are also testing the importance of predicted nuclear localization signals in the *D. melanogaster* ortholog for the protein's function in this species. These experiments show how testing the consequences of evolutionary divergence can lead to hypotheses about the functions of novel proteins. As a second example of this approach, we have also initiated experiments to test the functionality in *D. melanogaster* of orthologs of another, more slowly evolving *de novo* gene required for male fertility, *goddard*.

877S **Genomic diversity illuminates the environmental adaptation of *Drosophila suzukii*** Siyuan Feng[1], Samuel Degrey[2], Christelle Guedot[2], Sean Schoville[2], John Pool[1] [1]Department of Genetics, University of Wisconsin Madison, [2]Department of Entomology, University of Wisconsin Madison

Biological invasions carry substantial practical and scientific importance, and represent natural evolutionary experiments on contemporary timescales. Here, we investigated genomic diversity and environmental adaptation of the crop pest *Drosophila suzukii* using whole-genome sequencing data and environmental metadata for 29 population samples from its native and invasive range. Through a multifaceted analysis of this population genomic data, we increase our understanding of the *D. suzukii* genome, its diversity and its evolution, and we identify an appropriate genotype-environment association pipeline for our data set. Using this approach, we detect genetic signals of local adaptation associated with nine distinct environmental factors related to altitude, wind speed, precipitation, temperature, and human land use. We uncover unique functional signatures for each environmental variable, such as a prevalence of cuticular genes associated with annual precipitation. We also infer biological commonalities in the adaptation to diverse selective pressures, particularly in terms of the apparent contribution of nervous system evolution to enriched processes (ranging from neuron development to circadian behavior) and to top genes associated with all nine environmental variables. Our findings therefore depict a finer-scale adaptive landscape underlying the rapid invasion success of this agronomically important species.

878S **Investigating post-transcriptional regulatory mechanisms of putative *de novo* evolved genes required for *Drosophila* male fertility** Ishanpepe A Jagusah, Emily J Gualdino, Prajal H Patel, Geoff Findlay Department of Biology, College of the Holy Cross

De novo evolved genes arise when previously non-coding DNA sequences evolve an open-reading frame and a functional promoter. Across animals, these genes are often expressed in the testes, suggesting they could evolve essential roles in male fertility. In testis cells, the expression of many genes is also regulated post-transcriptionally. Thus, the evolution of post-transcriptional regulatory mechanisms may be another important aspect of *de novo* gene birth. We are characterizing post-transcriptional regulatory mechanisms for two putative *de novo* genes that are essential for male fertility: *atlas* and *saturn*. Single-cell RNA-sequencing data show that transcripts from both genes initially appear in pre-meiotic cells, but the encoded proteins are detectable only in post-meiotic spermatids. We found that rescue constructs for each gene that contain both upstream and downstream non-coding sequences restore fertility in null males. However, a *saturn* rescue construct lacking the sequences found downstream of its stop codon does not restore fertility, implying key regulatory regions in the gene's 3' UTR and/or after its transcription termination site. We are currently testing whether inclusion of either of these regions in the rescue construct is sufficient to restore fertility. The *atlas* gene has two isoforms, *atlas*-RA and *atlas*-RB, that differ in the length of their 3' UTRs. The shorter RA isoform is more prevalent in whole-male RNA-seq data and our RT-PCR data. To test whether the RB-specific portion of the gene is required for its function, we used CRISPR to specifically delete this region. Males homozygous for the RB deletion allele were more fertile than atlas null males, but exhibited reduced fertility in sperm exhaustive mating conditions, suggesting that the RB-specific region of the *atlas* gene may be important for maintaining high levels of sperm production. One possible mechanism through which the RB region could affect Atlas protein expression is by serving as a binding site for proteins that affect the localization, stability, or accessibility to ribosomes of *atlas* transcripts. We are performing *in situ* hybridization to test if the localization of *atlas*-RA and *atlas*-RB transcripts differ within the testes. Collectively, these results highlight additional evolutionary steps that may be important for newly evolved genes to acquire essential functions.

879S **It's all in good taste: Premating Isolation in the *Drosophila virilis* subgroup** Amisha Agarwala, Yasir H. Ahmed-Braimah Center for Reproductive Evolution, Department of Biology, Syracuse University

Mate discrimination by either sex can be an important form of premating isolation, but studies have largely focused only on female mate choice. Identifying the traits involved in behavioural isolation poses a significant challenge due to the complexity and environmental sensitivity of multimodal courtship signalling systems. The *Drosophila virilis* subgroup is a promising model to examine the genetic and molecular bases of male mate choice. *D. virilis* males mate with heterospecific (*D. novamexicana*) females at far lower frequencies (~10%) than with conspecific females. This preference is mediated by the cuticular hydrocarbon (CHC) profile of the female, and the genetic basis of the female component of isolation has been mapped to a single Quantitative Trait Locus on the X chromosome. Here, we investigate the genetic and mechanistic bases of male mate preference in *D. virilis* males. We find that the male mate preference is determined by the X chromosome by assaying mate preferences in male F1 hybrids from both reciprocal crosses between *D. virilis* and *D. novamexicana*. To analyse the mechanistic basis of the male mate preference, we examined courtship dynamics in conspecific and heterospecific interactions. *D. virilis* males tap the female abdomen with their foreleg tarsi during courtship, and this is hypothesised to be the mechanism by which they sample female CHCs. We amputated the foreleg tarsi of *D. virilis* males and assayed their mate preference. We find that mate preference is mediated by gustatory receptors on the foreleg tarsi as tarsi-less males lack a

preference. Localising the genetic basis to the X chromosome and identifying the sensory mechanism for CHC mediated mate preference allows us to leverage targeted functional genomics assays to further identify the genes and receptors involved.

880S **Discovery of adaptive structural genetic variation in repetitive genome using a pangenome graph of *Drosophila melanogaster*** Alejandra Samano, Mahul Chakraborty Department of Biology, Texas A&M University

Understanding the genetic basis of adaptation is a fundamental puzzle in evolutionary biology. Structural genetic variation involving repetitive sequences that comprise copy number variants (CNVs) and transposable elements (TEs) is an important source of adaptive genetic variation. However, a large proportion of CNVs and TEs are invisible to the standard methods used for identifying adaptive variants from population genomics data based on high-throughput short reads. Additionally, the standard approaches relying on mapping short reads to a reference genome suffer from reference biases and can mislead inference of adaptive evolution based on allele frequencies. To solve these problems, we constructed a *D. melanogaster* pangenome graph using highly contiguous genome assemblies of 15 strains from derived, cosmopolitan populations and 10 strains from an ancestral range African population constructed with long reads. We used this pangenome graph to calculate the allele frequency of comprehensive structural variants (SVs) comprising repetitive sequences in 84 lines from five populations of *D. melanogaster*. These populations are collected from diverse geographic regions, from the ancestral range of the species in tropical Sub-Saharan Africa to temperate, cosmopolitan regions in North America, Asia, Europe, and Australia. We identified many previously hidden candidate adaptive SVs involving TEs and CNVs in these populations. While some candidate adaptive SVs are shared between populations, others are population-specific. Several CNVs and TEs are strong candidates for explaining adaptive phenotypic variation in body and wing size, toxin resistance, thermal stress tolerance, lifespan, diapause incidence, and lifetime fecundity. Using reporter gene assays and CRISPR-Cas9 mediated allele replacements, we investigated the functional effects of a candidate adaptive duplicate and TEs associated with ethanol metabolism and Insulin signaling, respectively, to understand their adaptive significance. Our data suggest that the duplicate CNV contributes to adaptive high ethanol tolerance in temperate populations, and the TEs contribute to adaptive variation in life history traits as an allelic series. Our results demonstrate the utility of pangenome graphs in discovering novel adaptive SVs and highlight the role both large and small shifts in allele frequency of SVs play in adaptive trait variation in *D. melanogaster*.

881S **Genomics of postponed reproduction in *Drosophila melanogaster*** Giovanni A Crestani[1], Karen Walsh[2], Alejandro Moran[2], Hannah S. Dugo[1], Parvin Shahrestani[2], Molly K Burke[1] [1]Integrative Biology, Oregon State University, [2]California State University, Fullerton

Evolve and resequence (E&R) experiments with model organisms have the potential to reveal the genetics underlying complex traits and investigate the molecular dynamics of adaptation. Here, we sequence the genomes of Drosophila melanogaster populations experimentally-evolved for postponed reproduction for over 30 generations. These populations, now maintained on a 70-day generation cycle, rapidly evolved a suite of life-history phenotypes that differ from control populations kept on a standard 14-day generation cycle. These populations live significantly longer than controls and exhibit many correlated phenotypes including increased measures of stress resistance such as improved immune defense following infection with an entomopathogenic fungus. The experimental system we used involves four selection treatments, each consisting of five replicate populations. The two selection treatments on a 70-day (O-type) cycle differ in their recent evolutionary history; one treatment (OB) was derived from populations that had always been reared on a 14-day generation cycle, and the other (OBO) was derived from populations that had been recently reverted from a 70-day to 14-day generation cycle. From those same ancestral populations, we derived control treatments that maintain a 14-day (B-type) cycle; one (nB) that has always been on a 14-day cycle and another (nBO) derived from the same populations that founded the OBO treatment. Each of those four selection treatments represents a unique combination of past and present life-history phenotypes. By comparing the genomes of populations of the O-type selection regimes to those of the B-type selection regimes, we can test hypotheses about the genetic basis of longevity and correlated phenotypes in Drosophila. By comparing the genomes of populations of the same selection treatment, but with different evolutionary histories, we can test hypotheses about the degree to which past evolution constrains future adaptation. Using pooled-population sequencing, we collected whole-genome allele frequency data from all populations at multiple time points over 30 generations of O-type selection. Preliminary results suggest that allele frequencies are strongly predicted by selection treatment, but not by recent evolutionary history, consistent with prior work. We conclude that for standing genetic variation, adaptive differentiation of allele frequencies occurs rapidly, as does evolutionary convergence within selection regimes.

882S **Whole fly 16s microbiome profiles following long-term dietary selection of an outbred genetically diverse population of *Drosophila melanogaster*** Peyton Warren, Garrison Miller, Gaurav Kandlikar, Enoch Ng›oma Division of Biological Sciences, University of Missouri

Aging is a deleterious life history trait that constrains fitness and healthy longevity and has evolved in most species in

response to relaxation in selection late in life. Most efforts to pin down the causes and correlations of nutrition-based aging have focused on the analysis of genomic sequences and transcriptomic profiles, but there remains a large variation in aging phenotypes that is unaccounted for. In this study, we explore the effects of long-term nutritional selection on age-specific microbiome variations. We used large populations of *Drosophila melanogaster* originally maintained for 65 generations under three nutritional regimes: fluctuating protein content, deteriorating protein content, and constant high sugar. After at least 20 generations of inbreeding in common garden, we investigated the age-specific effect of long-term dietary selection on microbiome composition in *D. melanogaster*. We randomly sampled from six inbred selection lines in each selection regime and two lines from an experimentally unevolved population to serve as a control. From each replicate, we assayed whole female flies for 16S rRNA sequencing at three timepoints: 15, 35, and 60 days post-eclosion. Through independent species analysis, we identified 43 bacterial genera that signify significant changes across adult lifespan and 8 genera significantly different between dietary selection regimes. Further analysis of microbial phyla and genera composition suggest putative roles in immunological aging.

883S **A screen for modifiers in the sex determination pathway of *Drosophila melanogaster*** Frederick M Xu, Andrew G Clark, Daniel A Barbash Molecular Biology and Genetics, Cornell University

Sex determination mechanisms vary extensively across taxa, but how much variation exists *within* a sex determination pathway is not fully known. In *Drosophila*, sex is determined by counting five X-linked Signal Elements (XSEs) that activate the primary sex determination gene *Sex lethal* (*Sxl*). In females, there is sufficient XSE dosage from the two X chromosomes to activate *Sxl*; however, in males, the single X chromosome provides insufficient XSE dosage, and *Sxl* remains inactive. Sxl proteins go on to regulate somatic sex differentiation and dosage compensation pathways.

Thomas Cline previously found extensive variation across wildtype *Drosophila melanogaster* strains for sensitivity to perturbations in sex determination. The progeny sex ratios of some strains skewed heavily female-biased when XSEs were duplicated, and others skewed heavily male-biased when *trans*-heterozygous for XSE and *Sxl* LOF mutations—but strains more sensitive to one sex-specific lethality were more resilient to the other. Furthermore, these skews varied in intensity, suggesting an anticorrelated continuum of sensitivity to sex determination perturbations. This begs the question: what is causing this variation?

To genetically map the factors involved, we utilized the Drosophila Synthetic Population Resource (DSPR), a collection of ~1700 Recombinant Inbred Lines (RILs) generated from 15 unique Founder lines. We crossed males from mutant *D. melanogaster* lines containing XSE + *Sxl* LOF mutations or XSE duplications to virgin females from each RIL and scored the progeny sex ratios. We used these data to make QTL maps (at a resolution of ~0.5 – 2 cM) of genomic regions associated with significant signals of sex-specific lethality. We further pared our list of candidate genes within these QTL peaks by scoring the progeny sex ratios of crosses between these same mutant *D. melanogaster* strains with deficiency lines, reasoning that deficiencies should recapitulate the same sex ratio distortion phenotype as any LOF variants segregating in the DSPR. Additionally, several QTL peaks contain known sex determination or dosage compensation genes (*Sxl*, the *upd* gene family, *msl-3*, and *tra*), while other QTL peaks potentially implicate novel genes in either pathway. Using SNP data for each of the Founder lines, we are also identifying potential polymorphisms underlying the sex-specific lethality phenotype for each of the candidate genes.

884S **Gene regulatory targets of selection for enhanced heat tolerance in *Drosophila melanogaster* embryos** Kylie M. Finnegan, Brent Lockwood Biology, University of Vermont

Sensitive life stages may be a selective sieve through which selection acts to establish the genetic makeup of a population. Previous work has shown divergence in heat tolerance at the embryonic stage among populations of *Drosophila melanogaster.* Yet, we lack an understanding of the molecular mechanisms that underlie genetic variation in heat tolerance in this system. Given that thermal tolerance is a complex physiological trait, and that previous work has demonstrated the critical role of gene regulation for heat tolerance, we hypothesized that gene regulatory variation is the primary basis of thermally adaptive variation in heat tolerance. We utilized a combinatorial approach of lab selection and introgression, along with whole genome sequencing and RNA sequencing, to identify the gene regulatory basis of thermal adaptation in *Drosophila melanogaster* embryos. We identified individual genes and gene networks whose expression patterns were targets of thermal selection. We found that some of these genes colocalize to highly variable polymorphic regions across the genome. We discuss the potential functional roles of these genes in the physiology of temperature adaptation. Our results help to elucidate the mechanisms by which thermal tolerance is maintained and inherited in locally adapted populations.

885S **GxGxE for performance traits across 90 mitonuclear genotypes under mitochondrial stress in Drosophila** David M Rand[1], Leah Darwin[2], Yevgeniy Raynes[1], Jared Ingram[1], Faye Lemieux[3] [1]Department of Ecology, Evolutionary and Organismal Biology, Brown University, [2]Computational Biology & Ecology, Evolution and Organismal Biology, Brown University, [3]Department
